Matrix form of nonlocal OSM for electromagnetics

X. Claeys∗ F. Collino† E. Parolin‡

August 26, 2021

Abstract

The goal of the present paper is twofold. First, we revisit the derivation of the domain decomposition introduced in [Claeys&Parolin,2020] in the acoustic setting, adopting matrix based notations and remaining as explicit as possible. In addition, the presentation we give here covers Maxwell’s equations and considers the case where inductance operates over thick regions of the computational domain.

Introduction

In the context of wave propagation problems, it is known since the pioneering work of B. Després [11] that impedance type transmission conditions shall be used between subdomains to obtain convergence of non-overlapping domain decomposition methods (DDM). The class of such methods is often termed Optimized Schwarz Methods (OSM). In the simplest version of the method, the impedance operator introduced in the transmission conditions is local. Several alternatives for such operators were advocated, featuring both zeroth and second order (surface) differential operators. Without being exhaustive we mention for the acoustic setting [25, 21, 20] and for the electromagnetic case [8, 36, 15, 34, 16, 17, 18, 38]. These operators are often, but not always, constructed by mimicking absorbing boundary conditions. For this reason, it was proposed to approximate exact absorbing conditions by means of rational fractions of second order surface differential operators. This was done first for the Helmholtz equation [3] and then [19] for the Maxwell case. Alternatively, non-local impedance operators were advocated in order to obtain geometric convergence of the iterative solvers in the continuous analysis setting [7, 9, 10]. Such a result is out of reach with local operators for which one obtains algebraic convergence of the DDM in the best cases, see [28, Chap.3].

The presence of so-called cross-points i.e. points where strictly more than two subdomains meet, has been a major and ubiquitous difficulty in the design and analysis of efficient OSM strategies. For methods using second order surface differential operators, cross-points are associated to corners and motivate the development of compatibility conditions to mitigate their effects [13, 14, 29, 30]. Several other treatments inspired by available strategies developed for elliptic problems have been proposed for nodal type discretizations [11, 22]. Recently the geometric convergence result of [9, 10] have been extended to arbitrary geometric partitions, including partitions with cross-points [5, 6]. The new approach is based on a novel operator

∗LJLL (Sorbonne Université-Université de Paris-CNRS), INRIA, France
†Poems (CNRS-INRIA-ENSTA Paris), IP Paris, France
‡Dipartimento di Matematica, Università degli Studi di Pavia, Italia, emile.parolin@unipv.it
that communicates information globally between subdomains and replaces the standard local
exchange operator that operates pointwise on the interface. In addition, the method, which
is derived and analysed in the acoustic setting, is proved to be uniformly stable with respect
to the discretization parameter.

We extend the work of [6] in three directions. First, instead of the acoustic setting, we
consider the case of electromagnetic wave propagation problems. While no convergence result
for OSM applied to Maxwell problems in such a general context is known to us, the present
analysis leads to a convergence estimate (see coercivity property in Proposition 1) valid in the
case of heterogeneous media and general non-overlapping partitions, including the possibility
of cross-points. In the case of diagonal impedance, this yields a new result on the pre-existing
DDM strategy of Després applied to harmonic Maxwell’s equations.

Second, starting from the original undecomposed linear system, we perform the complete
derivation of the domain decomposition method and its analysis using only matrix notations.
We discard considerations related to functional analysis and only rely on finite dimensional
linear algebra and matrix calculus so as to ease the understanding of our method in the
perspective of actual implementation. In particular Section 5 provides explicit algorithms.

Third, we describe a new treatment of transmission conditions that possibly lead to thick
interfaces, see Figure 1. In this new approach, the external boundary of the computational
domain is not necessarily part of the skeleton where transmission conditions are imposed,
which is new and computationally more optimal compared to [5, 6].

The outline of the present contribution is as follows. In Section 1 we introduce several
definitions and the main notations. In Section 2 we describe the central ingredients of our
method namely the impedance matrices, the associated orthogonal projector and the commu-
ication matrix which concentrates the main originality of the approach. Subsequently, the
reformulation of the original problem as a skeleton problem common to OSM is addressed
in Section 3 followed by the analysis of the formulation that ends with the well-posedness
and convergence results given in Proposition 1. Next we provide two concrete choices for the
impedance operators in Section 4: a simple zeroth-order operator corresponding to the one
of Després and a more involved non-local operator that appears to us as one of the most
robust choice. We explain in particular how to implement efficiently the latter operator de-
spite its underlying non-local nature. This is followed by Section 5 in which we provide the
detailed algorithms in view of practical implementation of the method. We conclude with
some numerical results in Section 6. In particular, we provide a first particular test case that
aims at illustrating the need for the approach that we advocate. Besides, we investigate the
influence of several parameters: mesh refinement, wavenumber and number of subdomains.
Finally, a more involved problem featuring heterogeneous media is provided as evidence of the
robustness of the approach.

1 Geometry

We consider a (bounded) polyhedral computational domain $\Omega \subset \mathbb{R}^3$ and a regular simplicial
triangulation $\mathcal{T}(\Omega)$ of the domain $\Omega = \bigcup_{e \in T(\Omega)} \overline{\tau}$. We consider a non-overlapping domain
decomposition $\Omega = \Omega_1 \cup \cdots \cup \Omega_J$ of the computational domain that is conforming with respect
to the triangulation i.e. we have the following additional properties

\begin{align}
  i) & \quad \Omega_j \cap \Omega_k = \emptyset \text{ if } j \neq k \\
  ii) & \quad \text{each } \Omega_j \text{ is resolved by } \mathcal{T}(\Omega). 
\end{align}

2
In the sequel, we shall denote \( T(\Omega_j) := \{ \tau \in T(\Omega), \tau \subset \Omega_j \} \) which implies in particular \( T(\Omega) = T(\Omega_1) \cup \cdots \cup T(\Omega_J) \). This is the usual setting of non-overlapping substructuring domain decomposition methods. We shall denote \( \mathcal{E} \) (resp. \( \mathcal{E}_j \)) the edges of the triangulation \( T(\Omega) \) (resp. \( T(\Omega_j) \)). In particular we have \( \mathcal{E} = \mathcal{E}_1 \cup \cdots \cup \mathcal{E}_J \) which is a partition with overlap i.e. we a priori have \( \mathcal{E}_j \cap \mathcal{E}_k \neq \emptyset \) if \( \Omega_j \) and \( \Omega_k \) are neighboring subdomains. This leads to considering

\[
\Sigma := \bigcup_{1 \leq j < k \leq J} \mathcal{E}_j \cap \mathcal{E}_k
\]  

(2)

The edges of \( \Sigma \) provide a triangulation of what is usually called the skeleton in domain decomposition literature. Finally, we assume to have chosen a particular collection \( \Gamma \) of edges satisfying the following property

\[
\Sigma \subset \Gamma \subset \mathcal{E}.
\]  

(3)

and we set \( \Gamma_j := \Gamma \cap \mathcal{E}_j \), for \( j = 1, \ldots, J \). Of course \( \Gamma = \Sigma \) is one possible choice among many, but the forthcoming analysis is not restricted to this sole possibility. In practice \( \Gamma \) is chosen as a set of edges surrounding the interfaces of the decomposition The choice of \( \Gamma \) satisfying the condition above may be arbitrary. We will refer to \( \Gamma \) as the thick skeleton.

\begin{figure}[h]
\centering
\includegraphics[width=\textwidth]{figure1.png}
\caption{A 2D sketch of thick skeleton in the case of a partition in 5 subdomains, with skeleton \( \Sigma \) colored in red. Among many possibilities, the thick skeleton (edges colored in green and red) can be reduced to \( \Sigma \) (a), it may consist in a thick neighborhood of \( \Sigma \) (b), it may include both \( \Sigma \) and the external boundary of the computational domain (c), or even a combination of the latter two sub-cases.}
\end{figure}

1.1 Vector spaces

We also need to introduce vector spaces attached to the sets we just defined. In the forthcoming analysis, if \( \mathcal{F} \) is any finite set, we shall denote \( V(\mathcal{F}) \) as the vector space of complex valued tuples indexed by \( \mathcal{F} \) equipped with its canonical euclidean scalar product i.e.

\[
V(\mathcal{F}) := \{ \mathbf{x} = (x_f)_{f \in \mathcal{F}}, x_f \in \mathbb{C} \}.
\]

Elements of \( V(\mathcal{F}) \) are tuples that may be equivalently regarded as maps \( \mathbf{x} : f \mapsto x_f \) from \( \mathcal{F} \) into \( \mathbb{C} \). Any linear map from one such space to another \( M : V(\mathcal{F}_1) \to V(\mathcal{F}_2) \) is nothing but a matrix \( M = (M_{e,f}) \in \mathbb{C}^{\#\mathcal{F}_2 \times \#\mathcal{F}_1} \) where we denoted by \( \#\mathcal{F} \) the cardinal of the set \( \mathcal{F} \).
Following these notations, we can form in particular local spaces \( V(\mathcal{E}_j) \) and \( V(\Gamma_j) \) attached to each subdomain. We shall also consider cartesian products of these spaces: for \( \mathcal{F} = \mathcal{E}, \Gamma \) we set
\[
\mathcal{F}_\oplus := \mathcal{F}_1 \times \cdots \times \mathcal{F}_J \quad \text{and} \quad V(\mathcal{F}_\oplus) := V(\mathcal{F}_1) \times \cdots \times V(\mathcal{F}_J).
\]
We shall refer to \( V(\Gamma_\oplus) \) as the *multi-trace* space. This will be the space where we shall write our final reformulation of the boundary value problem to be solved. Let us emphasize that we use the term 'trace' even in the case where the skeleton is thickened. Because our final numerical method will take the form of a linear system posed in \( V(\Gamma_\oplus) \), we need a specific notation to refer to the dimension of this space i.e. the size of the final matrix of our method
\[
N := \dim V(\Gamma_\oplus) = \#\Gamma_1 + \cdots + \#\Gamma_J.
\]
We must emphasize that \( N > \#\Gamma \) because of overlapping between local edge sets \( \Gamma_j \) i.e. \( \Sigma \) defined by (2) is a priori non-trivial.

