Activation of an intron enhancer within the keratin 18 gene by expression of c-fos and c-jun in undifferentiated F9 embryonal carcinoma cells

Robert G. Oshima, Leslie Abrams, and David Kulesh
Cancer Research Center, La Jolla Cancer Research Foundation, La Jolla, California 92037 USA

The mouse forms of human keratins 18 and 8 (K18 and K8) are the first members of the large intermediate filament gene family to be expressed during embryogenesis. To identify potential regulatory elements of the human K18 gene, various recombinant constructions were expressed in cultured cells. An enhancer element was found in the first intron that functions on both the K18 and thymidine kinase promoters in differentiated cells. In F9 embryonal carcinoma cells, the level of expression was low in the presence or absence of the first intron. Cotransfection of F9 cells with K18 constructs that include the first intron and increasing amounts of an expression vector of c-jun results in a modest increase in the reporter gene expression. Cotransfection of the same construct with increasing amount of the mouse c-fos gene results in activation of the reporter gene by as much as 15-fold, with a near linear response to the amount of c-fos gene added. Site-specific mutagenesis of a putative AP-1 site within the intron abolishes trans-activation by c-fos in F9 cells. Furthermore, induction of c-fos in a derivative of F9 cells results in increased expression of the endogenous mouse form of K18. Cotransfection with c-jun or c-fos expression vectors had little effect on the expression of the K18 reporter construct in a parietal endodermal cell line already expressing the endogenous mouse gene. These results identify an enhancer within the first intron of K18 that may interact directly with c-jun and c-fos via a conserved AP-1-binding site. K18 expression in undifferentiated F9 cells may be limited by the low levels of c-jun and c-fos.

[Key Words: K18, Endo B, keratin, embryonal carcinoma, c-jun, c-fos, enhancer]

Received August 28, 1989; revised version accepted February 12, 1990.

The differential expression of the mammalian genome begins within the first several cell divisions and results in the formation of the first phenotypically distinguishable differentiated cell type, the trophectoderm of the blastocyst embryo. Among the earliest differentially expressed genes are members of the intermediate filament (IF) gene family, the keratins (Steinert and Parry 1985). Endo B, the mouse form of human keratin 18 (K18), is a type I keratin protein that is first expressed just prior to blastocyst formation along with its normally coexpressed and complementary type II keratin partner, Endo A (Brület et al. 1980; Oshima et al. 1983; Duprey et al. 1985). Expression of both proteins is restricted at the blastocyst stage to the trophectoderm and extraembryonic endoderm (Brület et al. 1980; Jackson et al. 1980; Chisholm and Houliston 1987). In adult tissues, K18 and keratin 8 (K8), the human form of Endo A, are coexpressed primarily in a variety of simple epithelial tissues (Moll et al. 1982). Sequence analysis indicates that K18 and K8 represent the first keratins from which more specialized keratins were derived (Blumenberg 1988).

The differentiation of cultured murine embryonal carcinoma (EC) cells has been used as a convenient model system of early mouse development (Hogan et al. 1983; Silver et al. 1983). Whereas undifferentiated murine EC cells do not express mouse K18 or K8, spontaneous or retinoic-acid-induced differentiation results in increased transcription of the respective genes (Oshima et al. 1988), appearance of the mRNAs and proteins, and their assembly into immunologically detectable IFs (Oshima 1981, 1982; Tabor and Oshima 1982, Duprey et al. 1985). Although neither EC cells nor most differentiated, nonepithelial cells such as fibroblasts express K18, the reasons that the two cell types do not express endogenous K18 appear to differ. The coding K18 gene in mouse fibroblasts (Endo B β-1) is hypermethylated and found in a DNase-resistant chromatin state. This apparently renders the gene unavailable for transcription because the Endo B β-1 gene remains silent even when placed in a permissive environment by somatic cell hybridization (Oshima et al. 1988). Exogenously intro-
Oshima et al.

The K18 gene is expressed efficiently in fibroblasts that do not express the endogenous gene (Kulesh and Oshima 1988). In contrast, the Endo B β-1 gene in F9 cells is not heavily methylated nor is it in a DNase-resistant chromatin state. Furthermore, F9 cells do not support the efficient expression of a transfected K18 gene (Kulesh and Oshima 1988; this work). Thus, it appears that expression of mouse K18 is restricted in nonepithelial differentiated cells by the accessibility of the gene to the transcriptional machinery. However, the restriction in F9 EC cells may be due to either the absence of necessary transcription factors or the presence of negative regulatory activities. In this study we show that the first intron of K18 has a tissue nonspecific enhancer activity. Furthermore, the enhancer activity can be activated in F9 cells by the expression of either c-jun or c-fos, suggesting that K18 expression in F9 cells may be limited, at least in part, by the low levels of these proto-oncogene transcription factors.

Results

Deletion analysis of K18 regulatory elements

In previous studies we showed that the K18 gene was expressed efficiently in mouse cell lines after DNA transfection of the whole gene (Kulesh and Oshima 1988). To begin to assess the degree to which the regulatory sequences of the K18 gene direct appropriate tissue-specific expression, a recombinant molecule termed K18P0Lac was constructed that substituted the bacterial LacZ gene (which codes for β-galactosidase) for the region of K18 from the beginning of exon 2 to near the end of the last exon [exon 7] (Fig. 1, construct 4). To identify regions of the K18 gene necessary for expression, K18P0Lac and the related recombinant constructs shown in Figure 1 were tested by transient transfection experiments in cultured cell lines. The results of transfecting these derivatives into Ltk− cells, which had been previously shown to express the whole K18 gene efficiently, are shown in Figure 2A.

