SUMMARY

The bone size and quality, acquired during adolescent growth under the influence of anabolic hormones, growth factors, and nutrients, determine the height and bone stability and forecast osteoporosis risks in late life. Yet bone size and quality control mechanisms remain enigmatic. To study the roles of mammalian target of rapamycin (mTOR) signaling, sensor of growth factors and nutrients, in bone size and quality regulation, we ablated Tsc1, a suppressor of mTOR, in mesenchymal stromal cells (MSCs), monocytes, or their progenies osteoblasts and osteoclasts. mTOR activation in MSCs, but much less in osteoblasts, increased bone width and mass due to MSC hyperproliferation, but decreased bone length and mineral contents due to defective MSC differentiation. mTOR activation promotes bone mineral accretion by inhibiting osteoclast differentiation and activity directly or via coupling with MSCs. Tuberous sclerosis complex patient studies confirmed these findings. Thus, mTOR regulates bone size via MSCs and bone quality by suppressing catabolic activities of osteoclasts.

INTRODUCTION

The organ size, determined by the number and size of cells in the organ, is regulated by genetic and environmental factors (Csibi and Blenis, 2012; Penzo-Mendez and Stanger, 2015). The size of bones determines the height, build, and stability of the skeleton, while the quality of bones, defined by bone matrix and mineral contents and microstructures, determines the bone strength (Whiting et al., 2004). It is estimated that peak bone mass accounts for 60% of the risk of osteoporosis (Baxter-Jones et al., 2011). The maximal bone size, mass, and strength are reached in humans at the age of 23–24 years and in mice at 10–12 weeks (Bonjour and Chevalley, 2014; Farr and Khosla, 2015). Bone growth and remodeling are carried out by coordinated osteoblastic bone formation and osteoclastic bone resorption (Henriksen et al., 2014; Karsenty et al., 2009). Osteoblasts (OBs) are derived from bone marrow-mesenchymal stalk cells (BM-MSCs), which can self-renew and differentiate into OBs, chondrocytes, or adipocytes, whereas osteoclasts (OCs) are derived from monocytes (Edwards and Mundy, 2011; Harada and Rodan, 2003; Lacey et al., 2012). Proliferation of stem cells and progenitors increases the pool of OBs or OCs, while proper maturation determines the activities of these cells. Bone size, mass, and quality can be regulated by the growth hormone-insulin growth factor (IGF) axis, nutrition, steroid hormones, vitamin D, and mechanical stimuli (Bonjour and Chevalley, 2014; Hendrickx et al., 2015; Rosello-Diez and Joyner, 2015; Zemel, 2013). It is generally believed that IGFs promote OB and chondrocyte proliferation and differentiation, which mediate the anabolic effects of IGFs on bone growth (Callawaert et al., 2010; Canalis, 2009; Yakar et al., 2010).

The mammalian target of rapamycin (mTOR) pathway is the sensor of growth factors, including IGF1, macrophage colony-stimulating factor (M-CSF), and nutrients (Hay and Sonenberg, 2004; Laplante and Sabatini, 2012), and is expected to play critical roles in bone growth spur during adolescence. Activated mTOR increases global protein synthesis to promote cell proliferation (Jewell et al., 2013; Johnson et al., 2013). In humans, tuberous sclerosis complex (TSC) patients carry mutations in one allele of TSC1 or TSC2, encoding negative regulators of mTOR, and they develop benign tumors in multiple organs due to loss of heterozygosity of the TSC genes (Laplante and Sabatini, 2012).
contribution of suppression of bone resorption to the regulating bone size and quality, and underscore the decisive uncover multifaceted roles for mTOR signaling in regul-

an increase in bone formation marker. These findings thus associated with a decrease in bone resorption marker and the patients show increased focal bone density, which is Han Chinese population revealed that more than 90% of mTOR inhibitor. Analysis of the TSC patients from the Cre were largely rescued by treatment with rapamycin, an mTOR activation induced by ablation of Tsc1 or Tsc2 deletion in committed OBs or chondrocytes established roles for mTOR signaling in bone mass accrual and endochondral ossification (Huang et al., 2015; Riddle et al., 2014), with the cartilage studies being limited to embryos or newborns due to survival problems of the mice (Chen and Long, 2014; Yan et al., 2016). Yet, the roles for mTOR signaling in bone size and quality control during adolescent growth, especially from the angle of the stem cells of the skeleton, remain largely unknown.