### 1.2 Restriction matrices

As is standard in domain decomposition, we need to introduce restriction matrices. First we introduce \( R_j : V(\mathcal{E}) \to V(\mathcal{E}_j) \) i.e. \( R_j \in \mathbb{C}^{\#\mathcal{E}_j \times \#\mathcal{E}} \). These restriction matrices are collected in a global matrix (that is not a restriction matrix) \( R : V(\mathcal{E}) \to V(\mathcal{E}_\oplus) \) defined as follows
\[
R^T = [R_1^T, \ldots, R_J^T] \\
R_j(x) := (x_e)_{e \in \mathcal{E}_j} \quad \text{for} \quad x = (x_e)_{e \in \mathcal{E}}.
\]
where “\(^T\)” stands for the usual matrix transpose. The matrix \( R \) is a boolean matrix, by which we mean that its entries can only take the values 0 and 1. Since \( \mathcal{E} = \mathcal{E}_1 \cup \cdots \cup \mathcal{E}_J \) the matrix \( R \) is injective \( \ker(R) = \{0\} \), but it is not surjective in general, which systematically occurs whenever \( \Sigma \neq \emptyset \). Hence \( V(\mathcal{E}) \) is isomorphic to the range of the matrix \( R \) which we shall denote by
\[
V_\mathcal{E}(\mathcal{E}) := \operatorname{range}(R) \subset V(\mathcal{E}_\oplus).
\]
Next we introduce similar restriction matrices associated to the thick skeleton \( Q_j : V(\Gamma) \to V(\Gamma_j) \) i.e. \( Q_j \in \mathbb{C}^{\#\Gamma_j \times \#\Gamma} \). These matrices are also collected in a global matrix (that is not a restriction matrix) \( Q : V(\Gamma) \to V(\Gamma_\oplus) \) i.e. \( Q \in \mathbb{C}^{N \times \#\Gamma} \) defined as follows
\[
Q^T = [Q_1^T, \ldots, Q_J^T] \\
Q_j(x) := (x_e)_{e \in \Gamma_j} \quad \text{for} \quad x = (x_e)_{e \in \Gamma}.
\]
The matrix \( Q \) is also a boolean matrix and there is only one single nonzero entry on each line. Similarly as for \( R \), the matrix \( Q \) is not surjective, but from the covering property \( \Gamma = \Gamma_1 \cup \cdots \cup \Gamma_J \), it follows that \( \ker(Q) = \{0\} \). Hence \( V(\Gamma) \) is isomorphic to the range of the matrix \( Q \) which we shall denote by
\[
V_\mathcal{E}(\Gamma) := \operatorname{range}(Q) \subset V(\Gamma_\oplus).
\]
The space above will be referred to as the *single-trace* space. It consists in those subdomain boundary tuples that match across interfaces. Characterization of this space will be pivotal in the forthcoming analysis.
We introduce matrices $B_j : V(\mathcal{E}_j) \rightarrow V(\Gamma_j)$ i.e. $B_j \in \mathbb{C}^{\# \Gamma_j \times \# \mathcal{E}_j}$ and $B : V(\mathcal{E}_\ominus) \rightarrow V(\Gamma_\ominus)$ as follows:

$$B := \text{diag}(B_1, \ldots, B_J) \quad B_j(x) := (x_e)_{e \in \mathcal{E}_j} \quad \text{for} \quad x = (x_e)_{e \in \mathcal{E}_j}. \quad (10)$$

These are boolean matrices and they have only one non-zero entry per line. The matrices $B_j^\top$ provide a lifting from $V(\Gamma_j)$ into $V(\mathcal{E}_j)$. In particular we have $BB^\top = I$ and thus $B^\top B$ is a projector whose action consists in cancelling those components that are not located on $\Gamma_1 \times \cdots \times \Gamma_J$.

**Lemma 1.**

A tuple of local subdomain contributions $u \in V(\mathcal{E}_\ominus)$ stems from a single global vector in $V(\mathcal{E})$ if and only if its (interior) traces at the boundary of subdomains match at all interfaces. This is summarized as

$$\forall u \in V(\mathcal{E}_\ominus), \quad u \in \text{range}(R) \iff B(u) \in \text{range}(Q).$$

**Proof:**

Take an arbitrary $x = (x_1, \ldots, x_J) \in V(\mathcal{E}_\ominus)$ with $x_j = (x_{j,e})_{e \in \mathcal{E}_j} \in V(\mathcal{E}_j)$. Assume first that $x = R(y)$ for some $y = (y_e)_{e \in \mathcal{E}} \in V(\mathcal{E})$, which writes $x_{j,e} = y_e$ for all $j = 1 \ldots J$ and all $e \in \mathcal{E}_j$. Since $\Gamma_j \subset \mathcal{E}_j$, we have in particular $x_{j,e} = y_e$ for all $j = 1 \ldots J$ and all $e \in \Gamma_j$ which is equivalent to $B(x) = Q(z)$ where $z = (y_e)_{e \in \Gamma} \in V(\Gamma)$ i.e. $B(x) \in \text{range}(Q) = V_s(\Gamma)$.

Now assume that $x = (x_1, \ldots, x_J) \in V(\mathcal{E}_\ominus)$ is such that $B(x) \in V_s(\Gamma) = \text{range}(Q)$. As a consequence there exists $z = (z_e)_{e \in \Gamma} \in V(\Gamma)$ satisfying $x_{j,e} = z_e$ for all $j = 1 \ldots J$ and all $e \in \Gamma_j = \mathcal{E}_j \cap \Gamma$. Next observe that $\mathcal{E} = \Gamma \cup (\mathcal{E}_1 \setminus \Gamma) \cup \cdots \cup (\mathcal{E}_J \setminus \Gamma)$ is a disjoint union due to $\Sigma \subset \Gamma$, see (2) and (3). This means that, for any $e \in \mathcal{E}$, either $e \in \Gamma$, or there exists a unique $j$ such that $e \in \mathcal{E}_j \setminus \Gamma$. As a consequence we can define $y = (y_e)_{e \in \mathcal{E}} \in V(\mathcal{E})$ by $y_e = z_e$ if $e \in \Gamma$ and $y_e = x_{j,e}$ if $e \in \mathcal{E}_j \setminus \Gamma$. Because $x_{j,e} = z_e$ on $\mathcal{E}_j \cap \Gamma$, we conclude that $y_e = x_{j,e}$ for all $e \in \mathcal{E}_j$ and all $j = 1 \ldots J$, which is equivalent to $x = R(y)$. \hfill \Box

The single trace space consists in those tuples of boundary traces that match at interfaces. It yields a criterion on boundary traces for determining whenever a tuple of subdomain contributions stems from a common global vector.

## 2 Orthogonal projection onto single traces

We will now discuss a more effective characterization of the space of single traces. Instead of using pointwise constraints to ensure that a multitrace is a single trace, we rely on a more
general characterization using a projector. The idea rests on the use of the following Lemma which is a direct consequence of Lemma 1.

**Lemma 2.**
If \( P : V(\Gamma_{\ominus}) \to V(\Gamma_{\oplus}) \) is any projector onto the single traces space i.e. \( P^2 = P \) and \( \text{range}(P) = \text{range}(Q) \), then for any \( u \in V(\mathcal{E}_{\oplus}) \) we have \( u \in \text{range}(R) \iff (I-P)B(u) = 0 \).

This observation points toward new ways to impose transmission conditions through interfaces. This characterization of transmission conditions is the original point of our approach.

The construction of appropriate instances of projection \( P \) is not a difficult task. We first explain the simplest of those projections. From \( \ker Q = \{0\} \) we deduce that \( Q \) admits a left pseudo-inverse \( Q^\dagger = (Q^\top Q)^{-1} Q^\top \). This operator can be computed explicitly since \( Q^\top Q \) is diagonal. We obtain that \( Q^\dagger Q = I \) hence \( Q^\dagger \) is in fact a left inverse for \( Q \). Besides, \( QQ^\dagger \) is a projection in \( V(\Gamma_{\oplus}) \) which is orthogonal with respect to the Euclidian scalar product and its range is \( V_s(\Gamma) \). We explain the construction of other appropriate projectors (which are orthogonal for different scalar products) in the next paragraph.

### 2.1 Inductance matrices

First, for each subdomain, we need to define so-called local inductance matrices \( T_j : V(\Gamma_j) \to V(\Gamma_j) \) (this terminology is deliberately chosen so as to fit the context of electromagnetics) that are assumed symmetric positive definite (SPD) which is equivalent to imposing

\[
(x, y)_{T_j} := x^\top T_j y \quad \text{for} \quad x, y \in V(\Gamma_j)
\]

is a scalar product over \( V(\Gamma_j) \).

The norm associated with this scalar product will be denoted \( \|x\|_{T_j}^2 := (x, x)_{T_j} \). The domain decomposition strategy we are going to describe applies for any choice of local inductances \( T_j \) as long as they satisfy (11), and inductances might be regarded as parameters of the method we propose here. In particular, this implies that \( T_j \) must be an invertible matrix. How to choose properly such matrices depends on functional analysis considerations that are discussed in [6], this choice having an impact on both the speed of convergence and the computational cost of our algorithms.

Gathering local contributions into a single block diagonal matrix, we form a global inductance matrix acting on the multi-trace space

\[
T = \text{diag}(T_1, \ldots, T_j)
\]

\[
(x, y)_T := x^\top T y = (x_1, y_1)_{T_1} + \cdots + (x_j, y_j)_{T_j}
\]

for \( x = (x_1, \ldots, x_j), y = (y_1, \ldots, y_j) \in V(\Gamma_{\ominus}) \) with \( x_j, y_j \in V(\Gamma_j) \). Consistently we shall define the norm attached to this scalar product by \( \|x\|_T^2 = (x, x)_T \). Clearly the block-diagonal matrix \( T \) induces a scalar product over \( V(\Gamma_{\ominus}) \) and is thus invertible.

The forthcoming analysis will heavily rely on the projection matrix \( P \in \mathbb{C}^{N \times N}, P : V(\Gamma_{\ominus}) \to V_s(\Gamma) \subset V(\Gamma_{\oplus}) \) that is \( T \)-orthogonal i.e. orthogonal with respect to the scalar product (12). For any \( u \in V(\Gamma_{\ominus}) \) the image \( w = P(u) \in V(\Gamma_{\oplus}) \) can be characterized as the unique solution to the following variational problem,

\[
\text{find } w = P(u) \in V_s(\Gamma) \text{ such that } (w, v)_T = (u, v)_T, \quad \forall v \in V_s(\Gamma).
\]
In particular we state now the counterpart of Lemma 2 for a $\mathbf{T}$-orthogonal projection $\mathbf{P}$. Note that, with $\mathbf{P}$ defined through (13), we have $[\mathbf{T}(\mathbf{I} - \mathbf{P})]^{\top} = \mathbf{T}(\mathbf{I} - \mathbf{P})$. The identities appearing in Lemma 3 are represented in Figure 3.

**Lemma 3.**
If $\mathbf{P} : \mathbf{V}(\Gamma_\oplus) \rightarrow \mathbf{V}(\Gamma_\oplus)$ is a $\mathbf{T}$-orthogonal projector onto the single traces space i.e. $\mathbf{P}^2 = \mathbf{P}$, $\mathbf{P}$ is self-adjoint with respect to the scalar product induced by $\mathbf{T}$ and $\text{range}(\mathbf{P}) = \mathbf{V}_s(\Gamma)$, then

$$
\text{range}(\mathbf{R}) = \ker(\mathbf{T}(\mathbf{I} - \mathbf{P})\mathbf{B}),
\ker(\mathbf{R}^{\top}) = \text{range}(\mathbf{B}^{\top}\mathbf{T}(\mathbf{I} - \mathbf{P})).
$$

(14)

**Figure 3:** Sketch of the mapping properties. The arrows denote surjective maps. The orthogonal complement $\perp$ is understood in the Euclidian sense.