Deletion of 1.45 kb of the 5′-flanking sequences of K18P0Lac [Fig. 1, construct 2] had relatively little effect on the expression of β-galactosidase activity [Fig. 2A, construct 2] relative to the parental vector [Fig. 2A, construct 4]. This deletion removes two sequence elements that are highly conserved in the distal portion of the 5′-flanking sequences of the K18 and Endo B β-1 genes [Fig. 3A]. Deletion of 2.2 kb of the 5′-flanking region of the K18 gene results in a plasmid that retained only 250 bp of 5′-flanking sequence of the K18 gene [Fig. 1, construct 1]. This plasmid had significant, but modestly decreased, activity when compared to the starting K0P0Lac construct [Fig. 2A, constructs 1 and 4]. Removal of 3.4 kb of 3′-flanking sequences [Fig. 1, construct 3] resulted in an increase in β-galactosidase expression relative to the activity of K18P0Lac [Fig. 2A, construct 3]. The increased activity of K18P0Lac−Bam could possibly result from the removal of a site of interaction with a negative regulatory factor. However, competition experiments involving the cotransfection of K18P0Lac with increasing amounts of a recombinant containing only the 3.4 kb of 3′-flanking sequences failed to provide evidence for such factors [data not shown].

In contrast to the deletions of 5′-flanking sequences, removal of the first exon and first intron from the K18P0Lac vector [Fig. 1, construct 5] resulted in much lower expression of β-galactosidase [Fig. 2A, construct 5]. This lower activity was not abrogated by the substitution of the SV40 t-antigen intron and polyadenylation signals for the 3′ end of the K18 gene [Figs. 1 and 2B, construct 6]. Thus, the lower activity of K18P1LacL is not due simply to the absence of an intron. When tested in HR9 parietal endodermal cells, the relative activity of each of the constructs was very similar to those shown for L cells [Fig. 2B and data not shown].

To compare the relative activities of a subset of the constructs shown in Figure 1 in different cell types, plasmids were again cotransfected with the β-actin chloramphenicol acetyltransferase (CAT) vector. The results of a typical set of experiments are shown in Figure 2B. In all cells tested, the two constructs that lack the first exon and first intron of K18 [Figs. 1 and 2, constructs 5 and 6] were least active. HR9 parietal endodermal cells repeatedly expressed the K18P0Lac−Bam [Fig. 2B, construct 3] and the K18P0Lac vectors [Fig. 2B, construct 4] best, but Ltk− cells also were capable of expressing these vectors well. These results are consistent with our previous analysis of stable cell lines that express the K18 gene [Kulesh and Oshima 1988] and indicate that Ltk− cells, which do not express the endogenous, homologous mouse gene, are capable of expressing K18 or K18 constructs after direct transfection. NT2 human EC (Andrews et al. 1984) cells differ from mouse EC cells in several respects, including the constitutive expression of K18. NT2 cells were more capable of expressing the most active K18 constructs than F9 cells were but were still only modestly active in comparison to the two differentiated cell types, HR9 and Ltk− cells.

To confirm that β-galactosidase mRNA resulted from properly initiated, K18-directed transcription, RNA protection experiments were performed. Figure 4 shows the results of mapping the initiation site of RNA resulting from the transient transfection of HR9 cells with the K0P0Lac−Bam vector [Fig. 1, construct 3; Fig. 4, lane 6]. The same size 240-nucleotide fragment of the probe was protected by RNAs derived from both NT2 cells that constitutively express K18 RNA [Fig. 4, lane 5] and HR9 cells transiently transfected with K0P0Lac−Bam [Fig. 4, bottom].

Transcriptional enhancement by the first intron of K18

Comparison of the sequences of the K18 gene [Kulesh and Oshima 1989] and the mouse homolog, Endo B β-1 (Ichinose et al. 1988; Oshima et al. 1988), revealed that the first intron of K18 contains a stretch of 47 bp that is identical in the mouse and human homologous genes [Fig. 3B, nucleotides 787–833]. In contrast, the 5′-flanking sequences of the two genes share no stretch of
Figure 1. Structure of recombinant derivatives of the K18 gene. The genomic sequences of the K18 gene are shown by a thick black line, plasmid sequences are shown by a thin line. Exons of the K18 gene are shown by black boxes. Open boxes with lines show the position of Alu repetitive sequences. The hatched boxes represent the bacterial LacZ gene coding for β-galactosidase. Shaded boxes in K18P1Lac represent SV40 sequences containing the small t-antigen intron (SVsp) and polyadenylation signals (SVpA). TATA boxes and polyadenylation signals (AATAAA) of the K18 gene are indicated. The restriction enzyme sites indicated are: (H) HindIII; (N) NsiI; (X) XhoI; (RV) EcoRV; (RI) EcoRI; (K) KpnI; (Bm) BamHI; (B2) BglII; (Ne) NaeI; (H2) HincII; (SI) SalI; (Xb) XbaI; and (Sph) SphI. Sites destroyed during construction are indicated with crossed lines. The size of each construct is indicated at right. Differences from the K18POLac starting vector are noted below the name of each vector.

identical nucleotides longer than 11 bp other than the two distal elements shown in Figure 3A. Embedded within the conserved intron sequence is a potential binding site for the AP-1 transcription factors, which include heterodimers of c-jun and c-fos (Angel et al. 1987; Lee et al. 1987; Chiu et al. 1988; Rauscher et al. 1988; Sassone-Corsi et al. 1988c). To test for enhancer activity, a 663-bp fragment of the first intron of K18 (Fig. 3B, nucleotides 505–1167) was placed both upstream and downstream of a CAT gene transcription unit driven by either 250 bp of 5′-flanking sequence of the K18 gene (XKCATspA) or the herpes simplex virus thymidine kinase [HSV TK] promoter (TKCATspA) [Fig. 5]. Both the normal orientation of the intron relative to the K18 gene [Is] and its inverted orientation [la] were tested. In addition, the intron sequence was placed upstream of a CAT gene that lacked a promoter [lsKOCAT and laKOCAT]. The results of transfecting these constructs into Ltk− cells are shown in Figure 6.