Here, we ablated Tsc1 in BM-MSCs and monocytes, as well as in their progenies, OBs and OCs, and found that mTOR regulates bone size in length and width by coordinating MSC proliferation and differentiation, and bone quality by suppressing osteoclastogenesis and bone resorption in cell-autonomous manners and by regulating the expression of OPG and RANKL by MSCs. The bone phenotypes induced by Tsc1 ablation mediated by Prx1-Cre or LysMCre were largely rescued by treatment with rapamycin, an mTOR inhibitor. Analysis of the TSC patients from the Han Chinese population revealed that more than 90% of the patients show increased focal bone density, which is associated with a decrease in bone resorption marker and an increase in bone formation marker. These findings thus uncover multifaceted roles for mTOR signaling in regulating bone size and quality, and underscore the decisive contribution of suppression of bone resorption to the achievement of peak bone mineral contents.

RESULTS

The mTOR Pathway Was Activated in Multiple Locations of the Bone during Adolescent Growth

mTOR can be activated by growth factors and nutrients. We found that in femurs of 1-day-old, 4-week-old, or 8-week-old mice, mTOR activation, manifested by S6 phosphorylation, was detectable in the proliferation and prehypertrophic zones of the growth plate (Figures 1A–1C), which are involved in longitudinal bone growth, the region underneath the growth plate, where trabecular bones are formed, and the periosteal and endosteal surfaces, which are responsible for bone radial growth (Figures 1A–1C). Staining of both p-S6 and Col2 or Osx confirmed that mTOR activation occurred in chondrocytes and OBs (Figure S1A). p-S6 signals were reduced in 8-week-old mouse bones compared with those in 1-day-old and 4-week-old mice, suggesting that mTOR is highly activated during adoles-

cent growth. Moreover, starvation inhibited mTOR activation, whereas feeding activated mTOR on mouse bone sections (Figures 1D–1F), confirming that food intake or nutrients can activate mTOR in the bone.

Prx1-Cre; Tsc1
deficient mice showed shorter and thicker long bones and joint defects

It has been reported that mTor ablation in BM-MSCs causes mouse neonatal lethality (Chen and Long, 2014). To further test the physiological function of mTOR activation in bone growth, we deleted Tsc1 in BM-MSCs by crossing floxed Tsc1 mice with Prx1-Cre mice (Figure S1B) (Logan et al., 2002; Meikle et al., 2007). Our previous studies have confirmed that Prx1 marks stromal cells with tri-lineage differentiation potentials and labels cells at the growth plate, trabecular region, and periosteal surface (Cong et al., 2016). Western blot and immunohistochemical analysis confirmed that Tsc1 was largely deleted in BM-MSC cultures and on bone sections, leading to an increase in p-S6 (Figures S1C and S1D). The Tsc1-deficient mice were born at the expected Mendelian ratio and showed unaltered body weight and length compared with wild-type (WT) litters (Figure S1E).

Micro-computed tomography (CT) analysis showed that the length of the long bones of the Tsc1-deficient mice was decreased compared with control litters of the same gender at 2.5 months of age (Figures 2A and 2B), when peak bone mass is achieved in mice. Histological analysis revealed that the mutant mice showed an increase in the height of growth plates and the size of chondrocytes compared with control mice (Figure 2C). The chondrocyte proliferation zone and hypertrophy zone were not clearly separated in the mutant mice (Figure 2C), likely due to disruption of the coordination between chondrocyte proliferation and differentiation. The mutant mice also showed a defect in articular cartilage and joint formation (Figure 2D). A similar perichondrium and cartilage anomaly has been reported in hereditary multiple exostoses patients, a disorder caused by mutations in EXT1 and EXT2 (Huegel et al., 2013; Jones et al., 2010), yet we found that mTOR activation did not alter the protein levels of EXT1 or EXT2 in MSCs, chondrocytes, or cartilage (Figures S2A–S2C).

On the other hand, the mutant mice showed an increase in the width of femurs and physseal growth plate (Figures 2A, 2E, and 2F). It is believed that, in addition to periosteal bone apposition, the width of the growth plate is an important factor determining the width of long bones (Wang et al., 2011). These results indicate that TSCI plays an important role in bone growth in both length and width, although in opposed ways.

It has been reported that TSCI also activates mTOR-independent pathways such as RAF and NOTCH. We found that in BM-MSCs, Tsc1 deletion did not affect the protein levels
Figure 1. mTOR Was Activated in the Bone during Adolescent Growth and by Feeding
(A–C) Immuno-staining of p-S6 on bone sections of 1-day-old (A), 4-week-old (B), or 8-week-old mice (C). The femur bones were de-calcified and embedded in paraffin. Antibodies against p-S6 and secondary antibodies conjugated with horseradish peroxidase were used to detect the signal.
(D–F) Starvation inhibited mTOR activation, whereas feeding activated mTOR on bone sections. P1 pups were starved overnight (D) by separating from the mother and then euthanized 2 hr (E) or 8 hr (F) after feeding. The femur bones were frozen sectioned and stained for p-S6. Scale bars, 200 µm (A–F left panels) and 50 µm (A–F right panels).
Figure 2. Ablation of Tsc1 in Prx1+ MSCs but Not in Derma1+ or Osx+ OBs Led to Shortened but Broadened Limbs and Joint Deformation

(A) Micro-CT images of the femur bones and the vertebrae (L3 and L4) of 2.5-month-old Prx1-Cre; Tsc1f/f, Dermo1-Cre; Tsc1f/f, and Osx-Cre; Tsc1f/f mice. Upper panel, coronal plane of femur; middle panel, transverse plane of femur; bottom panel, vertebrae.