### 2.2 Projecting a multiple trace in practice

Since $\mathbf{V}_s(\Gamma) := \text{range}(\mathbf{Q}) = \{\mathbf{Q}(\mathbf{z}) , \mathbf{z} \in \mathbf{V}(\Gamma)\}$, solving Problem (13) is equivalent to finding $\mathbf{u} = \mathbf{Q}(\mathbf{y}) , \mathbf{y} \in \mathbf{V}(\Gamma)$ such that $\langle \mathbf{Q}(\mathbf{y}), \mathbf{Q}(\mathbf{z}) \rangle_{\mathbf{T}} = \langle \mathbf{x}, \mathbf{Q}(\mathbf{z}) \rangle_{\mathbf{T}}$ for all $\mathbf{z} \in \mathbf{V}(\Gamma)$ which can be rewritten in matrix form as $\mathbf{Q}^{\top}\mathbf{T}\mathbf{Q}(\mathbf{y}) = \mathbf{Q}^{\top}\mathbf{T}(\mathbf{x})$. We finally arrive at the following explicit expression for the $\mathbf{T}$-orthogonal projector

$$
\mathbf{P} = \mathbf{Q}(\mathbf{Q}^{\top}\mathbf{T}\mathbf{Q})^{-1}\mathbf{Q}^{\top}\mathbf{T}
$$

where $\mathbf{Q}^{\top}\mathbf{T}\mathbf{Q} = \mathbf{Q}_1^{\top}\mathbf{T}_1\mathbf{Q}_1 + \cdots + \mathbf{Q}_J^{\top}\mathbf{T}_J\mathbf{Q}_J$ (15)

Formula (15) involves the inverse matrix $(\mathbf{Q}^{\top}\mathbf{T}\mathbf{Q})^{-1}$ which indicates that computing the action of the orthogonal projector $\mathbf{P} : \mathbf{V}(\Gamma_\oplus) \rightarrow \mathbf{V}(\Gamma_\oplus)$ requires the solution to an auxiliary linear system associated to the matrix $\mathbf{Q}^{\top}\mathbf{T}\mathbf{Q} : \mathbf{V}(\Gamma) \rightarrow \mathbf{V}(\Gamma)$. In practice, following the above formula for the projection matrix, the image $\mathbf{P}(\mathbf{u})$ of any element $\mathbf{u} \in \mathbf{V}(\Gamma_\oplus)$ can be computed as follows

$$
\mathbf{w} = \mathbf{P}(\mathbf{u}) \iff \mathbf{w} = \mathbf{Q}(\mathbf{v}) \text{ where } \mathbf{v} \in \mathbf{V}(\Gamma) \text{ solves } \mathbf{Q}^{\top}\mathbf{T}\mathbf{Q}\mathbf{v} = \mathbf{Q}^{\top}\mathbf{T}\mathbf{u}.
$$

(16)

This linear system is not a priori block-diagonal and, in general, will not be. It should be interpreted as a non-local operator. Despite the nonlocality of $\mathbf{P}$ and the fact that (15) only provides an implicit definition of $\mathbf{P}$, what really matters is fast evaluation of $\mathbf{u} \mapsto \mathbf{P}(\mathbf{u})$. The bottleneck here is of course the solution to the $\#\Gamma \times \#\Gamma$ linear system (16). This requires an efficient solution strategy for (13), which is an SPD problem. Current literature already provides many powerful techniques for solving such problems including adaptive multigrids, see e.g. [4], or two-level substructuring domain decomposition method [39 Chap.4-6]. A possible
solution strategy for treating this linear system relies on the Neumann-Neumann algorithm. Observe from Definition [3] that the matrix $D := (Q^\top T Q)^{-1} : V(\Gamma) \rightarrow V(\Gamma)$ is diagonal $D = \text{diag}_{e \in \Gamma}(1/d_e)$ where $d_e = \#\{j \in \{1, \ldots, J\}, \ e \in E_j\}$ is the number of subdomains an $e$ belongs to. The Neumann-Neumann algorithm \cite{33, 39} then consists in a preconditioned conjugate gradient solver (PCG) taking $D Q^\top T^{-1} Q D$ as preconditiioner. The preconditioned problem then writes

$$w = P(u) \quad \iff \quad w = Q(v) \quad \text{where} \quad v \in V(\Gamma) \quad \text{solves} \quad M \cdot (Q^\top T Q)v = M \cdot Q^\top T(u)$$

(17) with $M := D Q^\top T^{-1} Q D$.

2.3 Communication matrix

The projector $P$ leads to the definition of a so-called communication matrix $\Pi \in \mathbb{C}^{N \times N}$ defined as the matrix of the orthogonal symmetry with respect to $V_\delta(\Gamma)$ i.e.

$$\Pi := 2P - I \quad \text{so that} \quad P = (I + \Pi)/2.$$  

(18)

Observe that $\Pi = P - (I - P)$ and that $I - P = (I - \Pi)/2$ which is the $T$-orthogonal projector with $V_\delta(\Gamma)$ as kernel. The communication matrix satisfies a few elementary yet important properties that are summarized in the next lemma.

Lemma 4.

The communication matrix $\Pi$ defined by (18) is a $T$-isometric involution i.e. $\Pi^2 = I$ and $\|\Pi(x)\|_T = \|x\|_T$ for all $x \in V(\Gamma_\oplus)$.

Proof:

We have $P^2 = P$ since $P$ is a projector by construction, so that $\Pi^2 = 4P^2 - 4P + I = I$. On the other hand, taking $u = v = P(x) \in V_\delta(\Gamma)$ in [13] yields $\|P(x)\|_T = (P(x), P(x))_T = (x, P(x))_T = \Re\{(x, P(x))_T\}$. As a consequence

$$\|\Pi(x)\|_T^2 = \|2P(x) - x\|_T^2 = (2P(x) - x, 2P(x) - x)_T$$

$$= 4\|P(x)\|_T^2 - 4\Re\{(x, P(x))_T\} + \|x\|_T^2 = \|x\|_T^2.$$ 

2.4 Explicit expressions

Although the projection and communication matrices $P$ and $\Pi$ are non-local in general, there are cases where they get localized. There are choices of inductance $T$ for which it is possible to exhibit an explicit expression for the matrix $(Q^\top T Q)^{-1} Q^\top T(u)$. A first simple example is the case of a scalar inductance, namely $T = aI$ (with $a > 0$) for which we immediately get

$$P = Q(Q^\top Q)^{-1} Q^\top.$$  

Remarkably, the projection is independent of $a$ (hence of $T$).

Next, we give another example that is a generalization of the previous simple case to some diagonal matrices. For each $e \in \Gamma$ set $T(e) := \{j \in \{1, \ldots, J\}, e \in E_j\}$ and $d_e = \#T(e)$. Then, for any subset $\Upsilon \in \mathcal{P}(\{1, \ldots, J\})$ where $\mathcal{P}(E)$ refers to the subsets of $E$, denote $\Gamma_\Upsilon := \{e \in \Gamma, T(e) = \Upsilon\}$. The collection of $\Gamma_\Upsilon$ yields a disjoint partition of $\Gamma$ associated to
the equivalence relation $e \sim e' \iff \Upsilon(e) = \Upsilon(e')$, see [33 §2.5.1]. In particular $\Gamma_T \cap \Gamma_T' = \emptyset$ if $\Upsilon \neq \Upsilon'$. Next consider scalar products defined through the symmetric positive definite matrices $T : V(\Gamma_T) \to V(\Gamma_T)$, and assume that each local inductance $T_j : V(\Gamma_j) \to V(\Gamma_j)$ satisfies
\begin{equation}
\begin{aligned}
(T_j)_{e,e'} &= 0 & \text{if } \Upsilon(e) \neq \Upsilon(e') \\
(T_j)_{e,e'} &= (T \Upsilon)_{e,e'} & \text{if } \Upsilon(e) = \Upsilon(e') = \Upsilon.
\end{aligned}
\end{equation}
This means that each local inductance matrix $T_j$ is assumed block diagonal, each block $T_{\Upsilon}$ corresponding to one of the equivalence classes intersecting $\Gamma_j$. With such a choice of inductance, then $v = P(u)$ is given by the explicit formula
\begin{equation}
v = P(u) \iff v_{j,e} = \frac{1}{d_e} \sum_{k \in \Upsilon(e)} u_{k,e} \forall e \in \Gamma
\end{equation}
where $u = (u_1, \ldots, u_J) \in V(\Gamma_\oplus)$, $u_j = (u_{j,e})_{e \in \Gamma_j}$,
\begin{equation}
v = (v_1, \ldots, v_J) \in V(\Gamma_\oplus), \quad v_j = (v_{j,e})_{e \in \Gamma_j}.
\end{equation}
Notice that $P$ is independent of the inductance matrices $T_j$ (hence also $\Pi$). Let us examine the particular case where the domain decomposition does not involve any cross-point and $\Gamma = \Sigma$. Such decompositions are sometimes referred to as "onion skin" like. Hypothesis (19) then means that $T_j$ couples edges belonging to the same interface. In this special case we have $d_e = 2$, $\forall e \in \Sigma$ i.e. $\Upsilon(e) = \{j_-(e), j_+(e)\}$ where $j_-(e) < j_+(e)$ so, with the same notation as in [20], the orthogonal projection and the communication matrix are given explicitly by the formula
\begin{equation}
v = P(u) \iff v_{j,-(e),e} = v_{j,(e),e} = (u_{j,-(e),e} + u_{j,(e),e})/2, \quad \forall e \in \Sigma,
\end{equation}
v = \Pi(u) \iff v_{j,(e),e} = u_{j,(e),e} \quad \text{and} \quad v_{j,(e),e} = u_{j,-(e),e}, \quad \forall e \in \Sigma.
\end{equation}

3 The scattering problem and its reformulation

The present contribution is concerned with the efficient solution to electromagnetic scattering problems. Although the principles that we are going to develop apply to a wider range of problems, for the sake of clarity, we choose a specific model problem for explaining our method and we describe this model problem here.

3.1 Variational problem and Galerkin approximation

First we need to formulate a few reasonable assumptions regarding the coefficients modelling the propagation medium. We shall assume a strictly constant positive wavenumber $\kappa > 0$ as well as three measurable essentially bounded functions $\varepsilon, \mu : \Omega \to \mathbb{C}$ and $\eta : \partial \Omega \to \mathbb{C}$. We assume that these functions are also uniformly bounded below i.e. there exist constants $\varepsilon_*, \mu_*, \eta_* > 0$ such that $\Re\{\varepsilon(x)\} > \varepsilon_*, \Re\{\mu(x)\} > \mu_*$ for all $x \in \Omega$ and $\Re\{\eta(x)\} > \eta_*$ for all $x \in \partial \Omega$. We also assume
\begin{equation}
\begin{aligned}
\Im m\{\varepsilon(x)\} &\geq 0, \ \Im m\{\mu(x)\} \geq 0 \quad \forall x \in \Omega, \\
\Im m\{\eta(x)\} &\geq 0 \quad \forall x \in \partial \Omega.
\end{aligned}
\end{equation}
In the following $n : \partial \Omega \to \mathbb{R}^3$ shall refer to the outward pointing unit normal vector to the boundary of the computational domain. Given a volume source term $F \in L^2(\Omega)^3$, we consider
the model problem: find electric and magnetic fields \( \mathbf{E}, \mathbf{H} \in L^2(\Omega)^3 \) satisfying
\[
\begin{aligned}
\nabla \times \mathbf{E} - i\kappa \mu \mathbf{H} &= 0 & \text{in } \Omega, \\
\nabla \times \mathbf{H} + i\kappa \epsilon \mathbf{E} &= \mathbf{F} & \text{in } \Omega, \\
\mathbf{n} \times \mathbf{E} \times \mathbf{n} - \eta \mathbf{H} \times \mathbf{n} &= 0 & \text{on } \partial \Omega.
\end{aligned}
\]

Here of course \( \mathbf{n} \times \mathbf{E} \times \mathbf{n} \) is the tangential component of the electric field on the boundary \( \partial \Omega \). Eliminating the magnetic field \( \mathbf{H} \), this problem can be equivalently put in variational form with the electric field \( \mathbf{E} \) as sole unknown: find \( \mathbf{E} \in \mathbb{W}(\Omega) := \{ \mathbf{u} \in L^2(\Omega)^3, \nabla \times \mathbf{u} \in L^2(\partial \Omega)^3 \} \) such that \( a_\Omega(\mathbf{E}, \mathbf{E}') = \ell_\Omega(\mathbf{E}') \) for all \( \mathbf{E}' \in \mathbb{W}(\Omega) \) where
\[
\begin{aligned}
a_\Omega(\mathbf{u}, \mathbf{v}) &:= \int_\Omega \mu^{-1} \nabla \times \mathbf{u} \cdot \nabla \times \mathbf{v} - \kappa^2 \epsilon \mathbf{u} \cdot \mathbf{v} \, dx \\
&\quad - \iota \int_{\partial \Omega} (\kappa/\eta)(\mathbf{u} \times \mathbf{n}) \cdot (\mathbf{v} \times \mathbf{n}) \, d\sigma, \\
\ell_\Omega(\mathbf{v}) &:= \int_\Omega \mathbf{F} \cdot \mathbf{v} \, dx.
\end{aligned}
\]

