Abstract
Amazonian deforestation has accelerated during the last decade, threatening an ecosystem where almost one third of the regional rainfall is transpired by the local rainforest. Due to precipitation recycling, the southwestern Amazon, including the Amazon-Andes transition region, is particularly sensitive to forest loss. This study evaluates the impacts of Amazonian deforestation on the hydro-climatic connectivity between the Amazon and the eastern tropical Andes during the austral summer (December–January–February) in terms of hydrological and energetic balances. Using 10-years high-resolution simulations (2001–2011) with the Weather Research and Forecasting Model, we analyze control and deforestation scenario simulations. Regionally, deforestation leads to a reduction in the surface net radiation, evaporation, moisture convergence and precipitation (~ 20%) over the entire Amazon basin. In addition, during this season, deforestation increases the atmospheric subsidence over the southern Amazon and weakens the regional Hadley cell. Atmospheric stability increases over the western Amazon and the tropical Andes inhibiting convection in these areas. Consequently, major deforestation impacts are observed over the hydro-climate of the Amazon-Andes transition region. At local scale, nighttime precipitation decreases in Bolivian valleys (~ 20–30%) due to a strong reduction in the humidity transport from the Amazon plains towards the Andes linked to the South American low-level jet. Over these valleys, a weakening of the daytime upslope winds is caused by local deforestation, which reduces the turbulent fluxes at lowlands. These alterations in rainfall and atmospheric circulation could impact the rich Andean ecosystems and its tropical glaciers.

Keywords Deforestation · High-resolution climate modelling · Amazon basin · Amazon-Andes transition region · Energy and water balances

1 Introduction

The Amazon is the largest tropical rainforest in the world. It exchanges water, energy, and carbon with the atmosphere and is considered as an essential dynamic component of the climate system (Bonan 2008; Malhi et al. 2008). The Amazon ecosystem has been recognized as one of the major sources of evapotranspiration (Fisher et al. 2011), releasing large amounts of water vapor to the atmosphere and sustaining rainfall not only in the Amazon itself, but also in remote regions of the South American continent (Eltahir and Bras 1994; Van Der Ent et al. 2010; Martinez and Dominguez 2014; Zemp et al. 2014). In addition, the latent heat release linked to moisture recycling over the Amazon basin engines global and regional atmospheric circulation (Gill 1980; Eltahir 1996; Gedney and Valdes 2000). Therefore, understanding the impacts of continued deforestation on the regional and global hydroclimate has become an urgent and extensively explored scientific question.

The Amazonian forest has been intensively cleared since the 1970’s (Fearnside 1993; Nepstad et al. 2009). After a slowdown of deforestation rates during the period 2004–2012, the small-scale forest loss rates increased again over the last decade (Kalamandeen et al. 2018; Eiras-Barca
et al. 2020). Deforestation, as every effect of human activities on the climate system, disturbs the Earth’s radiation budget and can be an important forcing for climate change (Hartmann et al. 2013; Mahowald et al. 2017). Indeed, when the rainforest is replaced by cropland or grassland, the energy balance is disturbed by: (i) a reduction in surface roughness and actual evapotranspiration, decreasing the surface energy loss from turbulent heat removal and latent heat flux (Gash and Nobre 1997; Lee et al. 2011; De Noblet-Ducoudré et al. 2012); (ii) an increase in the incoming solar radiation at the surface linked to less clouds and less evapotranspiration rates (Salati and Vose 1984; Bala et al. 2007); (iii) a reduction in absorbed solar radiation due to an increased surface albedo (Berbet and Costa 2003; von Randow et al. 2004); and finally (iv) less incoming infrared radiation driven by drier air as a result of the reduced evapotranspiration (Eltahir 1996; Claussen et al. 2001). In-situ measurements find a decrease in the surface net radiation over cleared areas (Bastable et al. 1993; von Randow et al. 2004). Although at the annual time scales an air temperature warming of the layer close to the surface follows the forest clearance (Gash and Nobre 1997), the reduction in the net surface radiation generates a cooling of the upper atmosphere and a subsidence that weakens the regional circulation (Eltahir 1996). In this sense, perturbations that initially occur at the surface and within the lower part of the atmosphere modify the vertical transport of heat and moisture, altering convection and subsidence over extended regions and affecting large-scale features such as the Hadley and Walker cells (Zhang et al. 1996; Snyder 2010; Badger and Dirmeyer 2015).

Atmospheric circulation and Amazonian rainforest compound a coupled bio-geophysical balanced system. Perturbations in the vegetation state through deforestation can drive very different changes in atmospheric circulation depending on its spatial scale. Observations and theoretical works show small-scale deforestation (< 10 km) triggering thermally driven land breeze resulting from differences in sensible heat fluxes between pastured and forested areas (Pielke 1984, 2001; Atkinson 1989; Wang et al. 1996; Souza et al. 2000; D’Almeida et al. 2007; Lawrence and Vandecar 2015). However, thermally driven circulations seem to be scale-dependent and can weaken as deforestation areas increase (Avissar and Schmidt 1998; Patton et al. 2005). At spatial scales larger than 100 km, land surface heterogeneities cannot produce enough surface gradient to sustain thermal circulation (Dalu and Pielke 1993). In fact, a recent study in Rondonia-Brazil demonstrates how when cleared areas grow, a shift occurs from a thermally convective regime towards a dynamically driven state where the roughness length reduction dominates and favors (inhibits) convection over areas in the downwind (upwind) direction of the deforested zone (Khanna et al. 2017). Since deforestation impacts on hydrological and atmospheric processes are complex and scale dependent, regional and global climate models stand out as useful tools to better understand the response of the climate system to land-use perturbations.

Numerical climate models have been extensively used for analyzing the impacts of deforestation over regional and global climate (Nobre et al. 2016 and references therein). Mesoscale models are able to represent the observed changes in circulation and clouds that follow small-scale deforestation (Chen and Avissar 1994; Wang et al. 2000; Saad et al. 2010). Furthermore, the thermal-to-dynamical shift regime caused by the rainforest loss reported over south-western Brazil is also reproduced by these models (Khanna et al. 2017). Under different deforestation scenarios, models project more frequent dry events and a lengthening of the Amazonian dry season (Nobre et al. 1991; Costa and Pires 2010; Bagley et al. 2014; Alves et al. 2017; Ruiz-Vásquez et al. 2020). Although recent observational studies report similar changes in Amazonian dry season hydrology since 1979, the attribution of these alterations to deforestation is not straightforward and evidence suggest an additional influence of the tropical north Atlantic Ocean warming (Fu and Li 2004; Yoon and Zeng 2010; Butt et al. 2011; Marengo et al. 2011; Fu et al. 2013; Deportoli et al. 2017; Espinoza et al. 2019, 2021; Leite-Filho et al. 2020). It is important to remark that, taking into account the dependency of climate response to the size of deforestation, the current spatial scale of Amazonian cleared area is not enough for predictions of extreme deforestation scenarios to be manifested or detected (D’Almeida et al. 2007; Nobre et al. 2016). On the other hand, under extensive deforestation scenarios climate models predict a reduction in precipitation recycling and rainfall in places downstream of the cleared areas caused by the shut off of forest transpiration (D’Almeida et al. 2007; Moore et al. 2007; Correia et al. 2008; Swann et al. 2015). At the same time, empirical estimates have found that south-western Amazon is particularly dependent on evapotranspiration from other parts of the basin (Zemp et al. 2017b; Staal et al. 2018). Hence, several simplified and regional climate models present a decrease in rainfall and moisture transport over this particular area (Sun and Barros 2015a; Boers et al. 2017; Zemp et al. 2017a; Ruiz-Vásquez et al. 2020). However, an opposite effect of intensified moisture transport towards south-western Amazon and south-eastern South America has been suggested by some modelling studies as the result of deforestation induced decreasing in surface roughness (Lean and Rowntree 1997; Eiras-Barca et al. 2020). These different responses to similar deforestation scenarios suggest the need to further assess the impacts of Amazon forest clearance over the regional climate.

