Mild and selective base-free C–H arylation of heteroarenes: experiment and computation†

Hannes P. L. Gemoets,a Indrek Kalvet,b Alexander V. Nyuchev,ac Nico Erdmann,a Volker Hessel,a Franziska Schoenebeck*b and Timothy Noël*a

A mild and selective C–H arylation strategy for indoles, benzofurans and benzothiophenes is described. The arylation method engages aryldiazonium salts as arylating reagents in equimolar amounts. The protocol is operationally simple, base free, moisture tolerant and air tolerant. It utilizes low palladium loadings (0.5 to 2.0 mol% Pd), short reaction times, green solvents (EtOAc/2-MeTHF or MeOH) and is carried out at room temperature, providing a broad substrate scope (47 examples) and excellent selectivity (C-2 arylation for indoles and benzofurans, C-3 arylation for benzothiophenes). Mechanistic experiments and DFT calculations support a Heck–Matsuda type coupling mechanism.

Introduction

The ubiquity of the heterobiaryl motif in pharmaceuticals, agrochemicals and materials illustrates its scientific and commercial value.1 Traditionally, these moieties have been prepared via cross-coupling strategies which require pre-functionalized substrates.2 However, over the last decade, transition metal-catalyzed C–H arylation protocols have been developed to enable the formation of C–C bonds.3 In contrast to classical cross-coupling chemistry, C–H arylation strategies enable direct functionalization of simple heteroarenes. The direct arylation of heteroarenes can be achieved via radical pathways, e.g., visible light photoredox catalysis4 and Meerwein arylation.5 However, these methods suffer from a number of disadvantages, including long reaction times, large excesses of substrates, selectivity issues and limited substrate scopes. Recently, there has been an increase in the number of new methods, particularly in the use of metal-catalyzed processes.6 In particular, the work by Gaunt,7 Sames,8 Sanford,9 DeBoef,10 Glorius,11 Ackermann,12 Fagnou13 and Larrosa14 has increased the number of useful C–H arylation transformations to enable heteroaryl-(hetero)aryl bond formation. Furthermore, these examples have deepened our fundamental understanding of the underlying challenges inherent in such processes. However, the state of the art is still far from competitive with classical cross coupling strategies, e.g. Suzuki–Miyaura cross coupling. Current hurdles include harsh reaction conditions (i.e. high temperature), the necessity of stoichiometric amounts of oxidants and/or additives, use of toxic solvent systems, limited selectivity and high catalyst loadings (typically 5 to 10 mol%). Consequently, the development of new, mild and broadly applicable C–H arylation strategies is still highly desirable.15 We anticipated that the design of a mild and
selective C–H arylation protocol for heteroaromatics (i.e. indoles, benzofurans and benzothiophenes) could be of high interest for API synthesis (e.g. Bazedoxifene,\textsuperscript{46} Saprisartan\textsuperscript{17} and Raloxifene\textsuperscript{44}). Recently, Correia \textit{et al.} described a Pd-based arylation of heteroarenes using aryldiazonium salts.\textsuperscript{44} However, the protocol suffered from high catalyst loadings (10 to 20 mol\% Pd), limited scope and impractical reaction conditions (e.g. biphasic reaction conditions, large excesses of reagents, and high reaction temperatures). Herein, we describe the development of a mild and selective palladium-based C–H arylation strategy (Scheme 1). Notable features of our open flask protocol are its operational simplicity in conjunction with low catalyst loadings, broad substrate scope, green solvent system, and short reaction times. No additional oxidants or additives are required. The strategy uses equimolar amounts or slight excesses of aryldiazonium salts as convenient arylating reagents.\textsuperscript{6,19} Kinetic studies and DFT calculations suggest that a Heck–Matsuda-type mechanism occurs under our reaction conditions.