(B) Quantitation data showed that the length of Prx1-Cre; Tsc1f/f mouse long bones was decreased compared with control mice. N = 15 mice.

(C) H&E staining of the growth plates of 2.5-month-old Prx1-Cre; Tsc1f/f and control mouse femur bones. Right panel: quantitation data of the diameter of chondrocytes. Scale bars, 200 μm (left panel) and 20 μm (middle panel). N = 3 mice (6 views each).

(legend continued on next page)
of RAF or the activation of its downstream ERK kinases (Figure S2D). Tsc1 deficiency slightly increased the protein levels of NOTCH1 (Figure S2D), which may mediate the effect of mTOR activation on OB differentiation (Huang et al., 2015). To determine whether the skeletal phenotypes observed in Prx1-Cre; Tsc1f/f mice are caused by mTOR activation, we treated the mutant and control mice with rapamycin and found that rapamycin inhibited skeletal growth in WT mice (Figures S3A–S3M), as reported previously (Yan et al., 2016). Moreover, rapamycin largely rescued the skeletal phenotypes including bone width/length, bone mass, trabecular bone number, trabecular separation, the growth plate height, the size of chondrocytes, and the joint development anomaly in Prx1-Cre; Tsc1f/f mice (Figures S3A–S3M). These results indicate that mTOR signaling downstream of TSC1 deficiency plays an important role in bone growth.

The change in bone size and joint formation defects observed in Prx1-Cre; Tsc1f/f mice are not reported in mice with Tsc1 or Tsc2 ablated in OBs (Chen and Long, 2014; Huang et al., 2015; Riddle et al., 2014). Moreover, these defects were not obvious in Prx1-Cre; Tsc1f/f embryos or p1 newborn mice. The Prx1-Cre; Tsc1f/f embryonic skeletons (E18.5) appeared normal and the length of the long bones of day 1 pups was not significantly affected (Figures S4A and S4B). The p1 pups did not develop the joint problem either (Figure S4C). These results suggest that the bone size alteration and joint defects observed in Prx1-Cre; Tsc1f/f adult mice are developed during adolescent growth.

**Prx1-Cre; Tsc1f/f Mice Showed Increased Bone Volume but Decreased Bone Mineralization**

Micro-CT analyses revealed that the mutant mice showed an increase in the thickness of cortical bones and the volume and thickness of trabecular bones (Figures 3A–3C), accompanied by a decrease in the number of trabecular bones and bone separation (Figures 3D and 3E). Bone histomorphometry revealed that the 2.5-month-old mice showed an increase in bone formation rate but a decrease in bone mineralization rate (Figures 3F and 3G), suggesting that bone mineralization might be impeded even though bone formation is increased.

We found that the cortical bones appeared to have quality problems. Firstly, they were porous, accompanied by an increase in the number of blood vessels, as CD31, a marker for endothelial cells, could stain these pores (Figure 3H). Secondly, von Kossa staining and H&E staining showed that the mutant bone was rich in osteoids that were not fully mineralized (Figures 3I and 3J). The mineralization defects are similar to what have been reported in mice with Tsc1 or Tsc2 ablated in OBs, which were rescued by rapamycin treatment (Chen and Long, 2014; Huang et al., 2015; Riddle et al., 2014). Thirdly, the bones were more fragile than WT bones, based on three-point bending experiments (Figure 3K). These results, taken together, indicate that mTOR activation by ablation of Tsc1 in Prx1+ MSCs inhibits bone mineralization, disrupts bone microstructure, and reduces bone strength, thus lowering the bone quality.

**mTOR Activation Regulated Bone Size and Mass Mainly via MSCs but Not OBs**

To determine the contributions of mTOR signaling in MSCs and OBs to the bone phenotypes observed in Prx1-Cre; Tsc1f/f mice, we ablated Tsc1 in Dermo1+ MSCs and Osx+ OBs, respectively. Dermo1 is believed to be expressed in BM-MSCs after Prx1, while Osx is expressed in committed OBs after Runx2 (Figure S1B) (Rodda and McMahon, 2006; Yu et al., 2003). Western blot analysis of BM-MSCs and differentiated OB cultures confirmed that Tsc1 was largely deleted, leading to an increase in p-S6 (Figure S4D). We found that these two mouse lines showed normal body weight and body length (Figures S4E and S4F).