In the Amazon-Andes transition region lies the rainiest and biologically richest area of the entire Amazon basin
and which may be sensitive to impacts on surface energy/
System (SAMS; Vera et al. 2006; see Sect. 3.1 for details)
part of the development of the South American Monsoon
in the watershed hydrology. The strong summer convection
alterations in rainfall patterns may have a profound impact
recharge during wet periods can sustain forest transpiration
nearly 50% of total annual precipitation falls over the region
(December-January–February, DJF). During this season
Andes transition region during the heart of the wet season
Esinoza et al. 2015). This region encompasses complex
Andean topography, ranging between almost sea level in the
Amazon lowlands to more than 6000 m a.s.l. over the
Andean summits. This causes a strong orographic effect that
interacts with regional atmospheric circulation to produce an
exceptional spatial rainfall contrast (Chavez and Takahashi
2017; Junquas et al. 2018). There, high precipitation rates
lead to large values of runoff per unit area (Moquet et al.
2011), providing most of the sediment load to Amazon rivers
(Vauchel et al. 2017; Armijos et al. 2020). Consequently,
extreme hydrological events over this region can impact the
whole basin downstream (Espinoza et al. 2014). Particu-
larly, the Amazon-Andes transition region exhibits the larg-
est precipitation recycling (portion of the precipitated water
previously transpired by the Amazonian rainforest) of the
Amazon catchment (Eltahir and Bras 1994; Dirmeyer and
Brubaker 2007; Van Der Ent et al. 2010; Staal et al. 2018).
Therefore, this region can potentially be highly sensitive to
Amazon deforestation effects. Nevertheless, the surface-
atmosphere coupling over this area has been poorly studied
and most of the referent work has been focused over Brazil-
ian Amazon or was based on coarse horizontal resolution
modelling experiments insufficient to capture the required
details of the topographical influence on local convection.

This study aims to better understand the deforestation
effects on moisture transport and rainfall over the Amazon-
Andes transition region during the heart of the wet season
(December-January–February, DJF). During this season
nearly 50% of total annual precipitation falls over the region
(Espinoza et al. 2009). Since Amazonian groundwater
recharge during wet periods can sustain forest transpiration
rates during dry months (Miguez-Macho and Fan 2012), DJF
alterations in rainfall patterns may have a profound impact
in the watershed hydrology. The strong summer convection
in the region is controlled by atmospheric processes that are
part of the development of the South American Monsoon
System (SAMS; Vera et al. 2006; see Sect. 3.1 for details)
and which may be sensitive to impacts on surface energy/water fluxes induced by land use change (Li and Fu 2004).

Taking into account the potential sensitivity of the Amazon-
Andes transition region to deforestation and the need
for high-resolution studies, the present work analyzes the
deforestation land-use change impacts on regional energy
and water budgets, as well as rainfall alterations at a local
scale through the use of high-resolution simulations (up to
1 km horizontal grid size) with the regional climate model
Weather Research and Forecasting Model (WRF). Model
hourly outputs are compared with observational data from
rain-gauges and satellites in order to elucidate the possible
changes caused by Amazonian deforestation in the diurnal
and nocturnal precipitation inside two typical Andean val-
dues during 2001–2011 austral summers. We describe the
configuration of the model, the deforestation experiment
and reference data used in Sect. 2. In Sect. 3, we validate
the model skill to reproduce the precipitation, general cir-
culation and moisture transport at regional scale, as well as
its ability to properly represent the deforestation signal in
comparison with observations from the Large-Scale Bio-
sphere–Atmosphere (LBA) project. The impacts of defor-
estation on moisture transport and rainfall at regional, meso
and local scales are analyzed in Sect. 4. Finally, Sect. 5 sum-
marizes and discusses the main results.

2 Data and methods

2.1 Model description

This study uses the regional climate model WRF version
4.1 (Skamarock et al. 2019). The model WRF was used in
previous works to study the climatology of tropical South
America and the Amazon basin (Bagley et al. 2014; Sun and
Barros 2015b, a; Mourre et al. 2016; Junquas et al. 2018;
Spera et al. 2018; Trachte 2018; Heredia et al. 2018; Yang
and Dominguez 2019; Eiras-Barca et al. 2020; Saavedra
et al. 2020). WRF is a non-hydrostatic model with terrain-
following vertical levels (we use 49 vertical levels with
higher level density near the surface). We employ three one-
way nested modelling domains as shown in Fig. 1a. Table 1
summarizes the information of spatial and temporal resolu-
tion for each of the three domains used in this work. The
first domain encompasses tropical South America and has a
horizontal resolution of 15 km × 15 km with a time step of
90 s. The second and third domains have spatial resolutions
of 5 km × 5 km and 1 km × 1 km, respectively and cover the
south-western part of the basin. Time steps for these two
domains are 30 s and 6 s, respectively. Domain 3 comprises
the instrumented Andean valleys of Zongo and Huarinilla
used for model validation (Fig. 1b). In order to analyze the
diurnal and nocturnal atmospheric conditions we use an out-
put time resolution of 3 h for domains 1 and 2, and 1 h for
the finest domain.

Lateral boundary conditions from ERA5 reanalysis
(Hersbach et al. 2020) are used. This reanalysis presents an
enhanced horizontal resolution of 0.28°×0.28° (31 km) with
data available every 6 h (https://www.ecmwf.int/en/forec
asts/datasets/reanalysis-datasets/era5). Significant improve-
mements in the representation of several model processes in
this reanalysis are reflected in a better fit in winds, tem-
perature and humidity in the troposphere compared against
radiosonde data (Hersbach et al. 2020).

Preliminary tests for different model configurations (not
shown) allow selecting the parameterizations shown in
Table 2. Summarizing, we use the Yonsei University scheme
for representation of the boundary layer (Hong et al. 2006)
with the wind topographic correction activated (Jiménez and Dudhia 2012). This wind correction takes into account the momentum sink term generated by the unresolved terrain at sub-grid scale in the model. It has shown improvements in the simulated wind field over complex terrains (Jiménez and Dudhia 2012) and has already been tested in the tropical Andes (Junquas et al. 2018). Lin’s microphysics scheme is implemented (Lin et al. 1983) for phase change and precipitation. We also use Grell 3D parametrization for sub-grid scale convection over domains 1 and 2 (Grell and Dévényi 2002). Previous studies demonstrate convection parametrizations as one of the major uncertainties in the representation

Table 1 Characteristics of the domains used in WRF simulations

|                         | WRF-D01 | WRF-D02 | WRF-D03 |
|-------------------------|---------|---------|---------|

| Forcing                 | ERA5    | WRF-D01 | WRF-D02 |
| Vertical resolution      | 49 hybrid vertical levels | 49 hybrid vertical levels | 49 hybrid vertical levels |
| Run time step (s)        | 90      | 30      | 6       |
| Output time resolution (h) | 3       | 3       | 1       |

Fig. 1 a WRF simulation domains (black boxes labelled D01, D02, and D03 respectively), deforested area and locations of selected flux towers from the Large-Scale Biosphere–Atmosphere Experiment in the Amazon. Domains 1, 2 and 3 encompass the areas 24°S–10°N/90–40°W, 20–8°S/80–60°W and 18–15°S/69–66°W respectively. Delineated area represents the boundary of the Amazon River basin (black). b D03 subregion (red square in a) and locations of rain-gauges stations over two Andean mountain valleys. Land-use category distributions for: c Control and d deforested scenarios
of rainfall diurnal cycle (Brockhaus et al. 2008; Hohenegger et al. 2008). Taking this into account and considering that a spatial resolution higher than 4 km is considered enough for non-hydrostatic models to explicitly solve convection (Weisman et al. 1997; Ramos da Silva and Avisar 2006), we deactivate the cumulus parameterization over the finest domain. Additionally, we change the default WRF topography from the United States Geological Survey (USGS) to the Shuttle Radar Topography Mission (SRTM) product (Farr et al. 2007). This dataset presents a more realistic representation of the altitude of meteorological stations over the Peruvian Andes when compared with USGS and enhances the representation of rainfall and temperature in the same region with the model WRF (Saavedra et al. 2020). The SRTM dataset has a spatial resolution of 30 arc-second or approximately 1 km.