## Results and discussion

### Optimization of reaction conditions

We commenced our optimization studies with the Pd-catalyzed C–H arylation of 1-methylindole (1\textsuperscript{a}), which was reacted with 1.2 equivalents of benzenediazonium tetrafluoroborate (2\textsuperscript{a}) in the presence of 10 mol\% Pd(OAc\textsubscript{2})\textsubscript{2} in DMF. A satisfying yield of 66\% for 1-methyl-2-phenylindole (3\textsuperscript{a}) was obtained within only 30 minutes of reaction time at room temperature (Table 1, Entry 1). The main byproducts were 3-(arylazo)-1-methylindole (1\textsuperscript{aa}) and 2-aryl-3-(arylazo)-1-methylindole (3\textsuperscript{aa}), due to the uncatalyzed electrophilic substitution reaction between the highly electrophilic nitrogen of the aryldiazonium salt and the C-3 position of 1-methylindole (Fig. 1b). Lowering the catalyst loading to 5 mol\% Pd(OAc\textsubscript{2})\textsubscript{2} in DMF resulted in a significant drop in yield (34\%). An overnight control experiment showed that no product formation was observed in the absence of a palladium catalyst (Table 1, Entry 3). Using polar protic solvents (e.g. i-PrOH) resulted in generally high reactivity and moderate yields. A considerable amount of byproduct formation was consistently observed (see ESI†). It was generally found that carrying out the reaction in less polar (aprotic) solvents (e.g. DMF → THF → 1,4-dioxane) resulted in reduced byproduct formation. After solvent screening, THF was considered to be the best solvent (77\%), combining both the desired reactivity and selectivity (Table 1, Entry 5). A control experiment using Schlenk techniques indicated that the catalyst was not affected by air and moisture (Table 1, Entry 5). Therefore, all the following experiments could be performed as open-flask reactions, making this procedure appealing for future scale-up. A catalyst survey demonstrated that only Pd(OAc\textsubscript{2}), Pd(TFA\textsubscript{2})\textsubscript{2} and, to a lesser extent, Pd\textsubscript{2}(dba)\textsubscript{3} were active catalysts for this chemical transformation (Table 1, Entries 6–8). The use of Pd(OAc\textsubscript{2})\textsubscript{2} was preferred over Pd(TFA\textsubscript{2})\textsubscript{2} due to its cost efficiency and stability. Further optimization studies showed that it was possible to lower the catalyst loading further to 0.5 mol\% in THF (Table 1, Entry 9). Even lower catalyst loading resulted in only trace amounts of product (Table 1, Entry 10). Finally, 2-MeTHF was

### Table 1 Optimization for the Pd-catalyzed C-2 arylation of 1-methylindole

\textsuperscript{a} Reaction conditions: catalyst, 0.5 mmol heteroarene and 1.2 equiv. benzenediazonium tetrafluoroborate in 2.5 mL solvent at rt, 0.1 equiv. decalfluorobiphenyl as internal standard for GC-FID, open flask. \textsuperscript{b} Solvent: H\textsubscript{2}O, AcOH, ETOAc, propylene carbonate, DMF, acetone, MeCN, Et\textsubscript{2}O, 1,4-dioxane, MeOH, ETOH, i-PrOH n-BuOH, DCM, DCE, CHCl\textsubscript{3}, toluene. \textsuperscript{c} Schlenk line techniques used. \textsuperscript{d} Catalyst: 10% Pd/C, PdCl\textsubscript{2}, Cu(OAc\textsubscript{2})\textsubscript{2}, Cu[OTf\textsubscript{2}], Pd[P(C\textsubscript{6}H\textsubscript{5})\textsubscript{3}]\textsubscript{2}, (MeCN)\textsubscript{2}Pd(N\textsubscript{2})Cl\textsubscript{2} and (η\textsuperscript{5}-C\textsubscript{5}H\textsubscript{5})\textsubscript{2}PdCl\textsubscript{2}, PEPPSI-SIPr. \textsuperscript{e} 2 h premixing of Pd(OAc\textsubscript{2})\textsubscript{2} with 1-methylindole, 1.0 equiv. of benzenediazonium tetrafluoroborate used. \textsuperscript{f} Isolated yield.
evaluated. This solvent is recognized as a green solvent for synthetic organic chemistry because it can be readily produced from furfural, a common biomass material. Satisfyingly, 2-MeTHF showed even better selectivity for the desired product (87%), although an increased reaction time of 2 hours was required to obtain full conversion (Table 1, Entry 11). Continued optimization studies with green solvents revealed that the reaction time could be halved by using EtOAc : 2-MeTHF (1 : 1) for 2 hours could eliminate this observed induction period (Fig. 1a, red series). We surmised that Pd(II) is first reduced to a homogeneous Pd(0) complex and is stabilized by the π-donating character of 1-methylindole and/or by the ligand exchange of OAc with 2-MeTHF. Indeed, a reaction performed with Pd₂(dba)₃ as a stable homogeneous Pd(0) substitute showed that neither an induction period nor an initial acceleration occurred (Fig. 1a, green series). However, lower yields were obtained with Pd₂(dba)₃. This result gives us a first glimpse of the possible catalytic mechanism, indicating that palladium in its homogeneous zero state can act as an active catalyst.