X-ray imaging analyses revealed that unlike Prx1-Cre; Tsc1f/f mice, the length and the width of the femurs and the growth plates were not significantly altered in Dermo1-Cre; Tsc1f/f mice or Osx-Cre; Tsc1f/f mice compared with their control littermates (Figures 2A and S4G and data not shown). These two mouse lines showed an increase in trabecular bone volume and cortical bone thickness, with the increase in Dermo1-Cre; Tsc1f/f mice being greater than that in Osx-Cre; Tsc1f/f mice (Figures 3A, 3B, and S4H–S4J). The increase in trabecular bone volume and cortical bone thickness in these two mouse lines were much less than those of Prx1-Cre; Tsc1f/f mice (Figures 2A, 3A, and 3B). These results collectively suggest that mTOR signaling regulates trabecular and cortical bone mass mainly via MSCs.

We also compared the vertebrae (L3 and L4) of the three Tsc1-deficient mouse lines against their respective control littermates using micro-CT, and found that the bone
Figure 3. Ablation of Tsc1 in MSCs Increased Bone Mass but Reduced Bone Quality

(A) Ablation of Tsc1 in Prx1+ MSCs increased the cortical thickness of femur bones to a greater extent than ablation of Tsc1 in Dermo1+ or Osx+ OBs. N = 4 mice.

(B) Micro-CT analysis revealed that Prx1-Cre; Tsc1f/f mice showed a greater increase in trabecular bone volume than Dermo1-Cre; Tsc1f/f and Osx-Cre; Tsc1f/f mice. N = 4 mice.

(legend continued on next page)
mineral contents were not significantly altered in Prx1-Cre; Tsc1f/f mice or Osx-Cre; Tsc1f/f mice, whereas Dermo1-Cre; Tsc1f/f mice showed a modest increase in bone mineral contents (Figure 2A).

**Tsc1 Deficiency Increased the BM-MSC Pool but Inhibited MSC Differentiation**

We found that on bone sections of Prx1-Cre; Tsc1f/f mice, the number of Ki67-positive cells was greatly increased in the growth plate (Figures 4A and S4H). The heights of the Ki67-positive proliferation zone and the Col10-positive hypertrophic zone were increased (Figure S4H), suggesting that the balance between proliferation and differentiation of chondrocyte progenitors were disrupted by Tsc1 ablation. In addition, the number of OBs per bone surface was significantly increased (Figure 4B). Prx1-Cre; Tsc1f/f mouse bone marrow also contained an increased number of colony-forming units, an indicator of the number of MSCs (Figure 4C), suggesting that the pool of MSCs was expanded.

**Ablation of Tsc1 in MSCs but Not OBs Showed Suppressed Osteoclastogenesis and Bone Resorption**

We then stained for TRAP-positive OCs on femur bones and found that Prx1-Cre; Tsc1f/f mice showed a decreased number of OCs (Figure 5A). Bone histomorphometry analysis confirmed that the mutant mice showed a decrease in bone erosion surface and the number of OCs, which were rescued by rapamycin treatment (Figures 5B and 5C and data not shown). Furthermore, Prx1-Cre; Tsc1f/f mice showed a decrease in urine deoxypyridinoline (DPD) levels, an in vivo bone resorption marker (Figure 5D). On the other hand, Dermo1-Cre; Tsc1f/f and Osx-Cre; Tsc1f/f mouse lines did not show a change in the number of TRAP-positive OCs (Figure 5A). These results indicate that Tsc1 deficiency in MSCs, but not in OBs, suppresses osteoclastogenesis, which may help to promote bone mineral accrual.

To understand how mTOR signaling regulates the coupling between MSCs and osteoclastogenesis, we analyzed the mRNA levels of Rankl, Opg, and M-CSf in Tsc1f/f and control BM-MSCs and found that Tsc1 deficiency greatly increased the expression of Opg and decreased the expression of Rankl (Figure 5E). Similar results were obtained from immuno-staining for RNALK and OPG on bone sections and measurement of RNALK and OPG in the bone marrow (Figures S5A and S5B). These results suggest that mTOR in BM-MSCs might regulate OPG and RNALK expression to suppress osteoclastogenesis and bone resorption. In addition, M-CSf expression was upregulated in Tsc1-deficient MSCs (Figure 5E). We showed that decreased M-CSF production by MSCs compromised proliferation of OC progenitor cells in co-culture experiments (Figure S5C).

---

(C–G) Prx1-Cre; Tsc1f/f mice showed an increase in thickness (C) and the number (D), and a decrease in separation (E) of trabecular bones, and an increase in bone formation rate (BFR) (F) and mineral apposition rate (MAR) (G). N = 4 mice.