In order to obtain a climatological state of the south-western Amazon wet season, our simulations cover 10 years of austral summers for the time period 2001–2011. Each simulation starts on November 1st and the first month is removed as a spin-up for the output analysis.

### 2.2 Description of the experiments

For each austral summer in the period 2001–2011, we conduct two simulations with WRF sharing the same atmospheric lateral boundary conditions, but with different land-cover states. The control simulation (“Control” or “Con”) corresponds to vegetation conditions for the year 2000 using the land cover map developed for South America by Eva et al. (2004) (Fig. 1c). This dataset was implemented in WRF by Saavedra et al. (2020) and exhibits a spatial resolution of 1 km × 1 km. For the deforested simulation (“Deforrested” or “Def”), we use the deforested scenario 2050 business-as-unusual from Soares-Filho et al. (2006; Fig. 1d). This scenario reaches 45% of forest lost and assumes the continuation of the 1997–2002 registered deforestation rates, no definition of new protected areas in the basin and the building of all planned highways (Soares-Filho et al. 2006). This scenario does not include the forest impoverishment through logging and fires. The implemented deforestation polygon is shown in Fig. 1a. Amazon deforestation involves the replacement of native forest by mixed crops (mainly soybean and corn), as well as pasture for cattle feeding. For this reason, within the deforested polygon natural vegetation (this includes all types of forest, shrublands, grasslands and savannas) grid points are replaced by cropland/grassland mosaics.

### 2.3 Data

In order to validate the model’s ability to represent the rainfall spatial distribution in the region, we use the product Tropical Rainfall Measuring Mission 3B42 (TRMM; https://disc.gsfc.nasa.gov). This dataset, available from 1998, presents a 0.25° × 0.25° resolution and includes precipitation rates every 3 h (Huffman et al. 2007). However, previous studies have identified a strong rainfall underestimation by TRMM in the Amazon-Andes region (Espinoza et al. 2015; Zubieta et al. 2015; Chavez and Takahashi 2017). For this reason, we complement the model validation with daily information of 10 rain-gauge stations (Fig. 1b) from the Bolivian Electric Power Company (COBEE) and managed in collaboration with the Institute of Research for the Development (IRD)—France. Additionally, three stations with hourly data were used from Schwabe et al. (2011). Table 3 presents the general information of each rain-gauge station according to official records of COBEE. We complement this information with location and altitude information of the stations from author’s field campaigns (Table S1). The quality assessment of these rainfall stations was carried out by previous works (Molina-Carpio et al. 2019 and Laura Ticona, personal communication). The use of in-situ information also allows characterizing the model skill to capture the precipitation variability at small spatial scale in an Andean valley where local processes are important (Egger et al. 2005; Trachte et al. 2010; Junquas et al. 2018). Additionally, the representation of the regional atmospheric circulation and moisture transport are validated by a direct comparison between WRF outputs and ERA5 and NCEP-NCAR (Kalnay et al. 1996) data.

To test whether WRF responds realistically to the changes induced by land-use alterations, we use observations of

### Table 2 Physical parameterizations used in WRF simulations

| Parameterizations | References |
|-------------------|------------|

| Surface layer MM5 similarity | Paulson (1970) |
energy surface fluxes, air temperature, precipitation and wind speed from the Large-Scale Biosphere–Atmosphere (LBA) project (Saleska et al. 2013). This dataset is available at the website https://daac.ornl.gov/LBA/guides/CD32_Brazil_Flux_Network.html. The LBA project was a large scientific effort carried out between 1996 and 2006 for assessing the influence of tropical forest conversion in carbon storage, nutrient dynamics and trace gas fluxes in the Amazon. Since the region of interest of this study is the Amazon-Andes transition region, we only use the closest stations from the LBA project that fits inside our second modelling domain (Fig. 1a). Because of their geographical location, these stations experience annual cycles of precipitation and temperature similar to the south-western Amazon variability. The first station, Fazenda Nossa Senhora de Aparecida (yellow triangle labeled as “FNS” in Fig. 1a), is a cattle ranch located at the center of a deforested area of about 50 km in radius cleared in 1977 for crop cultivation. The tower flux stands at 306 m a.s.l., 10.75° S, 62.35° W and presents daily data for the period 1999–2002. The second station corresponds to Rondonia Jaru Biological Reserve and is located at 191 m a.s.l., 10.08° S, 61.93° W (green triangle labeled as “RJB” in Fig. 1a). This is a natural reserve of the Brazilian Environmental Protection Agency covered by tropical dry forest with a mean tree height of 33 m that was established in the 1960s and expanded in 2006. The proximity of these stations (around 87 km) allows testing the impacts of land use change on surface fluxes and the atmospheric bottom conditions. For validation we only use data for DJF 2001–2002 when WRF simulations and LBA data availability periods overlap in time.

2.4 Calculation of energy/water balances and atmospheric stability

The energy budget at the surface is described by Duveiller et al. (2018):

\[ N_R = (S_{in} - S_{out}) + (L_{in} - L_{out}) = Sens_H + Lat_H + Gr_H \]  \hspace{1cm} (1)

Here, \( N_R \) corresponds to net radiation and is the summation of contributions from shortwave and longwave components: \( S_{in} \) is the incident shortwave or solar radiation, \( S_{out} \) is the reflected solar radiation, \( L_{in} \) is the incoming longwave component and \( L_{out} \) is the emitted longwave radiation flux. The net turbulent heat flux is later distributed in sensible heat flux (\( Sens_H \)), latent heat flux associated with evaporation from the surface (\( Lat_H \)) and molecular conduction flux from the ground (\( Gr_H \)). All the terms in Eq. (1) are in W/ m². Land use change disturbances in the energy budget are assessed by computing the differences in DJF climatological means for each term of Eq. (1) between Deforested and Control scenarios.

The atmospheric water budget establishes how precipitation, evapotranspiration and net moisture transport entering/leaving an atmospheric column controls the temporal changes in the vertically integrated water content (Peixoto and Oort 1992). At seasonal timescales the temporal changes in atmospheric moisture are negligible and precipitation,
evapotranspiration and column moisture convergence nearly balances each other (Brubaker et al. 1993; Li et al. 2013). Hence, the climatological changes induced by deforestation in the water balance can be expressed as follows:

\[
\Delta P_{\text{Def} - \text{Con}} = \Delta E_{\text{Def} - \text{Con}} - \frac{1}{g} \nabla \cdot \int_{1000 \ hPa}^{200 \ hPa} q V_H dp
\]

(2)

In Eq. (2), \(P\) is precipitation, \(E\) is evapotranspiration and \(\nabla \cdot \int_{1000 \ hPa}^{200 \ hPa} q V_H dp\) is the divergence field of vertically integrated moisture flux from 1000 to 200 hPa. The bars denote climatological DJF means.

Finally, we evaluate the deforestation impacts on the atmospheric stability in tropical South America. Over the Amazon, the moistening of mid-tropospheric levels is associated with the development of deep convection in the region, which is related to the decreasing of atmospheric stability between middle and upper levels of the troposphere (Scala et al. 1990; Zhuang et al. 2017). For this reason, recent works use the difference of equivalent potential temperature (\(\theta_e\)) between middle (500 hPa) and upper (200 hPa) troposphere (\(\theta_{e500-200}\)) as an atmospheric stability index (Segura et al. 2020). The equation of equivalent potential temperature can be written following Stull and Ahrens (2011):

\[
\theta_e = \theta + \left( \frac{L_v \theta}{C_p T} \right) r
\]

(3)

where, \(\theta\) corresponds to potential temperature, \(L_v\) is the latent heat of vaporization, \(C_p\) is the specific heat for air at constant pressure, \(T\) corresponds to the air absolute temperature and \(r\) is the air mixing ratio. The first term of this equation is related to dry adiabatic processes while the second one includes the effect of moisture in the net energy of an air parcel. Thus, the changes in the difference between mid and upper tropospheric equivalent potential temperature (\(\theta_{e500-200}\)) allows separating the individual effects of dry and wet processes in the regional atmospheric stability. Again, climatological mean differences in each term of Eq. (3) between Deforested and Control scenarios allow evaluating the impact of deforestation in the regional atmospheric stability.