As expected, the product 3a was even more prone to undergo a side reaction (i.e. an electrophilic substitution reaction) with benzenediazonium salt, as the inductive effect of the phenyl substituent makes the C-3 position more nucleophilic. This was especially noticeable when a slight excess of benzenediazonium tetrafluoroborate was used (Fig. 1a, blue series). A small yield of approximately 10% was observed after prolonged reaction time, which accounts for the 0.1 equivalent excess. To counteract this consecutive reaction, an equimolar amount (1.0 equiv. benzenediazonium tetrafluoroborate) was used. As a result, 90% of the desired product could be isolated (Table 1, Entry 14). Note that the reaction time could be halved again, to approximately 30 minutes, when using the premixing strategy. In addition, a slightly higher selectivity was obtained because side reactions were minimized. More information regarding reaction optimization and reaction progress analysis can be obtained from the ESI.

Mechanistic studies: DFT calculations and experimental investigations

Since heteroarenes are good nucleophiles, it would be reasonable to assume a mechanism in which Pd(0) acts as an electrophile, consistent with numerous literature proposals in the context of C–H functionalization. Similar to S_{Ar}, these reactions are expected to be C-3 selective for indoles. However, our methodology yields C-2 arylated indoles selectively and thus
requires a subsequent C-3/C-2 isomerization. In this context, Gaunt and co-workers showed that the presence of acid would facilitate a switch from C-3 to C-2 in the Pd-catalyzed C–H olefination of indoles, suggesting that under acidic conditions, C-3 deprotonation of the indole moiety would be slowed. However, such a scenario appears unlikely in our case. For example, progressive $^1$H-NMR spectroscopy with equimolar quantities of Pd(OAc)$_2$ and 1-methylindole in d$_8$-THF showed that neither the HC-2 or the HC-3 peaks of 1-methylindole were affected (see ESI Section 3.1.1†). Therefore, the employed Pd(OAc)$_2$ likely serves as a precatalyst and is reduced to Pd(0) during the initiation period. Additionally, since we have shown that Pd(0) is catalytically active without any induction period (Table 1, Entry 8), it is reasonable to assume that the reaction proceeds via a Pd(0)/Pd(II) catalytic cycle. This cycle starts with an initial oxidative addition of the highly activated aryl diazonium salt to Pd(0) to yield a cationic Pd(II) complex which should subsequently serve as an electrophile in the reaction with the substrate (Scheme 2, I). The overall product selectivity would then again be determined by the C-3 to C-2 migration of Pd. However, our efforts to computationally locate the C-2 Pd complex yielded a structure that is 9.1 kcal mol$^{-1}$ higher in energy than the preferred $\eta^1$ π-complex Int1 (Fig. 2), suggesting that the migration is disfavored.

Intermediate Int1 may alternatively undergo a Heck-type carbopalladation reaction. Our calculations suggest this process to be energetically feasible, being characterized by a relatively facile free energy barrier of 17.5 kcal mol$^{-1}$ (Fig. 2). Thus, we subsequently calculated the expected selectivities (C-3 versus C-2) for C–H arylation for a carbopalladation mechanism. We considered several possible solvent coordinations to the cationic Pd; we determined that the coordination of two THF molecules is likely preferred. Our computed selectivities are in agreement with experiments. Complete C-2 selectivity was experimentally observed for 1-methylindole and benzo furan.

**Scheme 2** (a) Proposed Pd(0)/Pd(II) Heck–Matsuda-type cycle for the C-2 arylation of 1-methylindole. (b) Observed SN1 side-reaction in the case of benzo furan in MeOH.
consistent with our computational results ($\Delta \Delta G^\dagger = 2.4$ kcal mol$^{-1}$ and 0.7 kcal mol$^{-1}$ in favor of C-2, respectively). By contrast, benzothiophene yielded the C-3 arylated product exclusively, which was also reproduced by computations ($\Delta \Delta G^\dagger = 1.9$ kcal mol$^{-1}$ in favor of C-3) (see Fig. 2).