(H) Prx1-Cre; Tsc1f/f mice femur cortical bones appeared to be porous, some of which were stained positive for CD31. Black arrow, pores; red arrow, blood vessel. Scale bars, 200 μm (upper panel) and 50 μm (lower panel).

(I) von Kossa staining of Prx1-Cre; Tsc1f/f and control littermates showed that the mineralization was impeded in the mutant mouse bones. Scale bar, 200 μm.

(J) Masson staining of Prx1-Cre; Tsc1f/f and control littermates showed that the mineralization was impeded in the mutant mouse bones. Scale bar, 200 μm.

(K) Prx1-Cre; Tsc1f/f mice showed reduced bone strength, judged by the three-point bending experiment results. N = 4 mice. Error bars represent the SD. *p < 0.05; **p < 0.01.
Figure 4. Tsc1<sup>−/−</sup> MSCs Showed Increased Proliferation, but Defective Osteogenic and Chondrogenic Differentiation

(A) Ki67 staining of femur bones of Prx1-Cre; Tsc1<sup>−/−</sup> and control mice. Right panel: quantitation data. Scale bars, 200 μm (left panel) and 50 μm (middle panel). N = 3 mice (6 views each).

(B) Prx1-Cre; Tsc1<sup>−/−</sup> mice showed an increase in the number of OBs in the trabecular region. N = 8 mice.

(C) Prx1-Cre; Tsc1<sup>−/−</sup> mice showed an increase in the number of bone marrow colony-forming units (CFU). Right panel: quantitation data. N = 4 independent experiments.

(legend continued on next page)
Ablation of Tsc1 in Monocytes or OCs Increased Bone Mineral Contents

The above studies showed that mTOR signaling in MSCs regulated bone growth in size and volume via MSCs and that Tsc1 deletion in MSCs also led to a decrease in bone mineralization. Although mTOR activation in MSCs regulates the expression of OPG and RANKL to suppress bone resorption and increase bone mineral contents, this turns out to be inadequate to keep up with bone growth in size.

Figure 5. Ablation of Tsc1 in Prx1+ MSCs but Not in Dermo1+ or Osx+ OBs Suppressed Osteoclastogenesis and Bone Resorption

(A) TRAP staining of bone sections revealed that femurs of Prx1-Cre; Tsc1<sup>fl/fl</sup> mice, but not Dermo1-Cre; Tsc1<sup>fl/fl</sup> or Osx-Cre; Tsc1<sup>fl/fl</sup> mice showed a decrease in the number of OCs in vivo. Scale bar, 50 μm. Data are from three independent experiments.

(B–D) Prx1-Cre; Tsc1<sup>fl/fl</sup> mice showed a decrease in bone erosion surface (B) (N = 8 mice), the number of OCs (C) (N = 8 mice), and the levels of urine DPD (D) (N = 4 mice).

(E) Tsc1<sup>−/−</sup> MSCs showed altered expression of Rankl, M-CSf, and Opg. N = 4 independent experiments.

Error bars represent the SD. *p < 0.05; **p < 0.01.
Figure 6. Ablation of Tsc1 in LysM+ Monocytes or Ctsk+ OCs Led to a Decrease in Bone Resorption

(A) Micro-CT images of the femur bones and the vertebrae (L3 and L4) of LysM-Cre; Tsc1f/f mice, Ctsk-Cre; Tsc1f/f mice, and their respective control mice. N = 3 mice.

(B) The length of femur bones of LysM-Cre; Tsc1f/f mice (left panel) and Ctsk-Cre; Tsc1f/f mice (right panel) were not altered compared with those of control mice. N = 6 mice.

(legend continued on next page)
We then ablated Tsc1 in monocytes, the OC progenitors, using LysM-Cre mice (Figure S1B) (Clausen et al., 1999), to test whether mTOR signaling in monocytes might affect adolescent bone mineral content accretion (Figure 6A). The mutant mice were born at the Mendelian ratio and they had unaltered body weight, body length, and femur radius and length (Figures 6A and 6B and data not shown).

Micro-CT analyses revealed that the mutant mouse femur displayed an increase in trabecular bone mass (Figures 6A–6E). The osteopetrotic phenotypes were largely rescued by inhibition of mTORC1 with rapamycin (Figures 6C and S6B). Bone histomorphometry analysis confirmed these findings and revealed that LysM-Cre; Tsc1f/f mice exhibited normal bone formation rate, bone mineralization rate, and the numbers of OCs in vivo (Figure 6F and data not shown). TRAP staining of bone sections confirmed that the numbers of OCs were similar between LysM-Cre; Tsc1f/f and control mice (Figure 6G). However, LysM-Cre; Tsc1f/f mice showed a decrease in bone resorption, demonstrated by a decrease in the serum levels of C-terminal telopeptide (CTX) and urine levels of DPD, two in vivo bone resorption markers (Figure 6H).