We consider a Galerkin discretization of this problem by means of Nédélec edge’s finite elements: find \( \mathbf{E}_h \in \mathcal{N}_h(\Omega) \) such that \( a_\Omega(\mathbf{E}_h, \mathbf{E}'_h) = \ell_\Omega(\mathbf{E}'_h) \) for all \( \mathbf{E}'_h \in \mathcal{N}_h(\Omega) \), with discrete variational space defined by \( \mathcal{N}_h(\Omega) := \{ \mathbf{u} \in \mathbb{W}(\Omega), \mathbf{u}|_e \in \mathcal{N}(e) = \{ \varphi|_e, \varphi(x) = \alpha + x \times \beta, \alpha, \beta \in \mathbb{C}^3 \} \) where \( \varphi|_e \) is the only element \( \mathcal{N}_h(\Omega) \) satisfying \( \int_e \varphi|_e(x) \cdot \mathbf{t}_e \, d\sigma(x) = 1 \) and \( \int_e \varphi|_e(x) \cdot \mathbf{t}_f \, d\sigma(x) = 0 \) for \( f \in \mathcal{E} \) and \( f \neq e \). We finally obtain the matrix form of the problem: noting \( \mathbf{u}_\Omega = (\int_e \mathbf{E}_h \cdot \mathbf{t}_e \, d\sigma)_e \in \mathcal{E} \), we look for
\[
\mathbf{u}_\Omega \in \mathbb{V}(\mathcal{E}) \quad \text{such that} \quad \mathbf{A}_\Omega \cdot \mathbf{u}_\Omega = \mathbf{f}_\Omega
\]
where
\[
\mathbf{A}_\Omega = (a_\Omega(\varphi|_e, \varphi|_f))_{e,f \in \mathcal{E}}, \\
\mathbf{f}_\Omega = (\ell_\Omega(\varphi|_e))_{e \in \mathcal{E}}.
\]

Provided that the mesh is sufficiently fine, which we shall systematically assume thereafter, it is a consequence of classical analysis of Maxwell’s equations \cite{2, 24, 31} that Assumption \cite{22} implies the well posedness of the Galerkin variational formulation \cite{24} and thus the invertibility of the matrix \( \mathbf{A}_\Omega \).

### 3.2 Reformulation based on domain decomposition

Domain decomposition leads to considering restricted sesquilinear forms on each local subdomain. Denote \( \mathcal{N}_h(\Omega_j) := \{ \mathbf{v}|_{\Omega_j}, \mathbf{v} \in \mathcal{N}_h(\Omega) \} \), and \( a_{\Omega_j}(\mathbf{u}, \mathbf{v}) := \int_{\Omega_j} \mu^{-1} \nabla \times \mathbf{u} \cdot \nabla \times \mathbf{v} - \kappa^2 \epsilon \mathbf{u} \cdot \mathbf{v} \, dx - \iota \int_{\partial \Omega_j \cap \partial \Omega} (\kappa/\eta)(\mathbf{u} \times \mathbf{n}) \cdot (\mathbf{v} \times \mathbf{n}) \, d\sigma \) and \( \ell_{\Omega_j}(\mathbf{v}) := \int_{\Omega_j} \mathbf{F} \cdot \mathbf{v} \, dx \). The corresponding local matrices and right hand sides take the expression
\[
\begin{aligned}
\mathbf{A}_j &:= (a_{\Omega_j}(\varphi|_e, \varphi|_f))_{e,f \in \mathcal{E}_j}, \\
\mathbf{f}_j &:= (\ell_{\Omega_j}(\varphi|_e))_{e \in \mathcal{E}_j},
\end{aligned}
\]
In particular $A_j \in \mathbb{C}^{\#\mathcal{E}_j \times \#\mathcal{E}_j}$ and $f_j \in \mathbb{C}^{\#\mathcal{E}_j}$. The local contributions (24) are glued together, enforcing continuity across interfaces, by means of the restrictions matrices $R_j$ introduced in §1.2. The global linear system is then decomposed in the following manner

$$
A\Omega = R^\top A R = R_1^\top A_1 R_1 + \cdots + R_J^\top A_J R_J
$$

$$
f\Omega = R^\top f = R_1^\top f_1 + \cdots + R_J^\top f_J
$$

where $A := \text{diag}(A_1, \ldots, A_J)$ and $f := [f_1^\top, \ldots, f_J^\top]$ (26)

so that $A \in \mathbb{C}^{N \times N}$ and $f \in \mathbb{C}^N$.

Below we introduce several problems that are equivalent to the original Problem (24). By equivalent we mean that having a solution to one of the two problems yields a solution to the other one.

**Reformulation 1.** Let $u_\Omega$ be solution to the discrete problem (24), namely $R^\top A R u_\Omega = R^\top f$. Introducing $u = Ru_\Omega \in V(\mathcal{E}_\oplus)$ and $v = Au - f \in V(\mathcal{E}_\oplus)$ it is immediate to see that they are solutions to

$$
\text{find } (u, v) \in \text{range } R \times \ker R^\top \text{ such that } \\
A u - v = f.
$$

(27)

Reciprocally, if $(u, v)$ are solutions to (27) then there exists $u_\Omega \in V(\mathcal{E})$ such that $R u_\Omega = u$. Multiplying both sides by $R^\top A$ yields $R^\top A R u_\Omega = R^\top A u = R^\top (v + f) = R^\top f$ and $u_\Omega$ is solution to (24). In fact, the global solution $u_\Omega$ might be recovered from the solution $u$ of the problem above by the identity $u_\Omega = (R^\top R)^{-1} R^\top u$ which does not raise any computational difficulty since the matrix $R^\top R \in \mathbb{C}^{\#\mathcal{E} \times \#\mathcal{E}}$ is diagonal i.e. $R^\top R = \text{diag}_{e \in \mathcal{E}}(d_e)$ where $d_e = \#\{j \in \{1, \ldots, J\} \mid e \in \mathcal{E}_j\}$.

**Reformulation 2.** Problem (27) is a block diagonal system which will allow us to exploit the geometric partitioning of the domain. However the solution spaces, namely range($R$) and ker($R^\top$), are not convenient to work with in practice. This is why, taking advantage of Lemma 3 we can rewrite equivalently the condition $u \in \text{range}(R)$ as $T(I - P)B u = 0$. Besides the condition $v \in \ker(R^\top)$ is equivalent to the existence of some $q \in V(\Gamma_\oplus)$ such that $v = B^\top (I - P) q$. Note that $q$ is unique up to an element of ker($I - P$) = range($P$). We therefore find that the system of equations (27) is equivalent to the following saddle-point problem

$$
\text{find } (u, q) \in V(\mathcal{E}_\oplus) \times V(\Gamma_\oplus) \text{ such that } \\
A u - B^\top T(I - P) q = f, \\
T(I - P) B u = 0.
$$

(28)

**Reformulation 3.** The issue with the formulation of Problem (28) is that the matrix $A$ is not always invertible. To remedy to this, if $(u, q)$ are solutions to (28), we introduce a change of unknown and let $p = (I - P) q - i B u$, so that $(u, p)$ are solutions to the following problem

$$
\text{find } (u, p) \in V(\mathcal{E}_\oplus) \times V(\Gamma_\oplus) \text{ such that } \\
(A - i B^\top T B) u - B^\top T p = f, \\
(I - P) B u = 0, \\
P(p + i B u) = 0.
$$

(29)
Note that compared to (28), we dropped the (invertible) matrix $T$ in front of the second equation, since it was not playing any role. Besides, we point out that the third equation translates the fact that $(I - P)q$ is an element of $V_q(\Gamma)$. Reciprocally, having a solution $(u, p)$ to Problem (29), it suffices to take $q = p + iBu$ to obtain $(u, q)$ as solution to Problem (28).

The next lemma establishes that the linear system above is systematically well posed. The proof relies on Assumption (22) which implies in particular that $\exists m\{a_{qj}(v, v)\} \leq 0$ for all $v \in N_b(\Omega_j)$. We deduce that $\exists m\{\overline{v}^\top A_j v\} \leq 0$ for all $v \in V(\mathcal{E}_j)$. The sign property on the imaginary part of each local contribution $A_j$ naturally transfers to the global matrix $A$. This leads to introducing a quadratic functional $\mathcal{P} : V(\mathcal{E}_\oplus) \rightarrow \mathbb{R}$ associated to energy dissipation

$$\mathcal{P}(v) := -\exists m\{\overline{v}^\top A v\}$$

$$\mathcal{P}(v) \geq 0, \quad \forall v \in V(\mathcal{E}_\oplus).$$

Lemma 5.

The matrix $A - iB^\top TB$ is invertible.

Proof:

It suffices to show that the kernel is trivial. Pick $u \in V(\mathcal{E}_\oplus)$ satisfying $(A - iB^\top TB)u = 0$. This implies in particular $|Bu|^2 - 3m\{\overline{u}^\top A u\} = 0$ and, taking account of (30), we conclude that $Bu = 0$, and thus $Au = 0$. Next according to (17), there exists $u_\Omega \in V(\mathcal{E})$ such that $u = R(u_\Omega)$ so that $AR(u_\Omega) = 0$ and thus $A_\Omega(u_\Omega) = R^\top A R u_\Omega = 0$. Since $A_\Omega$ is invertible due to well posedness of the original wave scattering problem (24), this implies $u_\Omega = 0$ and thus $u = R(u_\Omega) = 0$. \hfill \Box

It is important to realize that, in the first equation above, the matrix $A - iB^\top TB = \text{diag}_{j=1,\ldots,J}(A_j - iB_j^\top T_j B_j) \in \mathbb{C}^{N \times N}$ is block diagonal since $A, B$ and $T$ are themselves block diagonal.

Reformulation 4. Further elaborating on Formulation (29), since $P$ is a $T$-orthogonal projector the two equations $(I - P)Bu = 0$ and $P(p + iBu) = 0$ are equivalent to the single statement $2P(p + iBu) + 2i(I - P)Bu = 0$. Then taking into account that $P = (\Pi + I)/2$ and $I - P = (I - \Pi)/2$, the latter equation can be rewritten $p + \Pi(p + 2iBu) = 0$. This shows that (29) can be written equivalently

$$\begin{align*}
\text{find } (u, p) \in V(\mathcal{E}_\oplus) \times V(\Gamma_\oplus) \text{ such that } \\
(A - iB^\top TB)u - B^\top Tp &= f, \\
p + \Pi(p + 2iBu) &= 0.
\end{align*}$$

Reformulation 5. Invertibility of the matrix $A - iB^\top TB$ allows to eliminate the volume unknown $u \in V(\mathcal{E}_\oplus)$ from Problem (31) and to reduce this problem to an equation posed on $\Gamma$ only. To achieve this, let us set

$$\begin{align*}
S &= I + 2iB(A - iB^\top TB)^{-1}B^\top T, \\
g &= -2iB(A - iB^\top TB)^{-1}f.
\end{align*}$$

The matrix $S \in \mathbb{C}^{N \times N}$ is commonly called “scattering matrix”. It is a block diagonal matrix $S := \text{diag} S_j$ with $S_j := I + 2iB_j(A_j - iB_j^\top T_j B_j)^{-1}B_j^\top T_j$ whose inversion can thus be
made fully parallel. Its definition guarantees that \( p + 2iBu = S(p) + 2iB(A - iB^TTHB)^{-1}f \).