The carboxylation step in the traditional Heck-type reaction would be followed by syn-$\beta$-hydride elimination. Due to the rigidity of the ring system, however, there is no possibility of conventional syn-$\beta$-hydride elimination from the formed intermediate Int2. In contrast, it has been previously suggested that a base or solvent assisted anti-$\beta$-deprotonation rearomatization could occur. While that step may also be involved in our case, due to the ionic and complex nature of the intermediates involved, an adequate computational description of the system would pose a number of difficulties. However, in situ $^1$H and $^{19}$F NMR analysis of the reaction have given us initial insights into the likely nature of the processes involved (see ESI Section 3.1.2 for a detailed description†). The data indicate that additional signals, assigned as BF$_3$·2Me–THF and HF, appear in the $^{19}$F NMR spectrum at the same rate as the product $5b$. Moreover, when using an alternative counterion for the aryldiazonium salt (e.g., 4-methoxybenzediazonium mesylate), no product was observed (Table 2, 3h). It is therefore hypothesized that the BF$_3$·2Me–counterion of the aryldiazonium salt plays a non-negligible role in the reaction mechanism, i.e. acting as a pseudo-base in the anti-$\beta$-deprotonation rearomatization step. In addition, a crude $^1$H-NMR spectrum acquired from the reaction mixture (using THF-d$_4$ as solvent) indicates that the lost proton appears quantitatively as a broad signal at 9.0 ppm (see ESI Section 2.3).

Alternatively, a radical mechanism could be envisioned for this transformation. However, a large excess (5 to 100 equiv.) of the heteroarene substrate is generally required for satisfying results under such conditions. In our case, optimal results were achieved with equimolar quantities. In addition, test reactions via the radical pathway did not lead to the desired product. Moreover, radical scavenging tests failed to trap any radical intermediates (See ESI Section 3.2 for details). Finally, in radical chemistry, mixtures of C-2 and C-3 arylation are frequently observed, while our system displays complete selectivity.

**Synthetic scope: heteroarenes and aryldiazonium salts**

With the optimized conditions in hand, we next explored the scope of our developed methodology on indoles (Table 2). These substrates were reacted with equimolar amounts of aryldiazonium salts in the presence of 0.5 mol% Pd(OAc)$_2$ in the case of 1-methylindoles and 1.0 mol% of Pd(OAc)$_2$ for NH-indoles. A 1 : 1 mixture of EtOAc : 2-MeTHF was used as the solvent. A broad set of substituted aryldiazonium substrates (3a–y) could be successfully coupled with 1-methylindole. Indole arylation with aryldiazonium salts bearing alkyl substituents (3c–g, 4a, b) proceeded well for both N-protected and free indoles, even in the presence of sterically demanding ortho-methyl substituents (3c, 3e). When using the more sterically hindered mesitylene-diazonium tetrafluoroborate as the arylation agent, a mixture (C-2 and C-3 arylated product) was found for both the N-ethylated and the free indoles (3f, 4c). Selectivity towards the C-3 arylated product was prevalent in 4c (C-2 : C-3 1 : 3.3). For all other reactions, complete selectivity towards the C-2 arylated product was observed. Next, a scope of aryldiazonium salts, containing hydroxy-, phenoxy- and methoxy-substituents, was explored (3h–p). It was demonstrated that aryldiazonium salts bearing a free hydroxyl group showed some reactivity, although in lower yield (3p, 16%). A para-phenoxy group as an electron-donating substituent on the aryldiazonium salt resulted in good reactivity (3o, 79%).

Moreover, all methoxy-containing aryldiazonium salts (3h–n) showed good to excellent reactivity (69% to 93%), except for 3l, where no full conversion could be obtained. The yields obtained for compounds 3h–n showcase the applicability of our methodology for the C-2 arylation of indoles with arylation agents bearing methoxy-substituents, which are often reported to be cumbersome. These substituents are functional handles which can be engaged in nickel-catalyzed cross-
Coupling chemistry via C–O activation. In addition, heterocyclic aryldiazonium salts were tolerated in this protocol: 3q was obtained in moderate yield (34%) overnight, while for 3r, a good yield (71%) was acquired within 1 hour reaction time. Notably, in the case of free NH-indoles (4a–d), an ortho-methyl substituent on the aryldiazonium salt proved necessary to avoid significant by-product formation (electrophilic substitution). However, it was found that by blocking the C-3 position of the NH-indole (i.e., via methylation), this side-reaction could be completely avoided (4ea vs. 4e).