When introduced into Ltk− cells, the truncated K18 promoter has relatively little activity [Fig. 6, XKCATspA]. Addition of the intron fragment results in an enhancement of CAT expression in either the upstream or downstream position and in either orientation. However, it is clear that the normal [sense] orientation of the sequence downstream of the CAT transcription unit (XKCATIs) was most effective, resulting in a 27-fold increase in CAT expression. This sequence was also capable of activating the HSV TK promoter. Again, the sense orientation of the downstream position (Fig. 6, TKCATIs) was the most effective orientation. We conclude that the K18 first intron has enhancer activity, and such activity is not limited to its homologous promoter. However, this enhancer activity is sensitive to both position and orientation.

Activation of the K18 intron enhancer by c-jun and c-fos in F9 cells

Undifferentiated F9 EC cells do not transcribe the Endo B β-1 gene homolog of K18 and fail to express efficiently either the transfected K18 gene or K18 constructs [Kulesh and Oshima 1988] (Fig. 2B). The presence of a consensus AP-1-binding site within the conserved portion of
Figure 2. Transient expression of β-galactosidase activity by K18 derivatives. (A) Plates (6-cm) of Ltk- cells initially containing 5 × 10^5 cells were transfected with a total of 10 μg of DNA containing 1, 3, or 9 μg of the indicated construct and 1 μg of β-actin–CAT. The balance of DNA was pUC9. (Left) Numbers indicate the constructions shown in Fig. 1. The β-galactosidase and CAT activities were determined on lysates prepared 48 hr after the addition of DNA. Values represent the mean and standard deviation of the β-galactosidase activity per microgram of construct DNA divided by the CAT activity per microgram of β-actin–CAT DNA. Activity units of β-galactosidase and CAT were nanomoles of substrate cleaved or acetylated per milliliter of lysate per hour at 37°C. The structures of the constructs are shown in Fig. 1 in the same relative order. (B) Approximately equal molar amounts of the indicated constructs and β-actin–CAT DNA (3.7 μg) were transfected into the indicated cell lines. Amounts of 2.7 μg of K18PoLac–Bam, 3.6 μg of K18PoLac, 3.4 μg of K18P1LacL, or 2.7 μg of K18P1Lac and, if necessary, pUC9 DNA, were used in a total of 7.3 μg for each 60-mm dish. β-Galactosidase and CAT activities of lysates were measured and calculated per microgram of vector DNA. CAT activities were then normalized to the apparent transfection frequency of each cell line shown in Table 1. Values represent the ratios of β-galactosidase activity per microgram of DNA and the individual normalized CAT activity. Raw values of β-galactosidase activities for each cell line were similar to the normalized values shown.

the first intron of K18 and the extremely low expression of both c-jun (Chiu et al. 1988) and c-fos (Muller and Wagner 1984; Ruther et al. 1985; Lockett and Sleigh 1987) in undifferentiated F9 cells suggested that K18 expression in F9 cells might be restricted by limiting amounts of these transcription factors. This hypothesis was tested by cotransfecting the XKCATIs construct into F9 cells along with either a c-jun expression vector or the c-fos gene to look for trans-activation of the XKCATIs construct. The results of these experiments are shown in Figure 7. The XKCATIs vector is significantly more active in F9 cells than the same vector lacking the intron (Fig. 7, columns A and D). However, the activity of XKCATIs is still very low in F9 cells. Cotransfection with increasing amounts of Rous sarcoma virus (RSV)—c-jun, a vector that expresses c-jun in F9 cells (Chiu et al. 1988), resulted in modestly increasing the activity of the reporter gene to a maximum of about fourfold (Fig. 7, columns F–I). This activation was not observed with a mutant c-jun expression vector (Angel et al. 1988; Chiu et al. 1988) (Fig. 7, column E) or with the reporter construct that lacked the first intron of K18 (Fig. 7, column B). Cotransfection of the XKCATIs reporter construct with increasing amounts of the c-fos gene resulted in increased CAT activity (columns J–N), which was linearly dependent on the amount of c-fos added. With the highest amount of c-fos used, the increase in CAT activity was ~15-fold (column N). Again, this activation was not observed when the reporter construct lacking the K18 intron fragment was used (column C). We conclude that both c-fos and, to a lesser extent, c-jun can activate the K18 promoter construct but only if the sequences of the first intron of K18 are included in the reporter gene. RNA protection experi-
Figure 3. Similar noncoding sequences found in the K18 gene and the mouse Endo B 6-1 gene. (A) Comparison of two sequence elements located in the 5'-distal flanking regions of the two genes. Numbering of the sequence is relative to the major start of transcription as +1 (Ichinose et al. 1988; Kulesh and Oshima 1989). Stars indicate identical nucleotides. Conserved elements are overlined, with the number of matches indicated above the sequence. Possible regulatory motifs are underlined, with their designation above the sequence as noted previously (Kulesh and Oshima 1989). (B) Sequence of the first intron of K18. Three regions of the intron identical in mouse K18 (Endo B 6-1) and human K18 are in uppercase letters, with the match indicated above the sequence. The longest stretch of identical nucleotides is also overlined. The region of the intron that was synthesized by the PCR method for testing for enhancer activity is between the two oligonucleotide primer sites designated PCR 1 and PCR 2 and underlined with the broken lines and arrows. The two fragments that were synthesized separately and subsequently ligated to form an intron fragment with a 54-nucleotide deletion are defined by the PCR 1 and PCR 3 primers and the PCR 4 and PCR 2 primers. Note that the potential AP-1-binding site is found at nucleotide 808 within the 47-nucleotide identity found in the human and mouse K18 genes. The mAP1 designation indicates the nucleotides of the AP-1 site that were altered by site-specific mutagenesis. The K18 sequence shown is 7 nucleotides shorter than published (Kulesh and Oshima 1989) because of a typographical error in that reference, resulting in the duplication of 7 nucleotides starting at nucleotide 871.

ments indicated that both the K18POLac–Bam and K18POLac–Xho constructs [Fig. 1, constructs 3 and 1, respectively] were also trans-activated by c-fos, and the resulting mRNAs were initiated properly. Results for K18POLac–Bam are shown in Figure 4 (lanes 7–10).