Plugging this into the second equation of (29), we finally arrive at what we shall call “skeleton formulation”, namely

\[
\text{find } p \in V(\Gamma_{\oplus}) \text{ such that } (I + iIS)p = g.
\] (33)

As mentioned above, once Equation (33) is solved, the global volume solution can be recovered by computing \( u = (A - iB^TTHB)^{-1}(B^TTP + f) \) which can be achieved in parallel since the matrix \( A - iB^TTHB := \text{diag}(A_j - iB_j^TTH_j) \) is subdomain-wise block diagonal.

To sum up, we have given different equivalent formulations (i.e. (27), (28), (29) then (31)) of the initial problem (24) and finally obtain the skeleton formulation (33) which is the one we propose to solve by an appropriate linear solver. This form is not new; the equation \((I + iIS)p = g\) with \(I\) the exchange matrix defined in §2.4, Formula (21), appears in [10, 9] where DDM algorithm is applied to Helmholtz equation with an onion skin domain decomposition i.e. no cross-point \(^1\). Although these previous works can easily be extended to Maxwell’s equations, they can only handle interfaces with edges of multiplicity two. Here we obtain a generalization that yields a treatment of cross-points with edges of greater multiplicity. The price to pay is a more elaborate definition of \(I\).

3.3 Analysis of the skeleton formulation

Besides the communication matrix \(I\), the scattering matrix \(S\) is a cornerstone of Equation (33). It models the wave propagation phenomena within each local subdomain. We dedicate the present section to deriving a few key properties of this matrix. Taking account of the identity \(I = BB^T = B(A - iB^TTHB)^{-1}(A - iB^TTHB)B^T\), a basic simple re-arrangement in the definition (32) of the scattering matrix \(S\) yields the expression

\[
S = B(A - iB^TTHB)^{-1}(A + iB^TTHB)B^T.
\] (34)

This expression can be further condensed by means of the Schur complement of the matrix \(A = \text{diag}(A_1, \ldots, A_J)\) following the standard approach in substructuring methods [33 chap.2], [37 chap.4], [39 chap.4-6]. Denote

\[
B_c = \text{diag}(B_{1,c}, \ldots, B_{J,c})
\]

\[
B_{j,c}(v) = (v_{e})_{e \in E_j \setminus \Gamma_j} \text{ for } v = (v_{e})_{e \in E_j}.
\] (35)

With this notation we have \(B_c^TBB_c + B^TTHB = I\) which offers a decomposition of unknown vectors into boundary (labelled "B") and interior (labelled "I") contributions. The matrix of the global problem can then be decomposed accordingly: up to a reordering, it writes as follows

\[
A = \begin{bmatrix}
A_{II} & A_{IB} \\
A_{BI} & A_{BB}
\end{bmatrix}
\]

with \(A_{II} := B_cAB_{c}^T, \quad A_{IB} := B_cAB_{c}^T, \quad A_{BI} := BAB_{c}^T, \quad A_{BB} := BAB_{c}^T.\)

(36)

The matrix \(A_{BB} - A_{BI}A_{II}^{-1}A_{IB} \in \mathbb{C}^{N \times N}\) is customarily referred to as the Schur complement of \(A\) (with respect to skeleton unknowns). With the help of the Schur complement, the expression of the scattering matrix becomes simple.

\(^1\)With a different sign convention though, that results in considering \(-S\) instead of \(+S\).
Lemma 6.
Assume that the matrix $A_{ii}$ is invertible, and denote $\tilde{A} := T^{-1}(A_{bb} - A_{bi}A_{ii}^{-1}A_{ib})$. Then the scattering matrix admits the expression

$$S = (\tilde{A} - iI)^{-1}(\tilde{A} + iI).$$

Proof:
Starting from Expression (34), pick an arbitrary $p \in V(\Gamma_{\oplus})$ and let us compute the expression of $q = S(p)$. Denote $v = (A - iB^T T B)^{-1}(A + iB^T T B) B^T p$ so that $q = B(v)$. Decomposing into interior and boundary contributions, with $v^T = [v_i^T, v_b^T]$, we have $q = v_b$ and the linear system

$$A_{ii}v_i + A_{ib}q = A_{ib}p$$
$$A_{bi}v_i + (A_{bb} - iT)v = (A_{bb} + iT)p.$$ 

Now eliminating the interior unknowns $v_i$ by "Schur complementing" this system then leads to the identity $(A_* - iT)q = (A_* + iT)p$ with $A_* := A_{bb} - A_{bi}A_{ii}^{-1}A_{ib}$. There only remains to multiply on the left by $T^{-1}$ which leads to the expression we were looking for.

The matrix $A_{ii}$ is not guaranteed to be invertible. A non-trivial kernel corresponds to a resonance phenomenon in a local subproblem. This however cannot occur if the maximum diameter of subdomains is small enough, see e.g. Lemma 11.4 in [39].

The previous lemma delivers the instructive insight that, under appropriate circumstances ($A_{ii}$ invertible), the scattering matrix takes the form of a Cayley transform. Let us underline however that, even when $A_{ii}$ is not invertible, $A - iB^T T B$ is invertible and the scattering matrix given by (34) is properly defined.

Lemma 7.
For any $p \in V(\Gamma_{\oplus})$, we have the estimate $\|S(p)\|_T \leq \|p\|_T$. More precisely the following energy conservation identity holds

$$\|S(p)\|_T^2 + 4\mathcal{P}(v) = \|p\|_T^2$$
with $v = (A - iB^T T B)^{-1}B^T T (p)$.

Proof:
According to (32), we have $S(p) = p + 2iBv$. Using this expression we have $\|S(p)\|_T^2 = \|p + 2iBv\|_T^2 = \|p\|_T^2 + 4\|Bv\|_T^2 - 4\Re\{i(p,Bv)_T\}$. On the other hand, the very definition of $v$ directly yields $-\chi^T A v + i(B\bar{v})^T T (Bv) = -(B\bar{v})^T T (p)$ which rewrites $\mathcal{P}(v) := -3m\{\chi^T A v\} = -\|Bv\|_T^2 + \Re\{i(p,Bv)_T\}$. From this follows the desired energy conservation identity and, since $\mathcal{P}(v) \geq 0$ according to (30), we also deduce $\|S(p)\|_T \leq \|p\|_T$.

From the previous identity, we deduce that $\|S(p)\|_T \leq \|p\|_T$ for all $p \in V(\Gamma_{\oplus})$ i.e. the scattering matrix is non-expansive. The previous energy conservation result actually paves the way to proving the invertibility of the matrix of (33).

Proposition 1.
The matrix $I + iS$ is invertible, all eigenvalues of $I + iS$ belong to the punctured disk $\{\lambda \in \mathbb{C} \setminus \{0\}, |1 - \lambda| \leq 1\}$. Moreover we have $\|(I + iS)p\|_T \leq 2\|p\|_T$ for all $p \in V(\Gamma_{\oplus})$, and there exists a constant $\alpha > 0$ such that, for all $p \in V(\Gamma_{\oplus})$,

$$\Re\{i(p, (I + iS)p)_T\} \geq \alpha \|p\|_T^2.$$
Proof:

The property on the location of eigenvalues and the upper bound stem directly from the inequality \( \| \text{IIS}(p) \|_T \leq \| p \|_T \) (see Lemma 1 and Lemma 7) and the invertibility that we establish next. We need to show that \( \ker(I + \text{IIS}) = \{0\} \). Pick any \( p \in V(\Gamma_\Omega) \) satisfying \((I + \text{IIS})p = 0\) and set \( u = (A - iB^T TB)^{-1}B^T T(p) \). As we already mentioned before, we have \( S(p) = p + 2iB(u) \) so the following equations hold

\[
(A - iB^T TB)u = B^T T(p),
\]

\[
p + \Pi(p + 2iBu) = 0.
\]

This means that the pair \((u, p)\) must be solution to \((31)\) with \( f = 0 \). The latter problem was shown to be equivalent to \((27)\). This implies that \( u \in V(\mathcal{E}_\Omega) \) solves \((27)\) with \( f = 0 \), and that \( u_\Omega = (R^T R)^{-1}R^T u \) solves \((24)\) with \( f_\Omega = 0 \). Since \((24)\) was assumed uniquely solvable, we deduce that \( u_\Omega = 0 \Rightarrow u = R(u_\Omega) = 0 \). This implies that \( B^T Tp = 0 \). Since \( BB^T = I \), multiplying on the left by \( B \) yields \( Tp = 0 \) hence \( p = 0 \) as \( T \) is assumed symmetric positive definite. This proves the invertibility of \( I + \text{IIS} \). To conclude set

\[
\alpha = \inf_{q \in V(\Gamma_\Omega) \setminus \{0\}} \frac{\text{Re}\{\langle q, (I + \text{IIS})q \rangle_T \}}{\|q\|_T^2}.
\]

(37)

Take \( p \in V(\Gamma_\Omega) \setminus \{0\} \) with \( \| p \|_T = 1 \) and \( \text{Re}\{\langle p, (I + \text{IIS})p \rangle_T \} = \alpha \). Applying Cauchy-Schwarz inequality together with Lemma 2 and Lemma 7 already gives \( \alpha = 1 + \text{Re}\{\langle p, \text{IIS}p \rangle_T \} \geq 1 - \| p \|^2_T \| \text{IIS}(p) \|_T = 1 - \| S(p) \|_T \geq 1 - \| p \|^2_T = 0 \) i.e. \( \alpha \geq 0 \). Next, proceed by contradiction, assuming \( \text{Re}\{\langle p, (I + \text{IIS})p \rangle_T \} = \alpha = 0 \). According to Lemma 4 and Lemma 7 again, we have

\[
\| p \|^2_T \geq \| S(p) \|^2_T = \| \text{IIS}(p) \|^2_T = \| (I + \text{IIS})p - p \|^2_T
\]

\[
= \| (I + \text{IIS})p \|^2_T + \| p \|^2_T - 2\text{Re}\{\langle p, (I + \text{IIS})p \rangle_T \}
\]

\[
= \| (I + \text{IIS})p \|^2_T + \| p \|^2_T.
\]

(38)

From this we finally conclude that \( \| (I + \text{IIS})p \|_T = 0 \) which shows that \( p = 0 \) since \( I + \text{IIS} \) was proved invertible. This contradicts \( \| p \|_T = 1 \) so we finally conclude that \( \alpha > 0 \) necessarily. \( \square \)

The previous result directly implies the convergence of standard fixed point algorithms such as the damped Richardson algorithm, hence necessarily the convergence of the restarted GMRES solver.

4 Concrete definitions of inductance operators

In the present section we examine and discuss two concrete choices of inductance operators.

4.1 Zeroth-order inductance operator

We discuss a first choice of inductance based on the \( L^2 \) scalar product of tangential traces. We assume here that \( \Sigma = \Gamma \), and the inductance matrix \( T = \text{diag}(T_1, \ldots, T_J) \) where the entries of the matrices \( T_j : V(\Gamma_j) \to V(\Gamma_j) \) are given by

\[
(T_j)_{e,f} = \int_{\Gamma_j} (\kappa/\eta)(\varphi_e \times n_j) \cdot (\varphi_f \times n_j) d\sigma.
\]

(39)
When $\epsilon, \mu$ are constant in each tetrahedron, the restriction of $\mathbf{\tau} : \Omega \to \mathbb{R}$ to each triangle $\tau$ of $\Gamma_j$ is chosen constant equal to the mean value of $\Re\{\sqrt{\mu/\epsilon}\}$ over all tetrahedrons of $\Omega$ admitting $\tau$ on their boundaries. With such a choice of inductance, local problems amount to numerically solving Maxwell problems in each subdomain $\Omega_j$ with the first order absorbing boundary condition $\mathbf{n}_j \times \mathbf{E} - \mathbf{n}_j \times \mathbf{H} = 0$ on $\Gamma_j$.