Next, we explored a more challenging class of aryldiazonium salts bearing weakly (e.g., F) to highly electron-withdrawing (e.g., NO2) substituents (3s–y). Gratifyingly, 4-fluoro- and 3-iodobenzenediazonium tetrafluoroborate readily reacted with 1-methylindole (3s, 3w). The latter (3w) is particularly appealing, since it indicates that palladium undergoes oxidative addition.

Table 2  Scope for the C-2 arylation of indoles

|-------------------------------|-------------------------------|
| R2 = 2-MeTHF (1:1) at rt, open flask | R2 = 2-MeTHF (1:1) at rt, open flask |
| 0.5 to 1.0 mol% Pd(OAc)2, 1.0 mmol heteroarene and 1.0 equiv. aryldiazonium salt in 5 mL EtOAc : 2-MeTHF (1:1) at rt, open flask, 2 h premixing of Pd(OAc)2 with heteroarene. | 1 mol% Pd(OAc)2, 1.2 equiv. aryldiazonium salt. |
| 4-Methoxybenzenediazonium mesylate was used. | 1.2 equiv. aryldiazonium salt. |
| Gram-scale experiment (10.0 mmol) yielded 2.47 g (83%), 4 h reaction time in 2-MeTHF as solvent. | 1.2 equiv. aryldiazonium salt at 40 °C; no full conversion obtained. |
| 0.01 M and 100 mol% Pd2(dba)3 was used. | |
at the electrophilic diazonium site (instead of breaking the C–I bond) at room temperature. In contrast, aryldiazonium salts bearing m-CF₃ (3ta), p-NO₂ (3ua), o-Cl (3va) and p-Br (3xa) as substituents did not deliver any arylated product when 1-methylindole was used as the substrate. It was observed that these aryldiazonium salts were too prone to electrophilic substitution reactions, resulting in the rapid formation of 3-(arylazo)-1-methylindoles (see Fig. 1b). However, as in the NH-indole case, this side reaction could be efficiently overcome by blocking the C-3 position. Consequently, the arylation scope could be expanded to electron-withdrawing substituents (3t, 3u, 3v, 3x) with high to excellent yields of the desired product (80% to 92%). This trend was also observed when aryldiazonium salts bearing an acyl moiety were used (3ya and 3y): 58% of the target product (3ya) was obtained for 1-methylindole, while an improved result was obtained for the C-3 methylated indole (80% yield, 3y)

Subsequently, several indole derivatives were subjected to the reaction conditions using benzenediazonium tetrafluoroborate as a benchmark coupling partner. For 5a and 5c, the reaction proceeded smoothly under equimolar conditions. 5d proved more challenging (22% yield) due to the electron-withdrawing nature of the methyl carboxylate substituent, which renders it a less nucleophilic substrate. Interestingly, an experiment with 1,2-dimethylindole and benzenediazonium salt showed that no C-3 arylated product could be formed over 5 hours. Instead, the substrate was fully converted to the electrophilic substituted product 1bb (93% yield). Moreover, during a control experiment with a stoichiometric amount of Pd₂(dba)₃, no 1bb was formed. This indicates that the benzenediazonium salt preferably underwent oxidative addition (see ESI Section 3.4†).

Next, a gram scale experiment was conducted to test the scalability of this mild procedure. The reaction was carried out with equimolar quantities of reactants (10 mmol) and 0.5 mol% Pd(OAc)₂ in 2-MeTHF. With a slightly longer reaction time of 4 hours, a satisfying yield of 83% (2.47 g) of 3k was achieved under open flask conditions.

Having established a good coupling protocol for indoles, we subsequently examined the scope of benzofuran (1i) with various aryldiazonium salts (Table 3). Since benzofuran is not prone to electrophilic substitution, MeOH could be used as

a more reactive solvent (see ESI Section 2.4†). These results are in agreement with the literature.38 Felpin et al. demonstrated with DFT and experimental results that the cationic palladium intermediates in the Heck cycle are exergic with MeOH as the solvent.37 Moreover, it was observed that the addition of 1.0 equivalent of TFA resulted in an impressive rate acceleration (overnight to 30 minutes) while maintaining its selectivity (6e, 81%). The use of the protic solvent MeOH resulted in the formation of 2-aryl-3-methoxy-2,3-dihydrobenzofuran (6ee). It was speculated that 6ee was formed from the proposed carbopalladation intermediate I through a SN1 mechanism, resulting in the observed syn/anti diastereomeric mixture (Scheme 2b). However, a simple workup procedure consisting of 15 minutes of reflux under acidic conditions (i.e. acetyl chloride) was found to be sufficient to eliminate MeOH from the compound, affording the desired product in overall high yield. Benzofuran could be readily coupled with benzenediazonium tetrafluoroborate in good yield (6a, 70%).