We then ablated Tsc1 in differentiated OCs using Ctsk-Cre mice. These mice showed normal body weight and size and femur length (Figure 6B and data not shown), with an increase in trabecular bone volume and bone mineral contents (Figures 6C–6E). The osteopetrotic bone phenotypes in the Ctsk-Cre; Tsc1f/f mice were more severe than those of LysM-Cre; Tsc1f/f mice.

Surprisingly, the Ctsk-Cre; Tsc1f/f mice showed an increase in the number of OCs (Figure 6F), which was confirmed by TRAP staining on bone sections (Figure 6G). However, the levels of urine DPD and serum CTX were decreased (Figure 6H), suggesting that OCs might be functionally incompetent. On the other hand, bone formation rate and bone mineralization rate were not altered in Ctsk-Cre; Tsc1f/f mouse lines (data not shown).

We also compared the vertebrae (L3 and L4) of LysM-Cre; Tsc1f/f and Ctsk-Cre; Tsc1f/f mouse lines against their respective control littersmates using micro-CT, and found that bone mineral contents were not significantly altered in LysM-Cre; Tsc1f/f mice, similar to the femur bone phenotypes (Figure 6A). However, the Ctsk-Cre; Tsc1f/f mice showed greatly increased bone mineral contents (Figure 6A).

mTOR Activation Inhibited OC Differentiation, Fusion, and Activity
To determine the cellular basis of the decrease in bone resorption in LysM-Cre; Tsc1f/f mice, we isolated bone marrow monocytes and carried out in vitro differentiation assays. mTOR was activated in monocyte cultures, yet its activation went down once undergoing differentiation (Figure S7A). It was found that Tsc1−/− mice showed increased proliferation rates (Figure 7A). Yet, in response to RANKL and M-CSF, the formation of TRAP-positive OCs and the expression of mature OC markers were decreased, while the number of TRAP-positive mononuclear cells was increased (Figures 7B and 7C). The OCs derived from Tsc1−/− progenitors showed much fewer nuclei than WT OCs (Figures 7C and S7B), accompanied by reduced levels of DC-Stamp and OC-Stamp (Figure 7D), which are required for OC fusion (Helming and Gordon, 2009). Moreover, differentiated osteoclasts derived from Tsc1-deficient monocytes showed a decrease in resorption activity on bone chips, which was associated with a decrease in the expression of enzymes involved in bone resorption (Figures 7D and 7E). These results suggest that mTOR activation inhibits osteoclast differentiation, fusion, and function, but promotes proliferation. As such, compromised differentiation may even increase the proliferation of OC progenitors. This may explain why the number of OC numbers in vivo was not significantly altered in LysM-Cre; Tsc1f/f mice.

To further understand how mTOR activation affects OC differentiation, we looked at the signaling pathways known to control osteoclastogenesis. Western blot results showed that Tsc1 deficiency led to a decrease in activation
Figure 7. mTOR Activation Suppressed OC Differentiation, Fusion, and Resorption Activity, but Enhanced Proliferation

(A) Monocytes isolated from LysM-Cre; Tsc1^{1/2} mice showed an increase in proliferation. The monocytes isolated from WT and LysM-Cre; Tsc1^{1/2} mice were cultured for 3 days in the presence of M-CSF and RANKL. Scale bar, 50 μm. Right panel: quantitation data. N = 4 independent experiments.

(B) Ex vivo differentiation assays revealed that monocytes isolated from LysM-Cre; Tsc1^{1/2} mice showed a decrease in the number TRAP-positive OCs. Monocytes were isolated from the bone marrow and were induced to differentiate by M-CSF and RANKL. The cell cultures were stained for TRAP 5 days later. Bottom panel: quantitation data. Scale bar, 100 μm. N = 4 independent experiments.
of the nuclear factor κB (NF-κB) pathway (Figure 7F). This is consistent with previous reports showing that mTOR activation downregulated NF-κB signaling (Ghosh et al., 2006; Weichhart et al., 2008), the master regulator of OC differentiation, fusion, and activity.

We also isolated bone marrow monocytes from Ctsk-Tsc1f/f mice and performed ex vivo differentiation assays. These cells only express Cre after differentiating into Ctsk-positive OCs, which would then lead to Tsc1 deletion. We found that the number and size of TRAP-positive OCs were slightly increased in the mutant cultures (Figure 7G). However, differentiated OCs derived from Ctsk-Cre; Tsc1f/f mice showed a decrease in bone resorption activity (Figure 7H). These results suggest that mTOR activation may promote proliferation and/or growth of differentiated osteoclasts, but interfere with their bone resorption activity. This may explain why Ctsk-Cre; Tsc1f/f mice showed an increase in the number of OCs.