This choice of inductance corresponds to the strategy originally used in the work of Després [11]. This work and the variants considered so far in the literature discards the issue raised by the presence of cross-points by adopting a different discretization scheme: a mixed hybrid discretization [12] where the degrees of freedom are associated to the faces of each tetrahedron and can thus be easily exchanged by a simple swap.

On the contrary, the approach we adopt here is able to deal with the presence of degrees of freedom at cross-points even for Nédélec finite elements. To be more specific, for onion skin domain decompositions, we only have to handle single interfaces with edges of multiplicity two and Choice (39) fits the situation described at the end of §2.4. Consequently, the communication operator is given explicitly by Formula (21) and our method is a simple extension of Després’ method to any conformal finite element method. However, by introducing a more general communication operator, our theory allows to deal with domain decomposition with simple transmission quantities involving degrees of freedom of multiplicity more than two for Nédélec’s elements. This appears to be new.

### 4.2 Schur complement based inductance

We shall now examine an alternative possible choice of inductance based on the Schur complement associated to the solution of some auxiliary strongly coercive problem. We dedicate a whole section to this particular inductance because it appears as one of the most efficient choices.

We first need to consider a subset $\Omega' \subset \Omega$ obtained as union of a subset of elements of the triangulation $\mathcal{T}(\Omega') \subset \mathcal{T}(\Omega)$ and such that $\Omega' = \bigcup_{\tau \in \mathcal{T}(\Omega')} \tau$. Setting $\Omega_j' := \Omega' \cap \Omega_j$ and $\Gamma_j' := \partial \Omega_j' \setminus \Gamma_j$, we have $\mathbf{\Pi} = \bigcup_{j=1}^J \mathbf{\Pi}_j'$ and $\partial \Omega_j' = \Gamma_j \cup \Gamma_j'$. Next denote $\mathcal{E}'$ the collection of edges of $\mathcal{T}(\Omega')$, as well as $\mathcal{E}'_j$ those belonging to $\mathcal{T}(\Omega'_j)$. We make the following important assumption that $\mathcal{T}(\Omega')$ is selected so as to guarantee that $\Gamma \subset \mathcal{E}'$ and $\Gamma_j \subset \mathcal{E}'_j$. The subset $\Omega'$ will be the computational domain for our auxiliary problem. It shall typically consist in layers of elements surrounding the skeleton $\mathbf{\Pi}$ of the subdomain decomposition, see Figure 1 (b). In each subdomain $\Omega'_j$ we consider a bilinear form

$$
c_j(\mathbf{u}, \mathbf{v}) := \int_{\Omega'_j} \Re\{\mu^{-1}\} \text{curl}(\mathbf{u}) : \text{curl}(\mathbf{v}) + \kappa^2 \Re\{\epsilon\} \mathbf{u} \cdot \mathbf{v} \, d\mathbf{x}
+ \int_{\Gamma_j' \cup (\partial \Omega_j \setminus \Gamma_j')} \Re\{\kappa/\eta\} (\mathbf{u} \times \mathbf{n}'_j) \cdot (\mathbf{v} \times \mathbf{n}'_j) \, d\sigma \tag{40}
$$

$$
\mathbf{C}_j : \mathcal{V}(\mathcal{E}'_j) \to \mathcal{V}(\mathcal{E}'_j), \quad (\mathbf{C}_j)_{e,f} := c_j(\varphi_j, \varphi_e).
$$

where $\mathbf{n}'_j$ refers to the vector field normal to $\partial \Omega'_j$. We also set $\mathbf{C} := \text{diag}(\mathbf{C}_1, \ldots, \mathbf{C}_J)$. By construction this is a symmetric positive definite matrix. Next we separate unknowns located on the skeleton from other unknowns by means of restriction matrices and we define the
auxiliary matrix $B' : V(\mathcal{E}') \to V(\Gamma_\partial)$ by
\[
B' := \text{diag}(B'_1, \ldots, B'_J)
\]
\[
B'_j(v) := (v_e)_{e \in \Gamma_j} \quad v = (v_e)_{e \in \mathcal{E}_j} \in V(\mathcal{E}_j).
\]  
(41)

The inductance that we propose to consider here is the Schur complement associated to the elimination of interior unknowns in the matrix $C$ defined above. To be more specific we consider the matrix $T : V(\Gamma_\partial) \to V(\Gamma_\partial)$ defined by
\[
T(u_b) = q \quad \text{where} \quad (v, q) \in V(\mathcal{E}) \times V(\Gamma_\partial)
\]
solves
\[
\begin{bmatrix}
C & -(B')^T \\
B' & 0
\end{bmatrix}
\begin{bmatrix}
v \\
q
\end{bmatrix}
= \begin{bmatrix}
0 \\
u_b
\end{bmatrix}.
\]  
(42)

As a Schur complement of a SPD matrix, it is itself SPD and is thus a valid candidate for the construction presented in Section 2. To obtain an expression for the final system to be considered in the global DDM strategy, we need to combine (42) with (31). In this process, one has $u_b = -iBu - p$ which leads to the system
\[
\begin{align}
\text{Find} & \quad (u, v) \in V(\mathcal{E}) \times V(\mathcal{E}), \\
\text{Find} & \quad (p, q) \in V(\Gamma) \times V(\Gamma) \quad \text{such that}
\end{align}
\]
\[
\begin{bmatrix}
A & 0 & B^T \\
0 & -iC & -B'^T \\
B & -B' & 0
\end{bmatrix}
\begin{bmatrix}
u \\
v \\
q
\end{bmatrix}
= \begin{bmatrix}
f \\
0 \\
i p
\end{bmatrix},
\]  
(43)

and $p = -\Pi(p + 2iBu)$.

Of course we also have to discuss actual computation of the operator $\Pi = 2P - I$ since, according to (18) and (17), it involves matrix-vector products for both $T$ and $T^{-1}$. Matrix-vector product by $T$ can be treated based on (42). Matrix-vector by $T^{-1}$ can be computed using the identity $T^{-1} = B'C^{-1}B'^T$.

We advocate the design of inductance operators like (42) because, under technical assumptions, it is shown [32, 6] that the coercivity constant of $I + \PiS$ is bounded from below independently of the meshsize which leads to robust convergence of linear iterative solvers applied to the skeleton formulation (33).

5 Algorithms

We wish now to describe in more concrete terms the practical implementation of the method. Our emphasis is on the parallel nature of the algorithms, in particular the for loops over the $J$ subdomains are written explicitly and can be parallelized. Recall that the problem that is solved in practice is Problem (33) which is posed on the thick skeleton.

5.1 General algorithms

We first provide the general forms of the algorithms by which we mean the definitions of the algorithms that can be applied for any generic scalar product $T$ given by a family of local contributions $T_j$. Such procedures are in particular well-adapted to the Desprès inductance.
Richardson algorithm. The damped Richardson algorithm is first considered, with damping parameter denoted by $r$. Besides the definitions of the restriction matrices, recall in particular the definitions of the local contributions $A_j$ and $f_j$ in (25). The general form of the Richardson algorithm is then given in Algorithm 1.

Algorithm 1 General form of the Richardson algorithm

1: for $j = 1, \ldots, J$ do
2: $p_j = 0$ \hspace{1cm} $\triangleright$ Initialisation
3: $u_j = (A_j - iB_j^\top T_j B_j)^{-1} f_j$ \hspace{1cm} $\triangleright$ Local solve (size: $\#\mathcal{E}_j$)
4: end for
5: for $n = 1, \ldots, n_{\text{max}}$ do
6: $g = 0$ \hspace{1cm} $\triangleright$ size: $\#\Gamma$
7: for $j = 1, \ldots, J$ do
8: $g = g + Q_j^\top T_j (p_j + 2iB_j u_j)$ \hspace{1cm} $\triangleright$ Local scattering
9: end for
10: $v = (Q^\top T Q)^{-1} g$ \hspace{1cm} $\triangleright$ Solved using PCG (size: $\#\Gamma$)
11: for $j = 1, \ldots, J$ do
12: $p_j = p_j + 2r(iB_j u_j - Q_j v)$
13: $u_j = (A_j - iB_j^\top T_j B_j)^{-1} (B_j^\top T_j p_j + f_j)$ \hspace{1cm} $\triangleright$ Local solve (size: $\#\mathcal{E}_j$)
14: end for
15: end for

Of course, in the above algorithm (and in the algorithms below) the inverse matrices $(A_j - iB_j^\top T_j B_j)^{-1}$ are not actually assembled. Instead, each matrix $A_j - iB_j^\top T_j B_j$ is factorized (offline precomputations) and the inversion of the linear system is performed in the course of the iterations using forward and backward substitution.

Besides, as explained above, the projection problem in Algorithm 1 appearing in Line 10 is performed using a preconditioned CG algorithm. To define the PCG algorithm, it suffices to provide a definition for a matrix-vector product routine for the problem matrix $Q^\top T Q$ as well as the preconditioner matrix $M$, see (17). Albeit the fact that such routines are straightforward, the procedure are respectively provided in Algorithm 2 and in Algorithm 3 to stress in particular that they are fully parallel. Notice that the matrix $D$ is diagonal.

Algorithm 2 Matrix-vector product for CG

```
Input: $g$ \hspace{1cm} $\triangleright$ size: $\#\Gamma$
1: $q = 0$ \hspace{1cm} $\triangleright$ size: $\#\Gamma$
2: for $j = 1, \ldots, J$ do
3: $q = q + Q_j^\top T_j Q_j g$
4: end for
Output: $q$
```

Algorithm 3 CG preconditioner

```
Input: $q$ \hspace{1cm} $\triangleright$ size: $\#\Gamma$
1: $q = Dq$
2: $p = 0$ \hspace{1cm} $\triangleright$ size: $\#\Gamma$
3: for $j = 1, \ldots, J$ do
4: $p = p + Q_j^\top T_j^{-1} Q_j q$
5: end for
6: $p = Dp$
Output: $p$
```

GMRES algorithm. The Richardson algorithm is rarely used in practice and Krylov methods are the preferred choice in real-life applications. Since the wave propagation problems
yields non-symmetric problems, one will typically resort to the GMRES algorithm.

To define the GMRES algorithm, it suffices to provide a definition for a right-hand side and a matrix-vector product routine. The right-hand side is denoted by $b$ and can be computed (offline) according to Algorithm 4. The matrix-vector product procedure, which takes as input a vector $p$ and outputs a vector $q$, is given in Algorithm 5. Again, the projection problem appearing in Line 8 of Algorithm 4 and in Line 8 of Algorithm 5 is performed using the same preconditioned CG algorithm that was defined for the Richardson algorithm.