3 Model validation

3.1 Regional scale

The development of the SAMS establishes a northerly cross-equatorial flow (Wang and Fu 2002) and enhances convection over central Amazon (Vera et al. 2006; Fig. 2a, c). A cloudiness/rainfall band known as the South Atlantic Convergence Zone (SACZ) extends from southern Amazon towards south-eastern Brazil and accompanies the mature phase of the SAMS (Kodama 1992; Figueroa et al. 1995; Zhou and Lau 1998; Fig. 2a). The diabatic heating released by the convective activity generates a large anticyclonic circulation at the upper troposphere centered around 15°S–65°W known as the Bolivian High (Lenters and Cook 1997; Fig. 2e). Latent heat release over central Amazon also promotes a low-level continental-scale gyre that transports water vapor from the Atlantic Ocean inland towards Amazon and La Plata basins (Rodwell and Hoskins 2001; Vera et al. 2006; Fig. 2c). Over the eastern flank of the Andes, this circulation reaches its maximum wind velocities forming the South American Low-Level Jet (SALLJ). Over its trajectory, the transport of moisture through the SALLJ encounters the topographical barrier of the Andes triggering forced convection in very localized places or rainy hotspots mainly in the Bolivian and Peruvian piedmonts (Espinoza Villar et al. 2009; Espinoza et al. 2015; Chavez and Takahashi 2017; Fig. 2a).

In general terms, the model is able to reproduce the main precipitation features during the austral summer (Fig. 2b). WRF-D01 represents the strong precipitation over central Amazon but with its maximum shifted eastward. The characteristic northwest-southeast rainfall band of the SACZ is present in WRF simulation. However, the model shows a considerable negative bias over the northern Peruvian lowlands (until −50% of dry bias when compared to TRMM; red contours in Fig. 2b). Rainfall Peruvian and Bolivian hotspots are also part of the model climatology. Nevertheless, WRF underestimates the former and overestimates the latter. The Atlantic ITCZ is strongly overestimated by WRF (up to +200% with respect to TRMM; red contours in Fig. 2b). This wet bias is related to a too strong vertically integrated moisture convergence in the model output (Fig. 2d). Finally, upper and lower atmospheric circulations are realistically represented by WRF (Fig. 2d, f). As in ERA5 outputs, WRF easterly low-level winds carry moisture from the Atlantic Ocean toward the continent (Fig. 2d). The moisture flow moves parallel to the Andes cordillera mechanically deviated exporting humidity toward southern latitudes both for ERA5 and WRF. At the altitude of 200 hPa, the model develops the anticyclonic circulation of the Bolivian High (Fig. 2f). Similar features of vertically integrated moisture flux and upper level atmospheric circulation are found in NCEP-NCAR reanalysis (see Supplementary material, Fig. S1).

3.2 Local scale

In order to validate if WRF reproduces the observed land use change impacts on surface fluxes and atmospheric variables at a local scale, we compare the selected LBA stations (Sect. 2.3) against the WRF-D02 Control simulation for
Fig. 2 DJF climatological means over the period 2001–2011 for: a and b precipitation from TRMM-3B42 (a) and WRF-Control (b) in mm/day. Red lines in b represent rainfall differences with respect to TRMM in percentage. c and d vertically integrated moisture flux (vectors, kg/m²s) and its divergence (shaded, kg/m²s) from ERA5 (c) and WRF-Control (d). e and f horizontal winds (vectors, m/s) and geopotential height (shaded, m) at 200 hPa from ERA5 (e) and WRF-Control (f). Orography elevation is shown at 500 and 3500 m a.s.l. as black and grey contours, respectively.
Deforestation impacts on Amazon-Andes hydroclimatic connectivity

DJF 2001–2002. We take the paired pasture/rainforest sites from the LBA project and compute the observed changes in surface variables in percentage respect to the forest values. Then, similarly, we take the coordinates of the LBA pasture and rainforest stations and extract information of atmospheric variables from model outputs in order to compute the percentage changes. For WRF outputs, we average variables of interest around each location inside a surrounding area of 15 km × 15 km (one grid-point-radius) but selecting only the grids corresponding to cropland/grassland or forest respectively and ignoring grid cells with a different land use category. Between a 15 km radius and a 50 km radius, no significant changes are found in the WRF deforestation response (not shown).

Figure 3 shows the simulated and observed (orange and blue bars, respectively) mean differences of surface variables due to deforestation. Significant differences are highlighted in red contour according to a t-test (p < 0.05). In general terms, WRF is able to properly represent the nature of most of the alterations in surface fluxes and atmospheric variables induced by the land use change. Land cover change is related to reduced precipitation by around −44% and −30% in observations and WRF, respectively. However, since precipitation is also related with non-local processes, it is difficult to establish a deforestation-rainfall causality relation. Consistently, significant reductions in surface specific humidity are observed but weakly simulated (around −11% and −1% in observations and WRF, respectively).

Accordingly, there is a significant decrease in latent heat flux for observations (−37%) with a weaker response by WRF (−14%). This implies that WRF underestimates the evapotranspiration response induced by deforestation. There is a significant increase in sensible heat flux and surface air temperature in LBA stations (68% and 1%, respectively). WRF strongly underestimates the sensible heat increase and even slightly invert the temperature response to land use change (1.49% and −0.02% respectively). The effects of the increased sensible heat and temperature (only sensible heat in WRF) act to give an increase in the outgoing longwave radiation flux in LBA stations of 1.6% (0.7% in WRF). Since pastures and croplands are brighter than forest (Oguntoyinbo 1970; Bonan 2008), an increase in the albedo raises the outgoing or reflected shortwave radiation by 86% for observations (Loarie et al. 2011). The albedo effect is overestimated by WRF, which presents an outgoing shortwave radiation pasture/forest difference of 104%. This overestimated energy loss can be related with the model underestimation of sensible heat flux increase. More incoming shortwave radiation reaches the surface in model and observations (4% and 7% respectively). This difference in WRF simulation is a consequence of cloud reduction over deforested areas (not shown). There is a disagreement between the modelled and observed changes in the incoming longwave radiation. While WRF exhibits a decrease in this variable (−1.64%), observations report an increase of about 1.38%. This difference is possibly explained by biases in the model representation of clouds or because of the drier WRF mid-upper troposphere (not shown). At the end, driven by the incremented energy losses through longwave radiation fluxes and shortwave radiation reflection, there is a reduction in net radiation (−15%) and LBA stations (−8%). Finally, the enhanced surface wind speed at 2 m is a direct consequence of the deforestation induced roughness-length reduction in both model (53%) and observations (95%).

4 Results and discussion

This section is composed of two subsections, in the first part we evaluate the effects of deforestation in the energy and water balances, as well as the atmospheric stability at regional-scale (90°–60° W, 24° S–9° N). The second subsection is focused on the alterations in the hydro-climatology at meso and local scales, especially over the Amazon-Andes transition region and Andean valleys of Bolivia.

4.1 Regional changes in energy and water balances

Climatological alterations in the surface energy balance (Eq. 1) induced by deforestation are shown in Fig. 4, in which significant differences are highlighted with black
Fig. 4 DIF seasonal climatological differences Defor-ested minus Control during 2001–2011 in surface energy balance variables: a Short-wave incoming radiation ($\Delta S_{in\text{Def} - \text{Con}}$). b Short-wave outgoing radiation ($\Delta S_{out\text{Def} - \text{Con}}$). c Longwave incoming radiation ($\Delta L_{in\text{Def} - \text{Con}}$). d Longwave outgoing radiation ($\Delta L_{out\text{Def} - \text{Con}}$). e Sensible heat flux ($\Delta S_{\text{SensH Def} - \text{Con}}$). f Latent heat flux ($\Delta S_{\text{LatH Def} - \text{Con}}$). g Net radiation ($\Delta NR_{\text{Def} - \text{Con}}$). All figures are in W/m². Significant changes (t-test, p < 0.05) are marked with black slashes. Orography elevation is shown at 500 and 3500 m a.s.l. as black and grey contours, respectively.
Deforestation impacts on Amazon-Andes hydroclimatic connectivity

slashes. The last term in Eq. 1 corresponding to soil heat flux is omitted because it exhibits much smaller magnitudes with respect to the other terms (± 1 W/m²). Indeed, in situ measurements report low soil heat fluxes below tropical forest (Shuttleworth et al. 1984), but important values for crops (Oliver et al. 1987; Gash and Shuttleworth 1991).

