Abstract

Aicardi-Goutières syndrome (AGS) is a genetically heterogeneous disorder reported previously as an inherited congenital infection-like syndrome. It is characterized by an early onset progressive encephalopathy, brain calcification, leukodystrophy, CSF chronic lymphocytosis, elevated CSF alpha-interferon, and negative results for common prenatal infections. It is autosomal-recessive or rarely autosomal-dominant and caused by mutations in one of several genes TREX1, RNASEH2A, RNASEH2B, and RNASEH2C, SAMHD1, IFIH1, and ADAR. The Magnetic resonance imaging findings of two male siblings diagnosed genetically with AGS 5 due to a homozygous mutation in SAMHD1 with very similar characteristics comprising profound psychomotor retardation, progressive microcephaly, spasticity, dystonic posturing, and tonic seizures are reported. The author reviewed the literature to delineate a specific MRI pattern of AGS.

Keywords: Aicardi-Goutières Syndrome; Neuro-radiologic findings; Magnetic Resonance Imaging (MRI); Leukodystrophy; SAMHD1 mutation

Abbreviations: AGS: Aicardi-Goutières Syndrome; MRI: Magnetic Resonance Imaging; CILS: Chronic Infection-Like Syndrome; MRI: Magnetic Resonance Imaging; VEP: Visual Evoked Potential; BAEP: Brain Auditory Evoked Potentials; CSF: Cerebrospinal Fluid; MRA: Magnetic Resonance Angiography

Introduction

Aicardi-Goutières (AGS) Syndrome is a rare genetically heterogeneous disorder: It was first described as a distinct Chronic Infection-Like Syndrome (CILS) with chronic CSF leukocytosis, basal ganglia calcification and a negative test for infection by Aicardi and Goutieréès [1], Lanzi, et al. [2], and La Piana, et al. [3]. It was further distinguished from other CILS by the classical bilateral calcification of the basal ganglia, leukoencephalopathy and/or cerebral atrophy.

It has a prevalence of 1-5/10,000. Currently, seven different types of AGS are described as mutations in 7 genes have been identified TREX1, RNASEH2A, RNASEH2B, RNASEH2C, SAMHD1, ADAR, and IFIHI [4]. AGS is generally inherited as an autosomal recessive trait although the dominant heterozygous gain of function mutations in TREX1, ADAR1, and all IFIH1 genes were observed [5]. Mutations in these genes enhance the production of type 1 interferon and upregulation of interferon-stimulated genes. Consequently, disturbance of both cellular and immunological function occurs, which results in elevation of interferon-α both in the CSF and blood [5].

Typically affected patients show severe, subacute encephalopathy characterized by irritability, feeding problems, psychomotor regression or delay associated with epilepsy (53% of cases), chilblain skin lesions on the extremities (43% of cases) and episodes of aseptic febrile illness (40% of cases), progressive microcephaly, spasticity, and dystonia, often followed by death in early childhood [2,6,5]. It is phenotypically heterogeneous as it shows inter- and intrafamilial variations with a range of onsets between the first month of life usually with life-threatening illness and a less severe form described during late infancy with preservation of language skills and cognitive function, and a normal head circumference. The disease is rapidly fatal or progresses to a vegetative state [7].

Elevated IFN-alpha levels and CSF lymphocytosis are very frequent but not constant findings (90% and 75% of cases, respectively) at the initial stage of the disease but tend to normalize or resolve within a few years [7]. Typical MRI features include early temporal lobe swelling followed by atrophy, early global cerebral atrophy and visible calcification [8].

Magnetic Resonance Imaging (MRI) findings of two male siblings diagnosed genetically with AGS 5 with very similar characteristics comprising profound psychomotor retardation, progressive microcephaly, spasticity, dystonic posturing, and tonic seizures are reported. The author reviewed the literature to delineate a specific MRI pattern of AGS.
Case Report

Patient 1

This boy, currently 5 years old, was initially evaluated because of global developmental delay and seizures at the age of 5 months. He was the first child of healthy consanguineous Saudi parents. There was no family history of epilepsy or neurological disorders or neonatal deaths. He was a product of term pregnancy and delivered by emergency caesarean section due to meconium liquor. Head circumference at birth was 35.5 cm (at 50th percentile). He had mild, transient jaundice at birth. Since the early neonatal period, he was noticed to have extreme irritability and poor feeding. He had poor visual tracking and hearing with no social smile. At 4 months of age, he had poor head control, was not rolling and showed intermittent stiffness of his limbs. He developed tonic seizures and episodes of spontaneous clonic movements and staring at the age of 4 months. Epilepsy was resistant to multiple antiepileptic medications, but he was maintained on phenobarbitone, carbamazepine, topiramate, and clonazepam with reasonable control. He had profound developmental delay and inability to communicate or ambulate. Examination at the age of 5 months showed a head circumference of 32 cm (25th percentile), no response to visual stimuli, head lag, axial hypotonia, and extremity hypertonia with hyperreflexia in both arms and legs. Follow-up exam at one year of age showed progressive spastic quadriplegia, and he developed joint contractures despite oral baclofen and physiotherapy. Initial evaluation included a normal abdominal ultrasound and dilated ophthalmological examination. Brain MRI (at 4 months of age) showed multiple subcortical cysts, extensive bitemporal cystic lesions, and significant thinning of the brain stem and cerebellar atrophy.