The recent demonstration that c-jun and c-fos interact [Chiu et al. 1988; Rauscher et al. 1988; Sassone-Corsi et al. 1988c] prompted us to transfect the XKCATIs reporter gene with both c-jun and c-fos [Fig. 7, columns O–V; Fig. 9B, column D]. Although the combination of both c-jun and c-fos resulted in trans-activation of the CAT gene, the linear response with increasing c-fos was
Oshima et al.

**Figure 4.** S1 nuclease protection analysis of the 5' ends of RNAs derived from cells transiently transfected with the K18POLac–Bam vector (Fig. 1, construct 3). A 480-nucleotide single-stranded DNA probe that overlaps with 240 nucleotides of the first exon of the K18 gene was used, as shown at bottom. Samples are as follows: (Lane 1) Size markers; (lane 2) probe alone; (lane 3) probe alone after nuclease digestion; (lane 4) 50 μg of tRNA; (lane 5) 5 μg of total RNA from NT2 human EC cells that express K18. Lanes 6–8 received the digestion products of 50 μg of total RNA from cells transiently transfected with 10 μg of the K18POLac–Bam vector and an additional 5 μg of pc-fos-3 DNA as indicated (+fos). Samples are as follows: (lane 6) HR9 cells; (lane 7) F9 cells; (lane 8) F9 cells, which also received the c-los gene. A 17-hr autoradiographic exposure of the dried gel is shown. Lanes 9 and 10 represent a 3-day exposure of lanes 7 and 8. (Left) The sizes of the markers are indicated in base pairs. The 240-nucleotide fragment indicative of proper initiation is indicated at right.

abolished when c-jun was also included. Of potential interest was the observation that when both oncogenes were included, the activation of XKCATIs was maximal at the same ratios of RSV-c-jun and c-fos (Fig. 7, columns Q and T). The activation of XKCATIs by c-jun and c-fos was neither synergistic nor additive.

In contrast to the activating effect of c-jun and c-fos on XKCATIs in F9 cells, the effects of the proto-oncogene expression plasmids in differentiated HR9 parietal endodermal cells were very modest (Fig. 8). Cotransfection with both the c-fos and c-jun expression vectors resulted in a 0.6-fold increase in CAT activity. The modest effect of c-jun and c-fos on XKCATIs in HR9 cells is consistent with the permissive state of these cells for K18 expression and the higher level of expression of c-jun and c-fos expected for these cells.

To identify the sequences necessary for the activation of the K18 enhancer in F9 cells more precisely, mutations of the intron sequence were introduced (Fig. 9A). Altered intron sequences were then inserted into the XKCAT vector. Deletion of 54 bp, including the 47-bp identity in the K18 and Endo B B-1 gene introns, which contains the putative AP-1-binding site, abolished the ability of the intron sequence to be activated by either c-jun or c-fos (Fig. 9B, columns E–F; Fig. 9C, columns E and F). It also abolished enhancer activity in HR9 cells (data not shown). However, insertion of the 54-bp fragment, itself, back into the XKCAT vector was not sufficient to restore enhancer activity (data not shown). Thus, the conserved region is necessary but not sufficient for the activity of the intron. Insertion of the 54 bp back into the context of the deleted intron sequence restored activity (Fig. 9C, lanes G and H). Alteration of 4 of the 7 nucleotides of the AP-1 site by site-specific mutagenesis abolished the ability of the intron sequence to be activated by c-fos in F9 cells (Fig. 9C, columns I and J).
c-fos activation of a K18 enhancer in F9 cells

Figure 5. Restriction maps of CAT expression vectors. All vectors contain a 133-bp HpaI-BamHI fragment of SV40 containing termination signals upstream of a polylinker region and the CAT gene. The CAT gene is followed by the SV40 t-antigen intron (SV40sp) and polyadenylation signals (SV40pA). The ampicillin-resistance gene of the starting vector Bluescript KSM13 + is indicated (amp). The HSV TK promoter (TK) is inserted upstream of the CAT gene in TKCATspA and its derivatives. XKCATspA and its derivatives contain the truncated K18 promoter (K18) (-251 to +43). The position of the 663-bp fragment of the first intron of K18 (I) (+505 to +1168) is indicated by the double-headed arrows. The orientation of the fragment, which is the same as that found in the gene, is followed by an s, and the opposite orientation is followed by an a.

and abolished enhancer activity in HR9 cells [data not shown]. This result identifies the AP-1 site as the target of the activation by c-fos in F9 cells.