Important changes in the incoming solar radiation are induced by the forest loss in the region (Fig. 4a). In general, more (less) incident solar radiation reaches the ground over places where reduction (rise) in precipitation and moisture convergence are located (see Fig. 5) such as in the central and south-western Amazon (north of South America and eastern Brazil). Hence, disturbances in incident solar radiation are closely linked with changes in clouds in WRF simulations as confirmed by analyzing top of the atmosphere (TOA) outgoing longwave flux and cloud water content (not shown). However, major changes in the energy balance occur in the outgoing shortwave radiation (Fig. 4b). A significant increase in about + 20 W/m² occurs only over deforested areas which reflects the very local response induced by the higher cropland/grassland albedo. With a minor response, reductions in the longwave incoming radiation occur over most of the Amazonian watershed (Fig. 4c) as a result of a drier atmosphere and lower cloud cover in the deforested scenario (not shown). On the other hand, there is a meridional dipole in longwave outgoing radiation changes (Fig. 4d). Important disturbances in this variable take place mainly over deforested areas which implies the influence of very local processes. North of the Amazon river (< 5°S) at the East of the basin, upward longwave radiation increases as a consequence of an increase in surface emissivity over this area (not shown). However, in the southern part of the basin, less outgoing longwave radiation is related to reductions in the air surface temperature. Sensible heat disturbances are linked to surface air temperature changes (not shown). Thereby, reductions (increments) in this turbulent flux are located over deforested areas (Fig. 4e) and are related to decreasing (increasing) surface temperature (not shown).

Fig. 5 DJF seasonal climatological differences Deforested minus Control during 2001–2011 in water balance variables: a Rainfall ($\Delta P_{\text{Def}} - \Delta P_{\text{Con}}$), b Evapotranspiration ($\Delta E_{\text{Def}} - \Delta E_{\text{Con}}$), c Vertically integrated moisture flux (vectors) and moisture flux convergence ($\Delta \dot{\nabla} \cdot \int_{200hPa}^{1000hPa} qV_H dp_{\text{Def}} - \Delta \dot{\nabla} \cdot \int_{200hPa}^{1000hPa} qV_H dp_{\text{Con}}$; shaded). d Vertical velocity at 500 hPa in m/s. e Meridional moisture (shaded, in g/kg) and moisture flux (vectors in g/kg·m/s) zonally averaged over the shaded region displayed at the upper right side. Only significant vectors are shown. Figure a–c are in mm/day. Significant changes (t-test, p < 0.05) are marked with black slashes. Orography elevation is shown in a–d at 500 and 3500 m a.s.l. as black and grey contours, respectively. The blue line in e represents the Andes’ profile calculated as the maximum topographic elevation inside the area displayed in red at the upper right side.
shown). Similarly, latent heat flux decreases over regions with evapotranspiration reductions (Figs. 4f, 5b). In the end, the enhanced energy loss through reflected shortwave radiation as well as the reduced incoming longwave radiation flux decrease the surface net radiation over the deforested and surrounding areas (Fig. 4g). This reduction in net radiation is very important for driving alterations in the regional moisture convergence as pointed out by Zeng and Neeling (1999). It is important to remark that the overestimation of the albedo effect and the weaker model responses in sensible heat and longwave outgoing radiation fluxes, as well as roughness length and surface wind velocity (see Sect. 3.2) constrain our conclusions in the following sections.

Figure 5 shows simulated changes in the water balance following Eq. (2). Significant reductions in the seasonal rainfall are found over central and south-western Amazon closely matching the deforestation area (Fig. 5a). To some extent, these precipitation changes are related to the local impact of the decreased evapotranspiration, especially over the center of Brazilian Amazon (Fig. 5b). Nevertheless, for analyzing the effect that evapotranspiration changes induced by deforestation have on rainfall, a quantification of precipitation recycling ratio should be assessed (e.g. Eiras-Barca et al. 2020). On the other hand, the drier conditions over Bolivian Amazon are closely linked with changes in the regional atmospheric circulation, where increased moisture divergence is a response to deforestation (Fig. 5c). Here, the observed northwest-southwest (Fig. 2d) integrated moisture flux at the east of the Andes weakened in the deforested scenario (Fig. 5c). It is interesting to note that near the surface (10 m), an opposite change in the moisture flux enhances the water vapor transport toward the southern and eastern parts of the continent (not shown). This result suggests that in the western Amazon the changes in the vertically integrated moisture transport are not dominated by the surface conditions; instead, alterations in the integrated humidity transport are related to regional circulation changes such as the decrease in moisture convergence and vertical velocity over most of the Amazon (Fig. 5c, d), the rise in the atmospheric pressure at lower levels (not shown), and a weakening of the regional Hadley cell (Fig. 5e). These changes are in agreement with the theoretical frameworks laid out by Gill (1980) and Eltahir (1996), and with modelling studies (Zhang et al. 1996; Sun and Barros 2015a; Badger and Dirmeyer 2016). Opposite to the forcing in Gill (1980), Amazon deforestation induces a lack of diabatic heating as a result of a drier atmosphere and less convection in the region (Eltahir 1996; Badger and Dirmeyer 2016). This feature is observed in Fig. 5e as a drier troposphere below 650 hPa over 10–18°S and as an enhanced subsidence over the same latitudinal band. These changes are also associated with slightly stronger westerlies at the upper troposphere and a small weakening of the Bolivian High (not shown). Similar changes in the regional circulation and in the regional Hadley cell have been reported by previous modelling and theoretical studies (Zhang et al. 1996; Eltahir 1996; Zeng and Neelin 1999; Badger and Dirmeyer 2016). In the linear model developed by Eltahir (1996), the tropical subsidence is a consequence of a reduction in the boundary layer entropy that follows large-scale deforestation. On the other hand, according to Zeng and Neelin (1999) and in agreement with Fig. 4, reductions in rainfall and moisture convergence over the Amazon basin induced by tropical deforestation can be partially initiated by the enhanced energy loss due to the albedo effect.

On the other hand, Fig. 6 shows the differences between Deforested and Control scenarios for the DJF climatology of the atmospheric stability index, as well as its adiabatic dry and diabatic moist process components following Eq. (3).
An increment in the equivalent potential temperature and the other terms of the equation (red colors in Fig. 6) indicates an increase in the atmospheric stability and an inhibition tendency of the convective activity. Conversely, a decrease in each term of Eq. (3) (blue colors in Fig. 6) implies a reduction trend in atmospheric stability favoring convection development. A first evident result is that dry adiabatic processes exhibit the tendency to reduce the atmospheric stability over the whole region (Fig. 6b). Although with deforestation the troposphere cools at all levels (not shown), the upper levels exhibit a stronger cooling than middle levels, generating the decrease in potential temperature shown in Fig. 6b. This effect is more pronounced over the center of the Brazilian Amazon, near the deforested area. On the contrary, changes in wet processes and latent heat release lead to an increase in the atmospheric stability over the central and western Amazon, including the southern Andes and its eastern foothills (Fig. 6c). It is interesting to highlight that these areas have been recognized to be very sensitive to evapotranspiration upstream of the Amazon basin (Zemp et al. 2017b; Staal et al. 2018). Over the northern and eastern parts of the continent, a decrease in atmospheric stability is related to the enhancement in precipitation and moisture convergence (Fig. 5). Since WRF exhibits an underestimated response in evapotranspiration and latent heat flux to deforestation (Sect. 3.2), the effects in atmospheric stability due to moist diabatic processes could be stronger. Similarly, earlier studies suggested two competing mechanisms as a response of tropical deforestation: (i) a dry atmosphere response linked to warmer surface that increases convergence; (ii) an enhanced divergence led by reductions in rainfall and latent heat release (Gill 1980; Lindzen and Nigam 1987; Eltahir and Bras 1993; Eltahir 1996). In summary, our results suggest that the combination of both dry adiabatic and moist (latent heat release) processes produces more stable atmospheric conditions and inhibits precipitation over the western part of the Amazonian basin and the eastern flank of the tropical Andes below the Equator (Fig. 6a). Colombia, Venezuela, Guyana and eastern Brazilian Amazon experience a net reduction in stability and more favorable conditions for convection in the deforested scenario. These alterations are more regional and not limited to deforested areas. Although changes in atmospheric stability are not statistically significant, the 10-year-period analyzed in this work might not be enough for identifying significant differences.