Figure 1: Brain CT scan (Axial) at 4 months of age showing intracranial calcification (A) at white matter and periventricular region, (B) at basal ganglia, (C) with a periventricular distribution.

Figure 2: Brain MRI scan at 4 months of age with a typical pattern of AGS (A) Axial FLAIR imaging with hypo intensity of white matter, (B) Axial T2-weighted image with hyperintensity of white matter, (C) Axial FLAIR imaging with multiple subcortical cysts, (D) Axial FLAIR imaging, and (E) Coronal T2-weighted imaging with extensive bitemporal cystic lesions, (F) Sagittal T1-weighted imaging with significant thinning of the brain stem and cerebellar atrophy.

Brain CT scan during infancy showed calcification at basal ganglia, and periventricular white matter (Figure 1, 2). Metabolic testing was normal and included the following: serum amino acids, plasma very long-chain fatty acids, plasma...
acylcarnitine profile, serum biotinidase level, serum ammonia, lactate, and urine organic acids. Chromosomal microarray was normal. Electroencephalogram (EEG) revealed slow background and multifocal epileptiform discharges. Visual Evoked Potential (VEP) and Brain Auditory Evoked Potentials (BAEP) were normal. Cerebrospinal Fluid (CSF) testing at 4 months of age showed normal cell count, protein, glucose, lactate and amino acid content. A follow-up brain MRI at 4 years of age showed severely atrophic brain parenchyma with enlargement of ventricles, reduced bulk of cerebral white matter, thinning of corpus callosum and brainstem. Cystic changes were noted at bilateral frontal lobes, left parietal lobe, and tiny cysts in anterior temporal lobes (Figure 3). Brain Magnetic Resonance Angiography (MRA) obtained concurrently was normal. Further molecular analysis confirmed Aicardi-Goutières syndrome 5 due to a homozygous mutation in SAMHD1 gene.

Patient 2
Patient 2 was the younger brother of patient 1. He was born at term by normal vaginal delivery following an uneventful pregnancy. Birth weight and head circumference were 3 kg (10th percentile) and 32 kg (at 5th percentile), respectively. He presented with a similar picture like his brother, though the severity of symptoms was less. He had episodes of sterile pyrexia. At the age of 5 months, he experienced partial tonic seizures and EEG showed slow background activity with infrequent sharp- and slow- wave activity at the temporo-occipital region. Seizures were controlled by carbamazepine and topiramate. Cranial CT performed at 8 months showed brain atrophy with periventricular and basal ganglia calcification. On physical exam at 1 1/2 years, he was noted to have a head circumference of 44 cm (< 5th percentile) with weight and length < 10th percentile. He had spastic quadriplegia with intermittent dystonia with no acquisition of motor skills.

EEG records showed background slowing associated with infrequent sharp- and slow- wave activity in the temporo-occipital region. Abdominal ultrasound and ophthalmological examination showed normal results. Brain MRI showed atrophic changes in the cortex, cerebellum and brainstem, mild ventromegaly and white matter loss.

Discussion
Aicardi-Goutières syndrome is a rare type of inherited leukoencephalopathy with variable clinical manifestations. It has autoimmune manifestations and large vessel vasculitits. Molecular detection of specific gene mutations is required to confirm the diagnosis, but certain neuroradiologic patterns can be detected initially, which may facilitate more precise and earlier diagnosis of this rare but probably underdiagnosed syndrome [8].

Both siblings in this report had the classic clinical picture of neonatal onset AGS, with subacute encephalopathy manifested with irritability, feeding problems, psychomotor delay, and epilepsy. Episodes of sterile pyrexia were seen in the younger sib. No autoimmune manifestations were recorded (chilblain skin lesions, hepatitis, arthropathy, or cardiomyopathy). The older sibling had primary hypothyroidism. They end with the typical phenotype of progressive microcephaly, irritability, spastic quadriplegia, dystonia, and GT insertion for feeding. The younger sib had less severe symptoms with a much slower course consistent with the previously reported data of inter- and intrafamilial variation [4,9].

A homozygous mutation in SAMHD1 gene at 20q11.23 confirmed the diagnosis of AGS 5. Currently prenatal diagnosis is feasible through molecular analysis of amniotic fluid or trophoblasts. Treatment is symptomatic, mainly for feeding problems, spasticity, dystonia, epilepsy, and irritability with sleep disturbance.