Activation of endogenous Endo B and Endo A by c-fos

The results of the transfection experiments presented above imply that the expression of K18 and its mouse homolog Endo B are restricted by the low level of c-fos within undifferentiated F9 cells. To determine whether supplementation of c-fos protein would result in the activation of the endogenous Endo B β-1 gene, a previously characterized derivative of F9 cells, designated 76/21-3, was utilized. This cell line contains a c-fos expression construct regulated by the human metallothionein promoter. It has a very low basal level of expression of fos. Treatment with cadmium results in a large and rapid increase in c-fos mRNA and protein [Ruther et al. 1985]. Treatment of this cell line with cadmium results in increased Endo B and Endo A protein synthesis within 8 hr [Fig. 10A,B, lanes 6] and was highest after 16 hr [the maximal duration due to the toxicity of cadmium]. In comparison, increased expression of Endo B and Endo A mRNA and protein is detectable in retinoic-acid-treated F9 cells only after ~48 hr [Oshima 1982; Tabor and Oshima 1982; Trevor and Oshima 1985]. The increased synthesis of the two proteins correlates roughly with the reported time of maximal expression of fos after cadmium treatment [Ruther et al. 1985]. Increased Endo B and Endo A expression in 76/21-3 cells was dependent on exposure to the metal ion [Fig. 10A and C, lanes 7]. Treatment of F9 parental cells with cadmium did not result in increased Endo B synthesis [Fig. 10A, lane 5]. Immunoprecipitation with laminin antiserum showed that cadmium treatment did not change the expression of the laminin A or B chains in either 76/21-3 or F9 cells [data not shown]. This latter result is consistent with the original reports on the effect of c-fos on the differentiation of F9 cells [Muller and Wagner 1984; Ruther et al. 1985]. It is clear that the genes for Endo B and laminin, both of which are expressed in differentiated derivatives of F9 cells, are regulated differently. In contrast, the induction of both Endo A and Endo B synthesis reinforces the presumption that the genes for these complementary subunits share regulatory mechanisms.

Discussion

The activation of K18 constructs in F9 cells that are cotransfected with plasmids expressing either c-jun or c-fos [Fig. 7] is consistent with the view that K18 may be limited by the absence of these transcription factors in F9 cells. Both factors are known to be either absent or extremely low in abundance in undifferentiated F9 cells [Muller and Wagner 1984; Ruther et al. 1985; Lockett and Sleigh 1987; Chiu et al. 1988]. Both are induced after
Figure 6. Enhancer activity of the K18 intron 1 fragment. Dishes (6-cm) of Ltk- cells were transfected with 2.1 μg of the indicated CAT constructs and 5 μg of β-actin-LacZ (approximately equal molar amounts of two vectors) in two separate experiments. CAT activity (picomoles of chloramphenicol acetylated per milliliter of lysate per hour at 37°C) per microgram of CAT plasmid CNA was divided by β-galactosidase activity per microgram of LacZ DNA. (Bottom) Values of the individual experiments. (Top) The average values of the two experiments in graphic form. The CAT designation is deleted from the abbreviated names of the constructs (top).

The demonstrated interaction between jun-related proteins and c-fos (Chiu et al. 1988; Nakabeppu et al. 1988; Rauscher et al. 1988; Sassone-Corsi et al. 1988b,c), the positive autoregulation of c-jun by its own product (Angel et al. 1988), and the negative regulation of c-fos by its own product (Sassone-Corsi et al. 1988c) provide multiple possibilities for modifying the expression of K18. The lack of additive effects seen when both c-jun

treatment of F9 cells with retinoic acid (Mason et al. 1985; Lockett and Sleigh 1987; R. Chiu and M. Karin, pers. comm.), a condition that results in the expression of mouse K18 (Oshima 1981, 1982). In addition, the expression of antisense c-fos RNA appears to inhibit the differentiation of F9 cells, including the expression of keratin-related filaments (Edwards et al. 1988). The modest activation by c-jun, alone, may reflect a limitation imposed by the concentration of c-fos. In contrast, the near linear response of the reporter gene on cotransfected c-fos leads to speculation that c-fos expression may induce c-jun. Previously, it has been shown that expression of c-fos in F9 cells leads to the appearance of partially differentiated cells that express mouse K8 and a complementary type I keratin partner, most likely mouse K18 (Muller and Wagner 1984). However, the expression of c-fos alone is not sufficient to induce the full complement of differentiation markers (Ruther et al. 1985). The results reported here suggest that the increased expression of keratins found in F9 cells transfected with c-fos may reflect a direct interaction of c-fos and c-jun with the mouse K18 gene. This interpretation is reinforced by the observed rapid activation of endogenous mouse K18 (Endo B) and K8 (Endo A) synthesis by c-fos [Fig. 10]. The increase in Endo B and Endo A expression in cadmium-treated 76/21-3 cells was much faster than that seen previously for retinoic-acid-treated F9 cells and appears consistent with the kinetics of synthesis of c-fos mRNA and protein in 76/21-3 cells (Ruther et al. 1985).
Figure 7. Activation of the XKCATIs construct in F9 cells by c-jun and c-fos. Dishes (9-cm) of F9 cells, which initially contained 1.5 x 10^6 cells, were transfected with the amounts of DNA indicated below each column, along with 1.5 μg of β-actin–LacZ and pUC9 DNA, for a total of 20 μg of DNA per plate. Values shown in the graph represent the averages of duplicate dishes, except for those shown with standard deviations, which are the averages of three or more plates in at least two separate experiments. CAT activities (×10) were normalized to β-galactosidase activity, as in Fig. 6.

and c-fos are cotransfected with the K18 constructs may be due to the complicated interaction of these two transcription factors or even similar related factors [Hai et al. 1988; Nakabeppu et al. 1988; Zerial et al. 1989]. One speculative alternative to the direct activation of the AP-1 site by c-fos and c-jun is the possible negative regulation at the AP-1 site by junB or junD. Relief of such repression could be effected by competition of junB or junD with c-fos and c-jun during heterodimer formation. The observation that particular ratios of the c-jun and c-fos gene were most effective in activating expression of the K18 reporter gene may be hints of the complicated interaction between the products of endogenous and exogenously coded products.