Next, we carried out several reactions by coupling benzofuran with several halogenated aryldiazonium tetrafluoroborates (6b–h). Satisfyingly, all reactions proceeded smoothly in the presence of only 0.5 mol% Pd(OAc)2, thus showcasing the mild reaction conditions of this protocol.

Finally, we turned our attention towards a more challenging heteroarene, i.e. benzothiophene (1j) (Table 3). Because benzothiophene is the least nucleophile heteroarene investigated herein, it was necessary to use slightly higher catalyst loadings (2.0 mol%) and 2.0 equivalents of aryldiazonium salt in order to achieve full conversion. Operating at 40 °C was decisive to obtain a good yield for both 7a (80%) and 7b (73%). In agreement with literature reports and DFT calculations (see above), we observed a complete shift in selectivity from C-2 to C-3 arylation. For compound 7a, a significant improvement in yield (80% vs. 69%) and a reduction in reaction time (16 h vs. 96 h) was observed, highlighting the relevance of our mild protocol.18 Taken together, this C–H activation protocol for the direct arylation of heteroarenes provides a convenient pathway towards a broad range of heteroaromatic arylated derivatives.

Application: synthesis of the drug precursor of Saprisartan

To further illustrate the efficacy of this mild strategy, we applied the C–H arylation process to the synthesis of methyl 2-{5-(methylbenzofuran-2-yl)benzoate (8a) (Scheme 3). Compound 8a is a key intermediate in the total synthesis of Saprisartan, an approved drug belonging to the sartan family.37 Sartans act as AT1-antagonists and are among the most prescribed drugs for the treatment of hypertension and heart failure.19 Our mild procedure allowed us to successfully isolate the key intermediate 8a in 70% yield, which compares favorably to the patented process, which requires four consecutive steps for the same transformation with an overall low yield of 11%.17,19

Conclusion

In summary, we have developed a mild and selective protocol for the C–H arylation of heteroarenes, including indoles, benzofurans and benzothiophenes, with aryldiazonium salts. The protocol is operationally simple and is insensitive to air and moisture. It utilizes low palladium loadings (0.5 to 2 mol% Pd), short reaction times, green solvents (EtOAc/2-MeTHF or MeOH) and is carried out at room temperature. Notably, no oxidants or other additives are required. The substrate scope is broad and displays excellent selectivity (C-2 arylation for indoles and benzofurans, C-3 arylation for benzothiophenes). To illustrate the efficacy of this procedure, a key intermediate (8a) for the drug Saprisartan was synthesized, comparing favorably to the patented process (70% vs. 11%). Mechanistic experiments and DFT calculations support a Heck–Matsuda-type coupling mechanism. Moreover, the first experimental results indicate that BF4- anions could be involved in the anti-β-deprotonation rearomatisation step of the catalytic cycle. We expect this protocol will find widespread application due to its mild character and excellent selectivity.

Financial support is provided by the Dutch Science Foundation (NWO) via an ECHO grant (Grant No. 713.013.001) and a VIDI grant for T.N. (Grant No. 14150). We also acknowledge the European Union for a Marie Curie CIG grant for T.N. (Grant No. 333659) and an ERC Advanced Grant for V.H. (Grant No. 267443). IK and FS gratefully acknowledge the computing time granted by the JARA-HPC Vergabegremium on the RWTHBull Cluster in Aachen (Grant JARA0091). HG and TN thank Cecilia Botteccia (TU/e) for helping with NMR analysis and Bart Hendricks (TU/e) for helping with the synthesis of aryldiazonium salts. We would like to thank referee 2 for stimulating discussions during the revision stage of this manuscript.

Various ligation states of Pd were considered: THF molecules, Indole substrate and the combination of both, with the THF molecules being the preferred one.

Benzofuran was reacted in MeOH, which offers various different likely coordination states. Thus, it is challenging to describe this system adequately with computations. For the coordination state considered, we predict selectivities in line with experiments. See ESI for additional information†.