AGS is classified under neurological disorders with mainly leukodystrophy pattern on brain MRI [4]. Earlier studies have shown that the cardinal features for diagnosis are intracranial calcification (involving the basal ganglia and white matter), cystic leukodystrophy (predominantly frontotemporal) and early cortical-subcortical atrophy. It is often associated with atrophy of the corpus callosum, brain stem and cerebellum [9,10].
Brain calcifications were typically small, multifocal, and seen mainly in the basal ganglia (putamina), lobar white matter, and dentate nuclei, but the globi pallidi, thalami, deep and subcortical white matter may be involved as well [8,11]. It identifies correctly up to 94.4% of AGS with a sensitivity of 90.9% and a specificity of 96.9%.

The subcortical and deep white matter typically are abnormal and appear as hypodense lesions on CT, hypo intense on T1-weighted image and high signal intensity on T2-weighted image or FLAIR image. These abnormalities are either diffuse or with anterior/posterior gradient mainly lobar with early involvement of subcortical arcuate fibers and with relative sparing of the corpus callosum, the capsules, and the optic radiations [12]. Imaging studies may also show ventriculomegaly, usually progressive, secondary to progressively reduced volume of white matter in the cerebral hemispheres [12]. In later stages of the disease, white matter may have signal intensity similar to CSF, particularly in the frontal lobes [12].

Both the calcification and white matter abnormalities increased in the first 2 years after diagnosis before becoming stable. Usually a significant degree of cerebral atrophy exists which remains substantially stable with time or worsens in some cases.

The cerebellum and brainstem may be small [13,14], but the cerebellar white matter is often spared. Abdel-Salam, et al. [15] reported a rare finding of unilateral cerebellar hypoplasia in a patient with homozygous missense mutation in RNASEH2B gene.

The presence of deep white matter cysts in the temporal or frontal lobes has been reported only in a few patients in certain case series reports [3,12,16]. They represent a severe cystic degeneration of the white matter and were commonly observed in patients with TREX1 mutations [3]. Early on, patients may present with temporal lobe swelling followed by atrophy with temporal horn dilatation [8]. Furthermore, Olivieri, et al. [17] and Abdel-Salam GM, et al. [15] reported the presence of small and large periventricular cysts, respectively.

Table 1: Neuroimaging findings: Aicardi-Goutieres syndrome.

| Brain CT scan | Intracranial calcification – Basal ganglia, dentate nuclei of the cerebellum, and periventricular white matter |
|---------------|-----------------------------------------------------------------------------------------------------|
| Brain MRI scan | White matter abnormalities (Leukodystrophy) with anterior/posterior gradients with hypo intensity on T1-weighted image, and hyperintensity on T2-weighted and FLAIR images. Sparing cerebellar white matter |
| Brain MRA scan | Extensive bifrontal or bitemporal cystic lesions |
|               | Diffuse cerebral and subcortical atrophy, deep white matter loss, progressive ventricular dilation |
|               | Significant thinning of the brain stem and cerebellar atrophy |
|               | Large vessels vasculitis, developmental vascular variants (noted with SAMHD1 mutation) |

A recent study by Al Mutiri F, et al. [18] described the neuroimaging findings in a series of 24 patients; leukoencephalopathy in 83 %, cerebral atrophy in 75 %, and calcification in 54 %. Thinning of corpus callosum as well as ventromegaly in the absence of hydrocephalus was also seen but to a lesser extent. Only one patient was reported with white matter cysts. Follow-up MRI showed improvement in myelination and a decreased degree of atrophy with increasing duration of AGS.

In AGS 5 with SAMHD1 mutation, it is expected to have some large vessels vasculitis with some vascular developmental variants [4, 5], but brain MRA was normal for both siblings. Follow-up of our patients showed further cerebral and white matter atrophy with the collapse of previously reported cysts. The typical pattern of MRI found in AGS (Table 1) helps to differentiate it from other causes of early infantile leukencephalopathy (Table 2).

Table 2: Differential diagnosis of AGS - early infantile leukodystrophies with and without temporal lobe cysts.

| Congenital infection such as cytomegalovirus (CMV) or rubella |
| Alexander disease (AxD) |
| Mitochondrial leukencephalopathies |
| Megalencephalic leukodystrophy with cysts (MLC) |
| Antenatal onset Vanishing white matter with e IF2B mutations (VWM) |
| CoatsPlus disease / leukencephalopathy with Calcification and cyst (CP/LCC) |
| Cystic leukencephalopathy without megalencephaly due to RNASET2 mutations |
| Various types of congenital muscular dystrophy (FCMD, Walker Warburg syndrome, MDC1D) |

An algorithm of such differential diagnosis with and without temporal lobe swelling was reported by Vanderver A, et al. [8] to differentiate it from AGS based on MRI analysis. With increased availability and high specificity of the MRI, detection of calcification on CT scan is no longer essential for the diagnosis of AGS.

In conclusion, AGS is an underdiagnosed hereditary leukodystrophy syndrome with a typical clinical picture of early irritability, psychomotor retardation, and microcephaly as well as combined pyramidal and extrapyramidal manifestations.