It remains to be determined whether c-fos and members of the c-jun family are the only limiting factors for the expression of K18 in EC cells. The induction in F9 cells of K18-directed β-galactosidase mRNA by cotransfection with c-fos results in much less RNA than that found in differentiated cells transfected with the same reporter construct [Fig. 4]. Although the interaction of c-fos and c-jun with each other and the AP-1-binding site may be necessary for expression of K18, additional steps may also be involved in the normal induction of mouse K18. There are multiple reports of negative regulatory activities in F9 cells [Gorman et al. 1985; Borrelli et al. 1986; Lenardo et al. 1989; Onclercq et al. 1989; Young et al. 1989]. Recently, it has been suggested that the mouse K8 gene (Endo A α-1) is negatively regulated by trans-acting factors that also recognize SV40 and polyomavirus sequences [Onclercq et al. 1989].

Figure 8. c-jun and c-fos have relatively little stimulatory activity on XKCATIs in HR9 parietal endodermal cells. HR9 cells were transfected with 10 μg of either XKCAT or XKCATIs and 1.5 μg of β-actin–LacZ DNAs. As indicated, the cells also received 2 μg of RSV-c-jun (cJUN) and/or 2 μg of pc-fos-3 (cFOS) plasmid DNAs and carrier pUC9 DNA, for a total of 20 μg per plate. Values were normalized to β-galactosidase activity, as in Fig. 7. Values represent the average of duplicate dishes.
Figure 9. Mutagenesis of the K18 intron fragment. (A) Schematic maps of the alterations of the K18 intron. The dark line represents K18 intron 1 sequences. The stippled box indicates the sequences deleted in the Iids fragment. Restriction sites are: (X) XbaI; (B) BamHI; and (Bg) BglII. Sequences from 783 to 836 of the K18 intron [Is] were replaced by a BamHI site generating the Iids fragment. Synthetic double-stranded oligonucleotides corresponding to either the wild-type sequence or one altered at 4 bp of the AP-1-binding site [mAP1] were inserted into the BamHI site of Iids to generate IB and IBmAP1. The wild-type AP-1 site TGAGTCA was changed to AGATCTA in mAP1. All fragments were inserted into the XKCATspA vector in the same orientation as the normal gene and tested by transient transfection. Values represent the average of duplicate dishes, as in Fig. 7. (B) F9 cells were transfected with 10 μg of either XKCATIs [XKIs] or XKCATIids [XKIds] plasmids. As indicated, the cells also received 2 μg of RSV-c-Jun and/or 2 μg of pc-fos-3 plasmid DNAs. In addition, all plates received 1.5 μg of β-actin-LacZ. Values represent the average of duplicate dishes of cells, as described for Fig. 7. Note that constructs containing the deleted intron [XKIds] are inactive and are not activated by either c-fos or c-jun. (C) F9 cells were transfected with 10 μg of XKCATI [XK] that contained no intron sequence, XKCATIs [XKIs], XKCATIids [XKIds], XKCATIB [XKIB], or XKCATIBmAP1 [XKIBmAP1] and 1.5 μg of β-actin-LacZ plasmid DNAs. Columns marked with plus signs (+) also received 5 μg of pc-fos-3 [cFOS] DNA. Additional pUC18 plasmid DNA was added, if necessary, to a total of 16.5 μg of DNA per plate.

However, deletion of the 3′-flanking sequences, 5′-flanking sequences, or the first exon and intron did not result in increased expression in F9 EC cells [Fig. 2B; additional data not shown]. Thus, it appears unlikely that a specific negative regulatory element is solely responsible for the lack of expression of K18 constructs in EC cells. Furthermore, F9 cells appear to lack DNA-binding proteins that recognize the nuclear factor [NF1] sequence motif [Speck and Baltimore 1987], which is found within the first intron of K18. The observation that a synthetic 54-bp fragment containing the 47-bp K18 intron identity cannot substitute for the full intron fragment indicates that the efficient expression of K18 gene requires the interaction of additional intron elements with their cognate proteins. The trans-activation of K18 constructs by c-jun and c-fos observed in transient assays does not rule out the possibility of further activation or stabilization by additional factors during the normal induction of the endogenous gene.

In addition to the possible roles of c-jun and c-fos in limiting expression of K18 in EC cells, these transcription factors could be involved in the modulation of K18 expression in differentiated cells. In cultured HR9 parietal endodermal cells, the expression of additional c-jun and c-fos has little effect on the expression of the K18 reporter construct. This is consistent with our observation that phorbol ester treatment of HR9 cells fails to increase the synthesis of mouse K18 and K8 [R. Oshima, unpublished results], because response to phorbol ester is mediated by the AP-1 site. However, there are a number of examples of dramatic modulations of K18 expression, such as the dramatic increase in K18 synthesis in explants of primary liver cells [Ben-Ze'ev et al. 1988]. The well-documented sensitivity of c-fos expression to a large variety of agents provides many possibilities for the modulation of K18 expression if c-fos is needed for optimal transcription of K18.

There are now multiple examples of enhancers located within introns [e.g., Rossi and de Crombrugghe 1987; Burbelo et al. 1988; Kawamoto et al. 1988; Karpinski et al. 1989]. The enhancer activity associated with K18 differs from that found for a bovine epidermal keratin in both its location relative to the start of transcription and its cell-type specificity [Blessing et al. 1989]. This rein-
forces the view that whereas the large intermediate gene family codes for closely related proteins, individual members are regulated quite differently.

In summary, we have identified an enhancer activity within the first intron of the K18 gene that appears not to be cell-type-specific but functions through the interaction of transcription factors with members of the jun and fos families. Low levels of these proto-oncogenes may, at least in part, limit the expression of the gene in undifferentiated EC cells and by analogy in early embryonic cells.