4.2 Mesoscale and local changes in daily scale precipitation

The previous section displays how deforestation reduces precipitation and moisture transport, as well as increases the atmospheric stability and inhibits convective activity over the western Amazon and the eastern Andes flank. We analyze the deforestation effect at meso and local scales for daytime and nighttime conditions over the Amazon-Andes transition region, with a particular focus on the Andean valleys of Huarinilla and Zongo in Bolivia (see Fig. 1 for precise location).

Daytime and nighttime rainfall patterns are shown in Fig. 7 for observations and WRF-D02. During the day, TRMM exhibits high precipitation values over the western part of the Altiplano and Andes highlands (Fig. 7a). Most tropical mountains display this daytime precipitation maximum over summits partially as a result of the thermally driven upslope winds (Garreaud and Wallace 1997; Garreaud 1999; Kikuchi and Wang 2008; Zardi and Whiteman 2013). There are also significant precipitation rates East of the Andes and over Amazonian lowlands during the day as afternoon convection develops (Machado 2002; Romatschke and Houze 2010; Chavez and Takahashi 2017; Fig. 7a). During the night, observed rainfall peaks are located over the eastern Andean piedmonts associated with the so-called rainfall hotspots (Killeen et al. 2007; Halladay et al. 2012; Espinoza et al. 2015; Fig. 7b). This nocturnal convective activity is driven by the convergence of downslope winds from the top of the Andes with the SALLJ nocturnal enhancement (Killeen et al. 2007; Romatschke and Houze 2010; Chavez and Takahashi 2017; Junquas et al. 2018).

In general, WRF-D02 is able to represent the main features of diurnal and nocturnal rainfall variability in the region when compared to TRMM. Rainfall peaks above the 3500 m a.s.l. and over the central Peruvian Altiplano are simulated during the day by WRF as shown in Fig. 7c. Daytime convection over Amazon lowlands below 500 m is also present in WRF outputs in agreement with TRMM. However, the model strongly overestimates daytime precipitation over the Bolivian Amazon plains and over the eastern Andes slopes. Nevertheless, dry biases have been identified by several studies in TRMM outputs over tropical Andes, which makes it difficult to properly quantify the model biases (Condom et al. 2011; Scheel et al. 2011; Rasmussen et al. 2013; Espinoza et al. 2015). During nighttime, WRF Realistically represents the rainfall hotspots but exhibits a positive (negative) bias over the Peruvian Andes highlands (Brazilian Amazon lowlands) (Fig. 7d).

Deforestation causes a general rainfall reduction in daytime and nighttime conditions but with different spatial distributions (Fig. 7e, f). During the day, significant precipitation reductions occur over the Amazon plains following the deforested area (between 10 and 20%), but no significant changes occur over the tropical Andes above 3500 m a.s.l. On the eastern Andean slope between 500 and 3500 m a.s.l., significant changes are found, like in the central Andean-Amazon valleys of Peru near the 10° S and 75° W (Fig. 7e). On the other hand, nighttime convection decrease (between 20 and 30%) is concentrated over the eastern flank of the Andes and particularly over the Bolivian piedmont (Fig. 7f).
Fig. 7 DJF climatological means (2001–2011) for daytime and nighttime precipitation from: a, b TRMM-3B42. c, d WRF-D02. e, f WRF-D02 Deforested minus Control differences. All figures are in mm/day. Significant changes (t-test, p < 0.05) are marked with black slashes. Orography elevation is shown at 500 and 3500 m a.s.l. as black and grey contours, respectively.
Taking into account that nighttime convection is responsible for nearly the 70–80% of the daily precipitation on the eastern tropical Andes slopes during austral summer (Perry et al. 2014; Chavez and Takahashi 2017), this nocturnal rainfall reduction can have a profound impact in the hydrology of the region. Since nocturnal precipitation over the eastern Andes slopes (including over rainfall hotspots) is closely related to the presence of the SALLJ, in Fig. 8 we evaluate the changes induced by deforestation in the vertically integrated moisture flux over the Bolivian piedmont inside our third modelling domain (Fig. 1). A northwesterly moisture transport is present in both daytime and nighttime conditions during DJF in the Control scenario associated with the SALLJ activity (Fig. 8; e.g. Marengo et al. 2004). This moisture transport is more parallel to the Andes during the day and is stronger and more perpendicular to the slopes during the night in agreement with previous works (Vernekar et al. 2003; Marengo 2004; Junquas et al. 2018; Fig. 8a, b). The humidity flux transported from Amazon toward the Andes is channelized both during day and night over the steepest valleys as modelling and observational works reported in the region (Zängl and Egger 2005; Perry et al. 2014; Junquas et al. 2018; Fig. 8a, b). The Andes act as a blocking barrier to this moisture laden winds coming from the Amazon lowlands, triggering forced convection mainly during nighttime when the trajectory is more perpendicular to the topography. This mechanism was hypothesized by Espinoza et al. (2015) based on in-situ stations and supported by modelling studies (Junquas et al. 2018).

In the Deforestation scenario, the daytime upslope moisture flux is enhanced over the major valleys (Fig. 8c). However, inside of our region of interest covering Zongo and Huarinilla valleys (black square in Fig. 8) this flux exhibits little changes during the day. Conversely, during the night there is a strong reduction in the humidity transport from the Amazon lowlands towards the Andes highlands over the entire region (Fig. 8d) in agreement with nocturnal rainfall reductions over eastern Andes slopes and Bolivian hotspots shown in Fig. 7f.

During nighttime, we hypothesize that the precipitation and moisture flux depletion in the region is caused by the following process: (i) the atmosphere dries up in the Deforestation scenario over the whole Amazon basin and the northerly moisture flux weakens (Fig. 5); (ii) precipitation decreases over the western Amazon causing less latent heat released to the atmosphere over the region; (iii) there is a
reduction in the local upslope moisture flux over the eastern flank of the Bolivian Andes. By suppressing the condensation latent heating due to rainfall in the Peruvian and Bolivian Andean slopes in a modelling experiment, Junquas et al. (2018) found a positive feedback with the reduction in the entrance of the upslope moisture flux coming from Amazon plains. Since latent heating is more important for sustaining circulation during the night (e.g. Souza et al. 2000), major impacts of such processes happen on nocturnal rainfall. Similarly, by preventing the energy influx into the atmosphere from latent heat fluxes over the eastern flank of the Andes in high resolution climate simulations, Sun and Barros (2015a, b) found a strong reduction in the energy available for moist convection, a decrease in rainfall, moisture convergence and cloudiness in the region, and a weakened upslope flow as a consequence of increased static stability. Our results points towards the same direction: the crucial role of moist processes for sustaining the atmospheric circulation and hydrological condition over the Amazon-Andes transition region.