Algorithm 4 RHS computation for GMRES

1: $b = 0$ \hfill $\triangleright$ size: $N$
2: $g = 0$ \hfill $\triangleright$ size: $\#\Gamma$
3: for $j = 1, \ldots, J$ do
4: \hspace{1em} $u_j = (A_j - \alpha B_j^T T_j B_j)^{-1} f_j$ \hfill $\triangleright$ Local solve (size: $\#\mathcal{E}_j$)
5: \hspace{1em} $b = b + 2\alpha Q Q_j^T B_j u_j$ \hfill $\triangleright$ size: $\#\Gamma_j$
6: \hspace{1em} $g = g + 2\alpha Q_j^T T_j B_j u_j$
7: end for
8: $v = (Q^T T Q)^{-1} g$ \hfill $\triangleright$ Solved using PCG (size: $\#\Gamma$)
9: $b = b - 2Qv$

Output: $b$

Algorithm 5 Matrix-vector product for GMRES

Input: $p$

1: $q = 0$ \hfill $\triangleright$ size: $N$
2: $g = 0$ \hfill $\triangleright$ size: $\#\Gamma$
3: for $j = 1, \ldots, J$ do
4: \hspace{1em} $u_j = (A_j - \alpha B_j^T T_j B_j)^{-1} (B_j^T T_j p_j)$ \hfill $\triangleright$ Local solve (size: $\#\mathcal{E}_j$)
5: \hspace{1em} $q = q - 2\alpha Q Q_j^T B_j u_j$ \hfill $\triangleright$ size: $\#\Gamma_j$
6: \hspace{1em} $g = g + Q_j^T T_j (p_j + 2\alpha B_j u_j)$ \hfill $\triangleright$ Local scattering
7: end for
8: $v = (Q^T T Q)^{-1} g$ \hfill $\triangleright$ Solved using PCG (size: $\#\Gamma$)
9: $q = q + 2Qv$

Output: $q$

5.2 Algorithms written for the Schur complement based inductance

We now turn to the particular case where one uses a Schur complement based inductance. As we already explained, the algorithms can be written so that no dense matrix is involved (i.e. the Schur complement is not performed in practice), albeit the underlying non-local nature of the inductance operator. This is particularly important for efficiency considerations because otherwise the naive implementation of the method requires the computation and storage of dense matrices as well as the solution to hybrid sparse-dense linear systems for which many factorization routines may struggle.
Before describing the algorithms let us define

\[ \tilde{C}_j := \begin{bmatrix} C_j & -(B_j')^T \\ B_j' & 0 \end{bmatrix}, \quad \text{and} \quad \tilde{A}_j := \begin{bmatrix} A_j & 0 & B_j^T \\ 0 & -C_j^-1 & -B_j'^T \\ B_j & -B_j' & 0 \end{bmatrix}. \] (44)

The matrices \( C_j \), \( \tilde{C}_j \) and \( \tilde{A}_j \) are fully sparse matrices than can be factorized (offline). In the algorithms below their inverses will appear, which correspond in practice to forward and backward substitutions.

**Richardson algorithm.** The Richardson algorithm written for the Schur complement based inductance is then given in Algorithm 6.

**Algorithm 6** Richardson algorithm for the Schur complement based inductance

1: for \( j = 1, \ldots, J \) do
2: \( \triangleright \) Initialisation
3: \( p_j = 0 \) \( \triangleright \) size: \( \#\Gamma_j \)
4: \((u_j, v_j, q_j) = \tilde{A}_j^{-1}(f_j, 0, 0) \) \( \triangleright \) Local solve (size: \( \#E_j + \#E'_j + \#\Gamma_j \))
5: end for
6: for \( n = 1, \ldots, n_{max} \) do
7: \( g = 0 \) \( \triangleright \) size: \( \#\Gamma \)
8: for \( j = 1, \ldots, J \) do
9: \( (v_j, q_j) = \tilde{C}_j^{-1}(0, p_j + 2iB_ju_j) \) \( \triangleright \) size: \( \#E'_j + \#\Gamma_j \)
10: \( g = g + Q_j^T q_j \) \( \triangleright \) Local scattering
11: \( v = (Q^T TQ)^{-1} g \) \( \triangleright \) Solved using PCG (size: \( \#\Gamma \))
12: end for
13: for \( j = 1, \ldots, J \) do
14: \( p_j = p_j + 2r(iB_ju_j - Q_jv) \)
15: \( (u_j, v_j, q_j) = \tilde{A}_j^{-1}(f_j, 0, ip_j) \) \( \triangleright \) Local solve (size: \( \#E_j + \#E'_j + \#\Gamma_j \))
16: end for
17: end for

Again in this particular case, the projection problem in Algorithm 6 appearing in Line 11 is performed using a preconditioned CG algorithm. The matrix-vector product routine for the problem matrix \( Q^T TQ \) is provided in Algorithm 7 and the one for the preconditioner matrix \( M \) is given in Algorithm 8.

**Algorithm 7** Matrix-vector product for CG

**Input:** \( g \) \( \triangleright \) size: \( \#\Gamma \)

1: \( q = 0 \) \( \triangleright \) size: \( \#\Gamma \)
2: for \( j = 1, \ldots, J \) do
3: \( (v_j, q_j) = \tilde{C}_j^{-1}(0, Q_jg) \)
4: \( q = q + Q_j^T q_j \)
5: end for

**Output:** \( q \)

**Algorithm 8** CG preconditioner

**Input:** \( q \) \( \triangleright \) size: \( \#\Gamma \)
1: \( q = Dq \)
2: \( p = 0 \) \( \triangleright \) size: \( \#\Gamma \)
3: for \( j = 1, \ldots, J \) do
4: \( p = p + Q_j^T B'_j C_j^{-1} B_j'^T Q_jq \)
5: end for
6: \( p = Dp \)

**Output:** \( p \)
GMRES algorithm. The Krylov algorithm for the Schur complement based inductance is now described. The right-hand-side is denoted by $b$ and can be computed (offline) according to Algorithm 9. The matrix-vector product procedure, which takes as input a vector $p$ and outputs a vector $q$, is given in Algorithm 10.

**Algorithm 9** RHS computation for GMRES with the Schur complement inductance

```plaintext
1: $b = 0$ \triangleright size: $N$
2: $g = 0$ \triangleright size: $\#\Gamma$
3: for $j = 1, \ldots, J$ do
4: \quad $(u_j, v_j, q_j) = \tilde{A}_j^{-1}(f_j, 0, 0)$ \triangleright Local solve (size: $\#\mathcal{E}_j + \#\mathcal{E}'_j + \#\Gamma_j$)
5: \quad $b = b + 2iQQ_j B_j u_j$ \triangleright size: $\#\Gamma_j$
6: \quad $(v_j, q_j) = \tilde{C}_j^{-1}(0, B_j u_j)$ \triangleright size: $\#\mathcal{E}'_j + \#\Gamma_j$
7: \quad $g = g + 2iQ_j q_j$
8: end for
9: $v = (Q^T TQ)^{-1} g$ \triangleright Solved using PCG (size: $\#\Gamma$)
10: $b = b - 2Qv$

Output: $b$
```

**Algorithm 10** Matrix-vector product for GMRES with the Schur complement inductance

```plaintext
Input: $p$
1: $q = 0$ \triangleright size: $N$
2: $g = 0$ \triangleright size: $\#\Gamma$
3: for $j = 1, \ldots, J$ do
4: \quad $(u_j, v_j, q_j) = \tilde{A}_j^{-1}(0, 0, p_j)$ \triangleright Local solve (size: $\#\mathcal{E}_j + \#\mathcal{E}'_j + \#\Gamma_j$)
5: \quad $q = q - 2iQQ_j B_j u_j$ \triangleright size: $\#\Gamma_j$
6: \quad $(v_j, q_j) = \tilde{C}_j^{-1}(0, p_j + 2iB_j u_j)$ \triangleright size: $\#\mathcal{E}'_j + \#\Gamma_j$
7: \quad $g = g + Q_j q_j$ \triangleright Local scattering
8: end for
9: $v = (Q^T TQ)^{-1} g$ \triangleright Solved using PCG (size: $\#\Gamma$)
10: $q = q + 2Qv$

Output: $q$
```

6 Numerical experiments

We present now a sequence of numerical experiments supporting the previous analysis and illustrating a few features of the novel approach.

In all our test cases we consider a transmission problem either in a disk (in 2D) or in a ball (in 3D). We set $F \equiv 0$ and consider a source that comes from an inhomogeneous condition on the exterior boundary which corresponds to an incoming plane wave. The propagation medium is always considered homogeneous with coefficients $\mu \equiv \epsilon \equiv \eta \equiv 1$, except in Section 6.5 where we consider a medium with varying coefficients $\epsilon$ and $\mu$. We consider the two transmission operators that were described in Section 4 (except in Section 6.1 where an alternative to the Schur complement approach is also considered). While this is not a requirement, for the
simplicity of the implementation, the Schur complement based inductance is constructed in our experiments with $\Omega' = \Omega$.

We will present some results where Problem (33) is solved using either a damped Richardson iteration scheme (with relaxation parameter $r = 1/2$) or a restarted GMRES algorithm (with a restart every 20 iterations). All numerical errors reported (including the relative error represented in convergence histories) are computed between the exact discrete solution of the original (undecomposed) linear system and the volume broken solutions computed at each iteration of the iterative solvers. The norm used is the $\kappa$-dependent energy norm which corresponds to the following $H(\text{curl})$ norm $\| \cdot \|^2 := \| \cdot \|^2_{L^2} + \kappa^{-2} \| \text{curl} \cdot \|^2_{L^2}$.

The numerical results were obtained using in-house demonstration codes built to test the approach. Meshes were obtained using Gmsh [23] and (unless specified otherwise) partitioned using the automatic graph partitioner Metis [27]. The code is mainly sequential (the inherent parallel nature of the algorithm is not exploited) and is of proof-of-concept nature. For these reasons, no run times will be reported and we compare different methods with respect to iteration counts only. One shall bear in mind though that the cost per iteration is different for each method.

6.1 Pie-like splitting

We propose a first test case which aims at illustrating the interest of the proposed approach. Our purpose is to give evidence that straightforward generalizations of more standard methods proposed in the literature, in particular [9, 10], are not adequate in presence of cross-points, even in the case where no degrees of freedom are attached to the cross-points.

In this test case, the unit disk in 2D is regularly split (this is a geometrically based partitioning, not using an automatic graph partitioner) into $J$ pie wedges pointing at the center of the disk. Therefore, by construction, there are $J$ boundary cross-points and one single interior cross-point (the center of the disk) which is shared by all subdomains. Since we use (low order) Nédélec edge finite elements, no degrees of freedom are attached to the cross-points.

As already mentioned, we consider in this section an alternative to the Schur complement approach, in addition to the two inductance operators that were described in Section 4. The difference lies in the location of the degrees of freedom against which the Schur complement is performed. In the approach of Section 4.2 they are considered in the full subdomain boundary. Here we consider also the case where the Schur complement is performed against each interface (between two subdomains) independently. This equivalently amounts to setting to zero off-diagonal blocks that couple two distinct interfaces in the matrix $T$ defined in Section 4.2. The end result is a block diagonal matrix $T$ with the number of blocks corresponding to the number of subdomains in the case of the operator Section 4.2 and to the number of interfaces in the alternative case considered in addition here. In some sense, the use of this operator is the most straightforward extension of already established approaches akin to [9, 10]. We included this operator in the numerical results to provide numerical evidence that the operator described in Section 4.2 is a much more suitable operator to use in practice within the framework of the proposed method together with cross-points.

Convergence history of iterative algorithms We report in Figure 4 the convergence histories of the three domain decomposition methods for the damped Richardson algorithm and in Figure 5 the corresponding results for the GMRES algorithm. The results are provided
Figure 4: Convergence history for the damped Richardson algorithm. With 3 (left) and 6 (right) subdomains.
Figure 5: Convergence history for the GMRES algorithm. With 3 (left) and 6 (right) subdomains.
for three different mesh refinements, indicated by $N_\lambda := \lambda/h$ which is the number of points per wavelength $\lambda$ if $h$ is the typical edge length.

We see the deterioration of the convergence of the iterative algorithms with the mesh refinement when the Després transmission conditions are used. This is a common feature to inductance operators based on local operators. When the interface based non-local transmission operator is used, we also see a deterioration of the convergence with mesh refinement, albeit less pronounced. Such observations were already reported in previous works [10, 32, 6]. On the contrary, the new approach based on a subdomain based non-local operator that we developed exhibits a perfectly uniform convergence with respect to the mesh size and converges faster than the other two strategies.

**Eigenvalues of the iteration matrix** To try to understand better those results, we report in Figure 6 the eigenvalues of the iteration operators that are involved in the three domain decomposition methods.