Materials and methods

The K18P0Lac expression vector was constructed as outlined in Figure 1. A minigene intermediate was made by cleaving the pCC1835 plasmid, which contains the K18 gene (Kulesh and Oshima 1988), with BglII fragment containing the LacZ gene derived from the pl3 plasmid was inserted into the new BglII site to create an open reading frame that fused the beginning of the second K18 exon to the eighth codon of the LacZ gene. The expected transcript would use the K18 polyadenylation signal. The plasmids K18P0Lac–Xho and K18P0Lac–Nsi were generated by cleaving K18P0Lac with either XhoI or NsiI, respectively, and with Nael. The blunted ends were then closed together. The two resulting vectors contain 251 bp and 1076 bp of K18 5′-flanking sequences, respectively. K18P0Lac–Bam was formed by deleting the 3.4-kb BamHI fragment of K18P0Lac, which contains sequences 3′ to the K18 gene. The K18P1Lac vector contains the 5′-flanking region and 48 bp of noncoding sequences of the first exon of K18 fused to the BglII fragment of pl3. The latter fragment contains 14 bp of the 5′-noncoding region and the first and second codons of the Moloney murine leukemia virus (MoMLV) env gene fused to the eighth codon of the LacZ gene. (C. Cepko, pers. comm. and confirmed by DNA sequencing). A 1424-bp PsiI fragment from pSV2Neo containing the t-antigen intron and the polyadenylation and termination signals of SV40 is positioned downstream of the LacZ gene. The K18P1Lac vector was constructed by replacing the 2.57-kb XhoI–EcoRV fragment of the K18P0Lac vector, which includes the first exon and the first intron of K18 and the 5′ end of the LacZ gene, with the 1.44-kb XhoI–EcoRV fragment of K18P0Lac.

The basic CAT expression vector KOCA1spA was constructed by first cloning the 1630-bp HindIII–BamHI fragment of pSV2CAT into the compatible sites of Bluescript KSM13+. The resulting vector was cleaved with either KpnI and Apal and ligated to a staggered double-stranded oligonucleotide. The sequence of one strand of the oligonucleotide was AAAGATCTGGTACCGG. The second oligonucleotide overlapped with the first sequence to create compatible ends for KpnI and Apal. The 133-bp Hpal–BamHI fragment of pSV2CAT that contains SV40 termination and polyadenylation signals was cloned into the unique BglII site of the synthetic oligonucleotide with the use of a BamHI linker for the Hpal end, thus creating KOCATspA. SV40 termination signals upstream of the transcription units decrease the potential background that results from readthrough transcription from inappropriate initiations within plasmids sequences. To construct XKCATspA, a 3′ exonuclease III deletion of the K18 gene in plasmid M13mp19 was cloned as an XhoI–EcoRI fragment into KOCATspA. The 3′ EcoRI site of the K18 deletion and the 5′ HindIII site of the CAT gene were blunt-end-ligated. The HSV-TK promoter was isolated from F101TKCATspA (Linneqy and Donerly 1983). The F101 mutant polyoma enhancer was first deleted by digestion with XhoI and self-ligation. The HindIII
fragment containing the TK promoter was then inserted into KOCA
TspA to create TKCATspA.

For testing sequences of the first intron of K18 for enhancer activity, a 663-bp fragment of the 742-bp intron was synthe-
sized by polymerase chain reaction (PCR) methods (Saiki et al. 1988). The sequence of the amplified fragment was confirmed by DNA sequencing. The primers started with CC and then contained either XhoI or Xbal and inserted into the unique XhoI site 5' of the K18 and TK pro-

tomer sequences of XKCATspA and TKCATspA, respectively,
or into the unique Xbal site 3' of the CAT gene and SV40 po-
yadenylation signals of the same vectors (Fig. 3B). The effective deletion of a portion of the K18 first intron (783-837 bp) was
constructed by synthesizing two fragments of the intron by
PCR. One primer of each set (Fig. 3B, PCR 3 or PCR 4) started
with CCGGATCC to create BamHI sites. The second primer of each set (Fig. 3B, PCR 1 or PCR 2) contained terminal XbaI
sites. After synthesis, the two fragments were digested with
BamHI and ligated together. After subsequent digestion with
XbaI, the appropriate size fragment was gel-purified and in-
inserted into the XhoI site of XKCATspA to create XKCATds
(Fig. 9). After verification by sequencing, the deleted intron
m fragment was moved to a XKCATspA vector, which had been
modified to remove the unique BamHI site by Klenow treat-
ment and self-ligation. The site-specific mutagenesis of the
AP-1 site was accomplished by synthesizing complementary oligonucleotides (Fig. 3B, nucleotides 783-826) with additional
BamHI-compatible ends. The mutant AP-1 oligonucleotides
differed from the wild-type sequence at four positions of the
AP-1 site, as indicated in Figure 3B, to create a BglII site. The
annealed synthetic oligonucleotides were inserted into the
BamHI site of the deleted intron (Fig. 9A, IB and IBmAP1) of the
modified XKCATds vector that contained only a single BamHI
site. The inserted fragments were sequenced to verify the orien-
tation and fidelity of the synthetic oligonucleotides.