We also investigated the mechanisms underlying the bone resorption defects caused by Tsc1 deficiency. Although autophagy has been reported to play a role in bone resorption (Chagin, 2016; DeSelm et al., 2011), we found that in OC cultures, autophagy markers p62 and LC3 were not significantly altered in the absence of Tsc1 (Figure S7C). However, OCs showed an increase in size on bone sections of Ctsk-Cre; Tsc1f/f mice but not of LysM-Cre; Tsc1f/f mice (Figure S7D). Moreover, the number of ring-like actin structures was decreased in both mouse lines, with the decrease in Ctsk-Cre; Tsc1f/f mouse bone sections being greater than that in LysM-Cre; Tsc1f/f mice (Figure S7E). These alterations may contribute to the resorption defects of Tsc1-deficient OCs and explain why Ctsk-Cre; Tsc1f/f mice showed a greater osteopetrotic phenotype than LysM-Cre; Tsc1f/f mice.

**DISCUSSION**

This study, by analyzing mouse models with mTOR activated in BM-MSCs, monocytes, or their progenies, demonstrates that mTOR signaling regulates adolescent bone growth in size, mass, and mineral contents by acting on different cell types. mTOR activation in chondrocytes and OBs appears to be strong during adolescent growth and declines when reaching adulthood. mTOR activation increases bone radial growth, trabecular bone volume, and cortical bone thickness, mainly by promoting proliferation of Prx1+ BM-MSCs and increasing the pools of MSCs. However, mTOR activation decreases the length of long bones.
and bone mineralization, likely caused by impeded MSC chondrogenic and osteogenic differentiation, respectively (Figure S7F). These findings suggest that mTOR signaling coordinates MSC proliferation and differentiation to regulate bone size and quality, and that expansion of the BM-MSC pool is an important step during bone growth. The mTOR signaling pathway may integrate the signals from growth factors, nutrients, and other pathways such as Pten or LKB1 to regulate bone growth in length (Ford-Hutchinson et al., 2007; Lai et al., 2013; Shima et al., 1998).

mTOR activation in MSCs appears to impede bone mineralization, indicating that mTOR activation does not mediate the anabolic effects of growth factors on bone mineral accretion. Instead, mTOR activation suppresses the catabolic effects of monocyte/OC in cell-autonomous manners. While several in vitro studies suggest that inhibition of mTOR with rapamycin impedes OC survival and differentiation (Sugatani and Hruska, 2005), our study provides genetic evidence that mTOR activation inhibits OC differentiation, fusion, and resorption activity, but promotes proliferation of monocytes and differentiated OCs, suggesting stage-specific effects for mTOR in osteoclastogenesis and function (Figure S7F). OC differentiation and fusion defects may be caused by compromised NF-kB activation and decreased expression of cell fusion gene DC-Stamp and OC-Stamp (Figure S7F), while OC resorption defects may be caused by mTOR-induced alteration in cell size and/or cytoskeleton. The more severe osteopetrotic phenotype of Ctsk-Cre; Tsc1f/f than LysM-Cre; Tsc1f/f mice can be explained by the difference in OC cell size and cytoskeleton (Figures S7D and S7E). The lack of increase in OC numbers in LysM-Cre; Tsc1f/f mice could be caused by opposite and stage-specific effects of mTOR activation on OC proliferation and differentiation. It is worth noting that the peak bone mass is a net result of 10 weeks of bone formation and resorption, which may not be reflected by the bone parameters measured at week 10 of age or in vitro assays.

In addition, mTOR activation in MSCs, but not in OBs, plays a role in coupling to osteoclastogenesis. mTOR signaling in Prx1+ MSCs alters the expression of M-CSF, OPG, and RANKL to inhibit osteoclastogenesis and bone resorption. Consistently, previous studies of mouse lines with Tsc1 abladed in Osx- or osteocalcin-expressing OBs failed to detect significant alterations in bone resorption (Chen and Long, 2014; Fang et al., 2015; Riddle et al., 2014). These findings support the concept that coupling exists between MSCs and monocytes in addition to the coupling between bone formation and resorption (Cong et al., 2016). Thus, mTOR increases bone mineral contents by directly inhibiting OC differentiation and activity, and by altering MSCs-secreted RANKL and OPG.

Our studies reveal that more than 90% TSC patients of Han Chinese develop focal sclerotic bone lesions at different locations in the skeleton. Analysis of TSC patient serum samples confirmed that bone resorption marker is reduced, whereas bone formation marker is increased. While it is assumed that increased focal bone density is secondary to increased bone formation (Umeoka et al., 2008), we found that, in mouse models, deletion of Tsc1 in BM-MSCs or OBs led to a decrease in bone mineral contents. In contrast, deletion of Tsc1 in monocytes especially in OCs led to a great increase in bone mineral contents. These data suggest that the increase in focal bone density in TSC patients is caused mainly by decreased bone resorption. Thus, sclerotic bone lesions should be deemed as “osteopetrotic lesions” in TSC patients.