In order to evaluate the potential impacts of Amazon forest loss on the hydro-climatology at local scales, our analysis is centered in two instrumented valleys located at the eastern flank of the Bolivian Andes: Huarinilla and Zongo valleys (Fig. 9a). The spatial distribution of rain-gauges within the two valleys allows analyzing how precipitation varies with orography and altitude in two opposite directions with respect to the Andean Cordillera. Stations inside the Zongo Valley are located from north-east to south-west in a perpendicular direction to the Andes (Fig. 9a). Conversely, stations located in the Huarinilla Valley are disposed parallel to the mountain chain. Following the rain stations from highlands to lowlands, two cross-sections were defined as shown in black solid lines of Fig. 9a. A third cross-section is analyzed in a perpendicular direction of the Zongo valley (northwest-southeast direction) in order to complement the understanding of local circulation alterations (black dashed line in Fig. 9a). The climatological relationship between precipitation and elevation is shown in Fig. 9b, c. There is an opposite relation between rainfall and terrain elevation in the two transects. For the Zongo Valley cross-section, precipitation generally decreases with elevation, reaching minimum values above 3000 m a.s.l. and rainfall peaks near the 1000 m a.s.l. (Fig. 9b). This rainfall behavior was previously reported by Espinoza et al. (2015). Chavez and Takahashi (2017) demonstrated how the rainfall change with elevation along cross-sections transversal to the Andes in the region follows the profile of the horizontal moisture flux carried by the SALLJ. In this sense, the rainfall-elevation relation in the first transect seems to be more related with synoptic processes such as the SALLJ and less with local upslope processes in accordance with previous studies (Romatschke and Houze 2010). An opposite behavior is observed in the Huarinilla Valley, where maximum rainfalls are located at high elevations around 3000 m a.s.l. (Fig. 9c). Here, daytime thermally-driven anabatic winds are responsible for transporting moisture transpired inside the valley in the upslope direction and generates a rainfall peak in the afternoon (Molina-Carpio et al. 2019).

WRF exhibits a realistic representation of the rainfall-elevation relationship for both cross-sections. The model reproduces the observed rainfall increases over very local orographic elevations such as the rain-gauges of Tiquimani, Santa Rosa and Sainani. However, a rainfall underestimation (around −30%) occurs in all the stations inside the Zongo Valley and is higher below the 3000 m a.s.l. The model also presents problems in the representation of the steep precipitation decrease that occurs between Cuticucho and Tiquimani and instead exhibits an almost linear rainfall reduction from Huaji to Plataforma. However, this issues in the local variation of precipitation in the Zongo Valley could be related with problems in the representation of local topography. By comparing Table 3 values with Fig. 9, it is easy to identify that for the Zongo Valley, WRF overestimates the real altitude of the stations (from 20 m at Plataforma to 476 m at Sainani). Major differences occur on stations located in places with very high slopes (such as Sainani or Botijlaca). Although our simulations use an enhanced digital elevation model instead of the default dataset in WRF, the complex and steep topography in the region is still poorly represented. This misrepresentation in the local topography can cause issues in the representation of moisture transport, surface circulation and can also affect rainfall and surface air temperature (e.g. Saavedra et al. 2020). On the other hand, taking into account that precipitation is very related to the SALLJ moisture transport in this valley, WRF rainfall underestimation could be related to the weaker SALLJ moisture flux present in the model simulation (not shown). Daytime and nighttime rainfall conditions for both transects are shown in Fig. 9d–g according to WRF outputs. In Zongo Valley, diurnal precipitation is much less than nocturnal values confirming that the dominant mechanism in this valley is the regional moisture transport of the SALLJ (Fig. 9d–f). At
this time, precipitation falls mainly over highlands for both transects as shown in Figs. 9d, e. At the bottom of the Zongo Valley there is a secondary rainfall peak as a consequence of convective activity related with the solar heating over Amazonian plains (Romatsche and Houze 2013). However, in terms of percentage of the summer climatological mean at each station, daytime lowlands rainfall is lower than in the highland. Nighttime rainfall is concentrated mainly at lowlands in agreement with the mechanism described before (Fig. 9f). It is interesting to note that for the Huarinilla Valley, similar precipitation magnitudes are simulated for daytime and nighttime conditions (Fig. 9f, g). This suggests that local and synoptic mechanisms are equally important in this valley as reported from previous works (Molina-Carpio et al. 2019).

Amazon deforestation induces significant reductions in the climatological rainfall mean over both Zongo and Huarinilla cross-sections but increases its interannual variability only in Huarinilla Valley (Fig. 9b, c). Major precipitation drop is located over areas below 2000 m a.s.l. in the Zongo Valley (Fig. 9b). For this cross-section, daytime precipitation presents little changes in its mean value (Fig. 9d). Conversely, during the night precipitation decreases, especially at lowlands, and no change in the variability occurs (Fig. 9f). This result confirms our hypothesis that rainfall depletion in this valley is mainly related with the decreased entry of SALLJ moist winds from Amazon towards the Andes highlands. On the other hand, the Huarinilla Valley cross-section does not present significant changes in daytime rainfall but increases its interannual variability (Fig. 9e). However, decreased rainfall take place during nighttime especially over highlands in agreement with the regional alterations in the SALLJ related moisture flux (Fig. 9g).

Aiming to complement the previous analysis, Fig. 10 displays the atmospheric humidity and moisture flux in the vertical cross-section along parallel (black solid line in Fig. 9a) and perpendicular (black dashed line in Fig. 9a) directions of the Zongo Valley. Similar results are found for the Huarinilla Valley (not shown). During daytime, upslope moisture flux (Fig. 10a) causes the rainfall peaks over summits described in Fig. 9d. Similar anabolic winds are present in the perpendicular direction of the Zongo Valley (Fig. 10c). During nighttime, surface moisture flux weakens, and light katabatic winds develop in the Zongo Valley (Fig. 10b–d). At the same time, the mid-tropospheric moisture coming from the Amazon plains is strengthened mainly in the perpendicular direction of the Zongo Valley (Fig. 8a, b, 10b–d). Another interesting feature of the nocturnal circulation in the perpendicular direction is the development of a moisture flux around 700 hPa in the opposite direction (northwest-south east) of the main mid-tropospheric flow (Fig. 10d). This returning flow seems to be a consequence of the ascending motion over lowlands summits to satisfy continuity.

Deforestation induces a weakening of the daytime upslope flow over both directions of the Zongo Valley (Fig. 10e–g). A reduction in the intensity of the daytime circulation increases the atmospheric moisture near the surface at the bottom of the valley (Fig. 10e, g). Based on the thermodynamics of heat engines, Souza et al. (2000) explain the physical mechanism behind the observed circulation over areas with different surface conditions in sloping terrains. According to this work, the intensity of the circulation depends on the absorption of sensible and latent heat by a parcel that moves along a closed streamline. They also recognize the hydrostatic pressure and non-adiabatic expansion/compression as important effects. Following this argument, we assess the surface energy balance along the Zongo Valley for the Control and Deforestation scenarios. We focus on daytime conditions, when local surface heterogeneities play an important role (Fig. 11). However, nighttime changes were also analyzed and are not significant (not shown). Small changes in the incoming shortwave radiation are induced by deforestation in the Zongo Valley and are linked with differences in clouds (Fig. 11a). On the contrary, a strong increment in the reflected shortwave radiation causes a loss of around −50 W/m² at the bottom of the valley where deforestation occurs (Fig. 11b). The longwave components of the energy balance remain almost unaltered (Fig. 11c, d). Due to the increase in the outgoing shortwave energy loss, the surface net radiation decreases at lowlands below Harca rain-gauge (Fig. 11e). This net radiation reduction generates a decrease in the altitude of the planetary boundary layer (PBL) (Fig. 11f) and is distributed in reductions in latent heat but mainly in sensible heat flux over lowlands (Fig. 11g, h). These fluxes are essential in the triggering and development of upslope flows (e.g., Junquas et al. 2018). The reductions in the sensible and latent heat fluxes explain the weakening of the upslope surface circulation during daytime described in Fig. 10. However, these results have to be taken with caution taking into account that WRF strongly underestimates (overestimates) the impact of forest loss on the sensible heat flux (reflected incoming radiation) (Sect. 3.2).

On the other hand, nighttime differences in circulation mainly occur at regional scale through mid-tropospheric moisture flux reduction in the deforested scenario (Figs. 8d, 10f–h). This moisture transport is very important for developing the nocturnal convection and its decrease causes less rainfall over the entire region (Fig. 9f, g). The nighttime conditions are also characterized by a strong reduction in atmospheric humidity above the 600 hPa as a consequence of deforestation (Fig. 10f, h).