To standardize the transfer of different plasmids and dif-
ferent cell lines, the CAT and LacZ genes were inserted into the
human β-actin expression vector pH5AP-1-Neo (Gunning et al. 1987). The 785-bp HindIII-XhoI fragment of KOCA
TspA containing the CAT gene-coding sequences and ending 194 bp
downstream of the putative CAT translational termination
codon was inserted between the unique HindIII and BamHI
sites of pH5AP-1-Neo to create β-actin-CAT. The LacZ gene
was cloned as a BglII fragment from pl3 into the unique BamHI
site of pH5AP-1-Neo, resulting in β-actin-LacZ. The expres-
sion vectors for c-jun and a mutant c-jun (containing a frame-
shift within the DNA-binding domain) and driven by the RSV-
LTR (long terminal repeat) promoter (RSV-c-jun and RSV-mc-
jun) (Angel et al. 1988) were kindly provided by Robert Chiu
and Michael Karin (University of California, San Diego, La
Jolla, CA). The pc-fos-3 plasmid containing the entire mouse c-fos gene (Curran et al. 1983; Miller et al. 1984) was provided
by Steven Edwards and Eileen Adamson (La Jolla Cancer Re-
search Foundation, La Jolla, CA).

DNA was introduced into cells by the calcium phosphate
precipitate method and assayed for CAT activity and β-galacto-
sidase activity as described by Gorman (Gorman 1985). In 6-cm
dishes, 5 x 10^5 cells were plated, whereas 1.5 x 10^6 cells were
plated when 9-cm dishes were used. A total of either 7 or 20 μg
of DNA was used for 6- and 9-cm dishes, respectively. DNA
precipitates were added the day after plating, and all lysates
were prepared 48 hr after addition of the DNA precipitate. The
protease inhibitor aprotinin (Sigma Chemical) was added to all
lysates (0.3 trypsin inhibitor U/ml lysate) because preliminary
experiments indicated that the linear portion of the β-galactos-
dase assay was extended with its addition and the activity of
CAT was stabilized in some lysates. In all experiments, the ac-
tivity of either the CAT or LacZ genes was normalized to the
activity of the same lysate of the appropriate cotransfected β-
actin vector. The large variability in the activity of the reporter
genes from experiment to experiment and even from plate to plate (see Table 1) was thus greatly reduced. However, the ac-
tivity of the CAT plasmid was not the same in every cell type,
as shown in Table 1. In a survey of several different CAT
expression vectors, the activity of the β-actin-CAT vector was
highest and most reproducible in most cell types. However, in
the case of F9 cells, standardization to β-actin-CAT leads to
artificially high values because of the relatively low activity of
this construct. To compare different cell lines, the individual
cat activities were first normalized to the average value found
for β-actin-CAT in independent experiments shown in Table
1. The β-galactosidase activity per microgram of plasmid DNA
was then divided by the normalized CAT activity.

S1 nuclease protection analysis of RNA was performed as de-
scribed previously (Kulesh and Oshima 1988) by using a 480-
nucleotide probe that overlaps with the K18 first exon by 240
nucleotides. Both authentic K18 mRNA and RNAs derived
from properly initiated vectors containing the first exon protect
the same portion of the probe.

The antisera and the immunoprecipitation methods have been
described previously (Oshima 1981, 1982). The 76/21-3 cells
(Ruther et al. 1985) were obtained from Robert Chiu. Cells
were labeled in methionine-free Dulbecco's modified Eagle

| Table 1. Cellular dependence of standard plasmid activity |
|-----------------------------|
| Cell line | β-Actin-CAT^ | pyF101TκCAT^ | β-Actin-LacZ^ |
|-----------------------------|
| F9.22 | 1.0 ± 0.6 | 5 | 0.8 ± 0.6 | 15 | 637 ± 1005 | 116 |
| HR9 | 33.4 ± 15.1 | 5 | 0.9 ± 0.8 | 16 | 6738 ± 4294 | 22 |
| Ltk^ | 47.8 ± 14.6 | 5 | 1.6 ± 0.7 | 10 | 2515 ± 732 | 14 |
| NT2 | 16.4 ± 8.1 | 6 | 0.8 ± 0.3 | 5 | — | — |

^The calcium phosphate precipitate of the β-actin-CAT vector DNA was added to 60-mm dishes initially containing 5 x 10^5
of the indicated cell line. Lysates were prepared 48 hr after the addition of a total of 7 μg of DNA, including 3.7 μg of β-
actin-CAT. Enzyme activity is represented by activity units [AU] [nanomoles of [14C]chloramphenicol acetylated per hour at
37°C] per milliliter of lysate normalized to 1 μg of plasmid DNA. All values were determined within the linear range of the
assay.
^Activity in transfected cells was determined as for β-actin-
CAT, except only 2 μg of PyF101TκCAT-PA4 plasmid DNA
was used. This plasmid contains a mutant polyoma enhancer
linked to a truncated HSV-TK promoter and a synthetic poly-
adenylation signal 3' of the CAT gene (Linney and Donnelly
1983).
^LacZ activity is represented by AU [nanomoles of o-nitro-
phenyl-β-D-galactopyranoside cleaved per hour at 37°C] per
milliliter of lysate per microgram of DNA. Calcium-phosphate-
precipitated DNAs were added to 9-cm dishes initially con-
taining 1.5 x 10^6 cells. β-Actin-LacZ DNA (1.5 μg) was com-
}
[DME] media supplemented with 400 μCi/ml of [35S]methionine and fetal bovine serum (10% vol/vol) for 30 min. The same amount of lysate (5 × 10^7 acid insoluble cpm) and antiserum (10 μl) was used for each immunoprecipitation.

**Acknowledgments**

We thank Ms. Grace Cecena for expert technical assistance, Dr. Tina Trevor (Wayne State University, Detroit, MI), who constructed one of the vectors and performed preliminary experiments in this study, and Robert Chui and Michael Karin for plasmids, 76/21-3 cells, and helpful discussion. In addition, we thank our colleagues at the La Jolla Cancer Research Foundation for their helpful criticism of the manuscript. This study was supported by grant CA42302 from the National Cancer Institute, Department of Health and Human Services and Cancer Center support grant CA30199.