Model animal and human sample studies have shown that hormone deficiency and undernutrition are the major factors affecting organ size, and which inhibit cell proliferation and cell size in the organ. Our current studies, together with the studies of OB- and chondrocyte-specific deletion of mTOR pathway molecules, indicate that mTOR signaling is an important regulator of bone size and quality. mTOR regulates bone size by acting on MSCs rather than OBs; its pro-proliferation activity in MSCs accounts for the bone radial growth and bone volume accrual, whereas its negative effects on MSC chondrogenic differentiation regulate bone growth in length. Therefore the coordination of MSC proliferation and differentiation controls bone growth in length and width.

In summary, we show that mTOR signaling regulates bone size mainly by coordinating MSC proliferation and differentiation, and bone quality mainly by suppressing OC differentiation and activity. Moreover, mTOR also plays a role in coupling MSCs and monocytes. Studies of TSC patient samples validated these findings. Collectively, our studies uncover multiple roles played by mTOR signaling in bone size and quality control.

**EXPERIMENTAL PROCEDURES**

**TSC Patients**

All the 64 TSC patients (38 women and 26 men; age range, 4–46 years; mean ± SD age, 26.1 ± 8.7 years) underwent CT examination of the chest, abdomen, and pelvis using a SOMATOM Definition Flash scanner (Siemens Medical Systems) and a Discovery CT750 HD scanner (GE Medical Systems) with slice thickness of 5 mm and tube voltage of 120 kVp. The protocol for this study was approved by our institutional review board. All patients gave written consent.

**Animal Studies**

Animal work was carried out following the recommendations from the National Research Council Guide for the Care and Use of Laboratory Animals, with the protocols approved by the Institutional Animal Care and Use Committee of Shanghai, China (SYXK(SH))...
2011-0112). The Prx1-Cre, Dermo1-Cre, Ox2-Cre, LysM-Cre, Ctsk-Cre, and floxed Tsc1 mouse lines were purchased from The Jackson Laboratory. For micro-CT and histomorphometry analysis, male mice at age 2.5 months were used, with the number of mice shown for each figure. For other mouse experiments, three mice (2.5-month-old male or female) were used.

Bone Histomorphometry and Three-Point Bending Experiment
Bone histomorphometry was performed on undecalcified sections as described in the Supplemental Information, and three-point bending experiments were conducted on a universal testing machine (RGM-2020, Shenzhen Regen Instrument) using fixed femurs.

Measurement of Serum Osteocalcin and CTX and Urine DPD
Fasting serum samples of TSC patients and normal individuals were collected to determine the levels of osteocalcin and CTX. Mouse urine samples were collected in the morning and were used to determine the levels of DPD and creatinine. The DPD values were normalized to creatinine.

BM-MSC Isolation and Differentiation
BM-MSCs were isolated and induced to differentiate as described by Cong et al. (2016).

Monocyte Isolation and Differentiation and Resorption Pit Analysis
BM-MSCs were isolated and induced to differentiate as described by Cong et al. (2016).

qPCR
Total RNA was extracted by using TRIzol Regent (Invitrogen). The RNA was reverse transcribed using a Transcriptor Universal CDNA Master (Roche) according to the manufacturer’s instructions. Real-time PCR was performed as described previously (Cong et al., 2016). See Supplemental Information for primer sequences.

Immunohistochemical Staining
See Supplemental Information for detailed protocols.

Statistical Analyses
Numerical data and histograms were expressed as the mean ± SD. Comparisons between two groups were analyzed using two-tailed unpaired Student’s t test. p Values < 0.05 were considered statistically significant. Analysis of mice was litter-based, and at least three litters were analyzed for every parameter. All experiments were repeated three to four times.

SUPPLEMENTAL INFORMATION
Supplemental Information includes Supplemental Experimental Procedures and seven figures and can be found with this article online at http://dx.doi.org/10.1016/j.stemcr.2017.04.005.

AUTHOR CONTRIBUTIONS
B.L., H.Z., Z.Z., and W.Z. designed the research. H.W., Z.W., P.L., Q.C., R.C., W.X., S.W., H.L., X.X., S.L., W.H., L.Z., J.Z., and S.L.H. performed the research. H.W., Z.W., and W.Z. analyzed the data; W.X., H.Z., W.H., and Z.Z. provided the TSC patient samples. H.L. and B.L. wrote the paper.

ACKNOWLEDGMENT
The work was supported by the National Key Scientific Program (2014CB942902 and 2012CB966901) and the National Natural Science Foundation of China (81520108012 and 91542120).