When the Després transmission conditions are used, we observe an accumulation close to the origin which will harm the convergence of both the Gmres and the damped Richardson algorithms. When the interface based non-local transmission operator is used, we see that the clusters are near the two points $(1, 1)$ and $(1, -1)$, which demonstrates that the evanescent modes are well taken into account. We see however a few isolated eigenvalues, close to the shifted unit circle, which seem to get closer to the origin as the mesh is refined. This is particularly visible on the configuration with 6 subdomains. In contrast, with the subdomain based non-local operators, the eigenvalues seem to be uniformly bounded away from the critical points.

**Nature of the error** We represent in Figure 7 the distribution of the error between the exact discrete solution and the discrete solution (obtained with the damped Richardson algorithm). More precisely, the absolute value of the error is represented as the elevation along the $z$-axis, after linear interpolation on the nodes of the mesh. For a better representation, the magnification factor is different for each figure, as indicated by the actual maximum and minimal values of the error on the colorbar. The convergence is stopped before machine precision is reached. In some sense, the nature of the remaining error gives us insight on the components that are troublesome for the convergence.

When Després transmission conditions are used, we see that the error is highly concentrated along each interface and decreases very rapidly away from them. The most likely interpretation is that the main components in the error consist in some sense of “evanescent waves”. Note also that the ratio between the maximum and minimum values of the error is very large.

In contrast, the error is highly peaked at the cross-point and (slowly) decreasing away from it when the interface based non-local operator is used. The transmission interfaces seem less visible. Note also that the ratio between the maximum and minimum values of the error is much smaller than for the Després transmission conditions.

As for the subdomain based non-local transmission operator, the error is more evenly distributed in the domain, albeit slightly accumulating near the interfaces. More importantly, no accumulation of the error at the cross-point can be observed in contrast to the result using also a non-local transmission operator but with the standard exchange operator (Figure 7b).
Figure 6: Eigenvalues of the iteration matrices. With 3 (left) and 6 (right) subdomains.
Figure 7: Nature of the error using different approaches (6 subdomains configuration). The absolute value of the error on the solution is represented as the elevation (after linear interpolation on the nodes of the mesh). Different magnification factors are used for the three figures.
6.2 Stability

We investigate now further the robustness of the proposed approach with respect to the mesh discretization, in particular with respect to mesh refinement now both in 2D and 3D. The refinement, namely decreasing the typical edge length $h$, is uniform in the domain $\Omega$. In the remainder of this manuscript and in contrast to the previous experiment, the domain $\Omega$ (a disk in 2D and a ball in 3D) will be partitioned using an automatic graph partitioner. For the following results, there are $J = 4$ subdomains in 2D and $J = 32$ subdomains in 3D. The results are reported in Figure 8.

![Figure 8: Number of iterations with respect to mesh refinement $\lambda/h$, for 2D (left) and 3D (right) configurations.](image)

We observe a quasi-linear increase in the number of iterations required to reach a set tolerance for the Després inductance. This is in stark contrast with the results using the Schur complement approach which are completely immune to the mesh refinement. Such an effect, which was already observed in the previous experiment, is expected and not new, see [10, 9, 32] and in particular the numerical analysis and numerical experiments of [6] obtained in the acoustic setting. In fact, it is one of the core strength of the approach based on the use of underlying non-local operators in transmission conditions.

We shall point out however that in previous works [10, 9] such an effect was observed, and as a matter of fact rigorously proved, only in absence of cross-points in the partition. This is not the case here where such points are indeed present in practice. In addition, notice that in the 3D configuration there are degrees of freedom actually attached to edges that are shared by at least three sub-domains (such points form the so-called wire-basket). This feature, namely the robustness with respect to mesh refinement even in presence of cross-points, is precisely enabled by the somewhat unusual choice of communication operator based on the global projection that was described in the previous sections, see Section 2.2.

Besides, we report in Figure 9 the number of iterations of the inner preconditioned CG algorithm that is used to solve the global projection problem on the skeleton, see (17). We stress that these iteration counts do not correspond to the outer iterations of the GMRES algorithm that is still used to solve the skeleton problem (33).

In 2D, we observe that a moderate number of iterations is required to solve the projection problem using the operator based on a Schur complement. It is moreover stable with mesh
refinement. For the Després operator, we report exactly one iteration regardless of the mesh refinement. This is due to the fact that there are no degrees of freedom attached to the cross-points in the two-dimensional configuration. As a result, the linear system involved in the projection problem is actually diagonal and there is no need to use the PCG algorithm in this particular case.

In 3D, we observe that a moderate number of iterations, stable with mesh refinement, is required to solve the projection problem in the Després case. This is expected since now there are actually degrees of freedom on the junctions lines (or wire-basket) shared by at least three subdomains. In contrast, we observe a linear growth of the number of iterations for the Schur complement based approach. Such a strong effect was not observed in the acoustic setting, see [32]. It turns out that for the Maxwell setting, a more involved (auxiliary space) preconditioning approach, based on a suitable Helmholtz-type splitting of edge element vector fields, is necessary to tackle this issue [25, 26] but was not further explored in this first work.

6.3 Influence of the number of subdomains

We study now for both the 2D and 3D configurations the influence of the number of subdomains $J$ on the number of iterations to reach a set tolerance with a domain $\Omega$ growing in size. Specifically, the size of the domain is chosen to grow like $J^{1/d}$ where $d$ is the dimension of the ambient space, in order to keep a fixed size (in terms of the number of degrees of freedom) for the local subproblems. In 2D the domain is a disk of radius increasing from $R = \sqrt{2}$ to $R = 16$ as the number of subdomains increases from $J = 2$ to $J = 256$. In 3D the domain is a sphere of radius increasing from $R = 1$ to $R = 4$ as the number of subdomains increases from $J = 2$ to $J = 128$. Notice that for this test case, despite the fact that the size of the problem increases, the number of points per wavelength is kept constant. As a result the pollution effect is not taken into account here. The results are provided in Figure 10.

The growth of the number of iteration to reach the set tolerance also appears to scale like $J^{1/d}$ and the phenomenon seems to apply to all the transmission operators considered. This
non-optimality is expected and can be understood in this wave propagation context from the fact that the waves (hence the information) need to travel longer distances as the size of the global domain increases. Such an observation motivates the search for optimal solvers immune to this effect, for instance using multi-level techniques and coarse spaces somehow mimicking algorithms used for elliptic systems. However, in this work, we did not pursue in this direction.

Figure 10: Number of iterations with respect to the number of subdomains $J$, for 2D (left) and 3D (right) configurations.

### 6.4 Influence of the frequency

We now study the dependency of the iteration counts with respect to the wavenumber $\kappa$. To take the pollution effect into account, the mesh is refined as the frequency increases. Since we are using low order finite elements, we need to keep the quantity $\kappa^3 h^2$ fixed throughout the computations. Here $h$ denotes the typical edge length in the mesh. In both the 2D and 3D configurations, this quantity is fixed to $(2\pi)^2 / 400$ in order to have at least 20 points per wavelength for the smallest wavenumber considered. The domain $\Omega$ is partitioned into $J = 4$ subdomains in 2D and $J = 16$ subdomains in 3D. The results are reported in Figure 11.

As the wavenumber $\kappa$ increases, the discrete (as well as the continuous) problem gets harder (the condition number of the original undecomposed matrix increases). We notice a sub-linear increase of the number of iterations to reach the set tolerance for all inductance operators studied. The increase seems to be stronger in the 3D configuration.

### 6.5 Domain heterogeneity

To conclude this section on numerical experiments we present a more involved test case with more complicated medium of propagation. The objective is to illustrate the robustness of the proposed approach. Specifically we consider three types of propagative medium in our usual unit disk in 2D and unit ball in 3D.

The first medium is heterogeneous and purely propagative. If $(r, \theta) \in [0, +\infty) \times [0, 2\pi)$ and $(r, \varphi, \theta) \in [0, +\infty) \times [0, \pi) \times [0, 2\pi)$ are respectively the cylindrical and spherical coordinates,
the coefficients $\mu = \mu_0$ and $\epsilon = \epsilon_0$ are defined as follows

$$
\mu_0 := \begin{cases}
2\Delta\mu, & r < \rho(\theta)/5, \\
1 + \Delta\mu \psi(\theta), & \rho(\theta)/5 < r < \rho(\theta), \\
1, & \rho(\theta) < r,
\end{cases}
$$

$$
\epsilon_0 := \begin{cases}
2\Delta\epsilon, & r < \rho(\theta)/5, \\
1 + \Delta\epsilon \psi(\theta), & \rho(\theta)/5 < r < \rho(\theta), \\
1, & \rho(\theta) < r,
\end{cases}
$$

where we set $\Delta\mu = 5/2$, $\Delta\epsilon = 3/2$ and

$$
\rho(\theta) := 1 + \cos(6\theta)/2, \quad \psi(\theta) := 2(1 + \cos(6\theta)/6)/3, \quad \forall \theta \in [0, 2\pi).
$$

See the left panel of Figure 12 for a representation of the profile of the $\mu_0$ coefficient in 2D. The coefficients are therefore both varying inside the domain and have surface discontinuities. The wavenumber is set to $\kappa = 5$ in 2D and $\kappa = 1$ in 3D.

The second medium is homogeneous, constructed by averaging the coefficients of the previous medium. Specifically we used $\mu = \epsilon = 1$ and the wavenumber is set to $\kappa = 5\kappa_0$ in 2D and $\kappa = \kappa_0$ in 3D where $\kappa_0$ is the product of the averages on the domain $\Omega$ of $\mu_0$ and $\epsilon_0$ defined previously.

Finally, the third medium considered is heterogeneous and dissipative, constructed by adding a strictly positive imaginary part to the coefficients of the propagative heterogeneous medium previously defined. Specifically we used $\mu = \mu_0(1 + i/4)$ and $\epsilon = \epsilon_0(1 + i/6)$. The wavenumber is set to $\kappa = 5$ in 2D and $\kappa = 1$ in 3D.

To simplify the comparison and discussion we used the same mesh (and partition) in the three cases. Despite the possible heterogeneity of the medium, the mesh is uniform, constructed such that the typical edge length parameter is $h = \lambda/50$ (resp. $h = \lambda/30$) with $\lambda = 2\pi/(5\kappa_0)$ (resp. $\lambda = 2\pi/\kappa_0$) in 2D (resp. 3D). The domain $\Omega$ is partitioned into $J = 25$ subdomains in 2D and $J = 50$ subdomains in 3D, see Figure 12. Since we are using an automatic graph partitioner independently of the definition of the medium under consideration, some interfaces between two subdomains are cut by the surface discontinuities of the coefficients (in the heterogeneous case). There are a total of $\#\mathcal{E} = 432,103$ degrees of freedom in 2D and $\#\mathcal{E} = 310,615$ degrees of freedom in 3D.
Figure 12: Heterogeneous medium profile for the coefficient $\mu_0$ (top left), skeleton of the partition (top right) and modulus of the 2D solution for the purely propagative heterogeneous medium (bottom).
A solution is represented in the right panel of Figure 12, which corresponds to the 2D propagative and heterogeneous medium configuration. As before, the source comes from an impinging plane wave (coming from the left in the Figure 12). Notice that, due to the heterogeneity, the modulus of the solution is rather large in some part of the domain.

![Figure 13: Convergence history for heterogeneous, homogeneous and dissipative medium, for 2D (left) and 3D (right) configurations.](image)

We report in Figure 13 the convergence histories of the GMRES algorithm. In the 2D case, we notice that a larger number of iterations is required in the purely propagative heterogeneous medium (which is the notoriously more difficult wave propagation problem) whereas the fastest convergence is achieved in the dissipative scenario. This is to be expected but we stress that the increase in the number of iterations remains somewhat moderate.

In the 3D case, the convergence results are somewhat similar in the three medium considered. We explain this observation by noting that due to the relatively larger frequency considered, the 2D test case corresponds to a more difficult wave propagation problem than the 3D configuration.