Rainfall reductions and increased rainfall variability over Huarinilla and Zongo valleys can impact the wet ecosystems of local humid-montane forest and its endemic biological species (Ibisch et al. 2001; Mueller et al. 2002;
Fig. 10 Vertical cross-section for daytime and nighttime DJF climatological means (2001–2011) in atmospheric moisture (shaded, g/kg) and moisture flux (vectors, g/kg*m/s) for the Zongo Valley in two opposite directions: parallel to the transect (see black solid line in Fig. 9a) and perpendicular to the transect (see black dashed line in Fig. 9a). Daytime (a) and nighttime (b) WRF-Control conditions for the transect parallel to the Zongo Valley. Daytime (e) and nighttime (d) WRF-Control conditions for the transect perpendicular to the Zongo Valley. Daytime (c) and nighttime (f) Deforested minus Control differences in the transect parallel to the Zongo Valley. Daytime (g) and nighttime (h) Deforested minus Control differences in the transect perpendicular to the Zongo Valley. Red dots represent rain-gauge stations. Vertical component of the moisture flux is exaggerated by a factor of ten.
Kessler and Kluge 2008). Additionally, the area encompasses part of the Cordillera Real-Bolivia and the Huayna Potosí Massif where several glaciers (e.g. Zongo Glacier) are located (Francou et al. 1995). The glacier surface mass balance variability of the tropical glaciers is strongly controlled by the precipitation amount and temporal distribution that determine the glacier surface albedo and therefore the surface energy balance (e.g. Sicart et al. 2005; Rabatel et al. 2013), as well as regional atmospheric circulation (Favier et al. 2004; Sicart et al. 2016). Our results state that Amazonian large-scale deforestation can have an important effect in the regional circulation and precipitation. This means that retreat of the tropical Andes glacier documented since the early 1980s and linked to climate change (e.g. Ramírez et al. 2001; Francou et al. 2003; Rabatel et al. 2013) is likely to be further increased as extensive Amazonian deforestation can also have an impact on precipitation and therefore on the surface mass balance of tropical glaciers.

It is important to remark that widespread deforestation can have strong nonlocal atmospheric responses (Avissar and Werth 2005; Hasler et al. 2009). Thus, the use of a regional model where both control and deforested scenarios present the same lateral boundary conditions generates a bias where these nonlocal effects are not included (Medvigy et al. 2011). In this sense, the results discussed above do not include the possible remote responses of deforestation in the boundary conditions of our analysis domain. On the other hand, a strong perturbation in the land surface conditions (such as the implementation of a deforestation scenario) can require a long spin-up period for a regional climate model to reach a physical equilibrium state. Surface hydrological variables such as evapotranspiration and soil moisture require long spin-up periods ranging from several months to several years (Christensen 1999; Cosgrove et al. 2003). Since these variables are crucial for surface energy and water budgets, the evaluation of the spin-up window influence in deforestation scenarios is a relevant topic to be evaluated by future studies. Nevertheless, the atmospheric component (which is the main interest in the present study) responds faster to dynamical/thermo-dynamical forcings (de Ela et al. 2002; Cholette et al. 2015; Jerez et al. 2020).

5 Summary and conclusions

This study aims to evaluate the impacts of Amazonian deforestation on the hydro-climatic connectivity between Amazon and eastern tropical Andes during the austral summer in terms of hydrological and energetic balances. To this end, we use 10-year December–January–February high-resolution simulations (2001–2011) with the regional climate model WRF. Two scenarios are used: (i) a control simulation corresponding to vegetation conditions for the year 2000; (ii) a business-as-usual deforested scenario (45% of forest lost) designed by Soares-Filho et al. (2006).

By comparing with reanalysis (ERA5 and NCEP-NCAR) and precipitation satellite outputs (TRMM), we find a realistic representation of the main atmospheric circulation (e.g. SALLJ, the Bolivian High) and rainfall features (e.g. SACZ, Amazon convection) during austral summer by WRF at a regional scale. The model is also able to reproduce the daytime and nighttime rainfall conditions over the Amazon-Andes transition region and the rainfall-elevation relation at a local scales inside instrumented Andean valleys. However, at local scale, in regions with high orography, day and night rainfall conditions were only compared with rain-gauge estimations for a very short period (1 year) in Huarinilla valley. The lack of observations at intra-diurnal time scale in the region is an important limitation for assessing the high-resolution model representation of local atmospheric mechanisms and its interaction with mesoscale features. We complement the validation by assessing the model skill to reproduce the observed land use change impacts on surface fluxes and atmospheric variables at a local scale against LBA stations. We find a realistic model response to deforestation for most of the surface atmospheric variables in Amazon lowlands. However, WRF overestimates the effect of the albedo on the reflected shortwave radiation and strongly underestimates the sensible heat flux and evaporation/latent heat response to forest loss. These model biases constrain our conclusions about the impacts of deforestation on the regional climate. How these errors interact with each other is something that remains unexplored in this work.

At a regional scale, the energy balance is profoundly disrupted by the forest loss. The combined effect of enhanced energy losses through shortwave radiation reflection, longwave incoming and outgoing radiation fluxes leads to a decrease in the surface net radiation over most of the basin. According to the deforestation theory developed by Zeng and Neeling (1998), this reduction in surface net radiation may lead to alterations in the regional moisture convergence. Accordingly, deforestation reduces precipitation almost over the entire Amazonian basin.
Fig. 12 Schematic representation of DJF climatological atmospheric conditions at regional (a, b) and local scales (c–f) for normal conditions (a–d) and deforestation induced anomalies (b–f) in WRF simulations. The red square in a indicates the approximated location of the Zongo Valley sketched in c–f. Black solid (red dashed) thin arrows represent surface moisture transport under normal conditions (deforestation anomalies). Black (red) thick arrows represent mid-tropospheric moisture flux under normal conditions (deforestation anomalies). Vertical thick arrows represent ascending and descending motions. Black (red) curved arrows represent evapotranspiration under normal conditions (deforestation anomalies). Blue and red shaded areas indicate vertically integrated moisture convergence (divergence, respectively). Purple areas indicate pressure changes. Red (blue) shaded areas indicate vertically integrated moisture convergence (divergence, respectively). Red (blue) thick arrows represent surface moisture transport under normal conditions (deforestation anomalies).

lowlands towards the Andean highlands during nighttime in agreement with previous modelling studies.

Finally, at a local scale, Amazon deforestation induces significant reductions in the climatological rainfall mean over both Zongo and Huarinilla valleys (~25%) and increases its interannual variability. For the Zongo Valley, major precipitation drop occurs over areas below 2000 m a.s.l. In this valley, daytime precipitation presents little changes in its mean value. However, during the night precipitation decreases, especially at lowlands. The rainfall depletion in this valley seems to be mainly related with the decreased entry of SALLJ moist winds from Amazon towards the Andean highlands (Fig. 12d–f). Similarly, the Huarinilla Valley does not present significant changes in daytime rainfall but exhibits decreased precipitation especially over highlands during nighttime. However, as a result of numerical modelling these conclusions have to be taken with caution as they are partially dependent on the model configuration. More efforts have to be done to understand the sensitivity and robustness of these results to model parametrizations. Finally, this work and most of deforestation modelling studies are focused on forest loss impacts on atmospheric processes at climatological time scales. How deforestation can alter rainfall distribution and the atmospheric circulation patterns that drive moisture advection at synoptic intra-seasonal time scale is a question that should be addressed to better understand the deforestation disturbances at longer time scales.

Supplementary Information The online version contains supplementary material available at https://doi.org/10.1007/s00382-021-06025-y.

Acknowledgements We would like to thank Marcus Schawe for providing the rain-gauge data for Hornuni Valley.

Author contributions All authors contributed to the study conception and design. Material preparation, data collection and analysis were performed by JPS. The first draft of the manuscript was written by JPS and all authors commented on previous versions of the manuscript. All authors read and approved the final manuscript.

Funding This research has been supported by the French AMANECER-MOPGA project funded by ANR and IRD (ref. ANR-18-MPGA-0008). Jorge Molina-Carpio was supported by the Universidad Mayor de San Andres (UMSA) within the framework provided by the PHYBAAM (Processus Hydrologiques des Bassins Andins Amazoniens) Project and HYdrogéochimie du Bassin AMazonien (HYBAM) program.

Availability of data and material All dataset sources except WRF modelling results have been properly referenced by showing the source (web site links). The datasets generated during the current study (WRF outputs) are available from the corresponding author on reasonable request.
