A Subquadratic-Time Distributed Algorithm for Exact Maximum Matching

Naoki Kitamura* Taisuke Izumi†

Abstract

For a graph $G = (V, E)$, finding a set of disjoint edges that do not share any vertices is called a matching problem, and finding the maximum matching is a fundamental problem in the theory of distributed graph algorithms. Although local algorithms for the approximate maximum matching problem have been widely studied, exact algorithms has not been much studied. In fact, no exact maximum matching algorithm that is faster than the trivial upper bound of $O(n^2)$ rounds is known for the general instance. In this paper, we propose a randomized $O(s_{\max}^{3/2} + \log n)$-round algorithm in the CONGEST model, where $s_{\max}$ is the size of maximum matching. This is the first exact maximum matching algorithm in $o(n^2)$ rounds for general instances in the CONGEST model. The key technical ingredient of our result is a distributed algorithms of finding an augmenting path in $O(s_{\max})$ rounds, which is based on a novel technique of constructing a sparse certificate of augmenting paths, which is a subgraph of the input graph preserving at least one augmenting path. To establish a highly parallel construction of sparse certificates, we also propose a new characterization of sparse certificates, which might also be of independent interest.

1 Introduction

1.1 Background and Our Result

A fundamental graph problem is the maximum (unweighted) matching problem of finding the maximum cardinality subset of edges not sharing endpoints. In this study, we address the problem of computing exact maximum matchings in a distributed setting, namely, the CONGEST model. The CONGEST model is a standard computational model for distributed graph algorithms, where the network is modeled as an undirected graph $G = (V, E)$ of $n$ nodes and $m$ edges. Each node executes the deployed algorithm following round-based synchrony, and each link can transfer a small message of $O(\log n)$ bits per round. However, the limited bandwidth in the CONGEST model precludes a trivial universal solution for every graph problem, where the leader node collects all the topological information of $G$ and solves the problem using a centralized algorithm. This approach takes $O(n^2)$ rounds in the worst case of $m = \Omega(n^2)$. The technical challenge in designing CONGEST algorithms concerns how each node computes a fragment of the solution without information on the whole input instance. The recent development of design techniques for CONGEST algorithms has yielded many efficient solutions for various graph problems such as the minimum spanning tree [15, 23, 25, 30, 31, 35], distance problems including shortest-path computation [6, 15, 22, 26, 27, 36, 38], and flow and cut [10, 11, 19, 20, 39]. Owing to the existence of the

Theorem 1. For any input graph $G$, there exists a randomized CONGEST algorithm to compute the maximum matching that terminates within $O\left( s_{\max}^{3/2} + \log n \right)$ rounds with probability $1 - 1/n^{\Theta(1)}$.

To the best of our knowledge, the proposed algorithm is the first to compute the exact maximum matching algorithm in $o(n^2)$ rounds for general input instances in the CONGEST model.

1.2 Technical Outline

Our algorithm follows the standard technique of finding augmenting paths. If an augmenting path is found, the current matching is improved by flipping the labels of matching edges and non-matching edges along the path. It is well known that the current matching is the maximum if and only if there exists no augmenting path in $G$ with respect to the current matching. Hence, the maximum matching problem is reduced to the task of finding augmenting paths $s_{\max}$ times. In the CONGEST model, this approach faces difficulty in the situation where any augmenting path with respect to the current matching is long (i.e., consisting of $\Theta(n)$ edges). It should be emphasized that BFS-like approaches do not work for finding augmenting paths in general graphs because the shortest alternating walk is not necessarily simple because of the existence of odd cycles. Thus, it is not trivial to even compute an augmenting path with a running time linearly dependent on its length. The key ingredient of our approach is two new algorithms for finding augmenting paths. They run in $O(\ell^2)$ rounds and $O(s_{\max})$ rounds respectively, where $\ell$ is the length of the shortest augmenting path.
path for the current matching. Roughly, our algorithm switches between these two algorithms according to the current matching size. The running-time bound is obtained using the following seminal observation by Hopcroft and Karp:

**Proposition 1** (Hopcroft and Karp [28]). Given a matching $M \subseteq E$ of a graph $G$, there always exists an augmenting path of length less than $\lceil 2s_{\max}/k \rceil$ if the current matching size is at most the maximum matching size $s_{\max}$ minus $k$.

Our augmenting path algorithms utilize Ahmadi’s verification algorithm of maximum matching [1], in which each node returns the length of the shortest odd/even alternating paths from a given source (unmatched) node. The construction of the $O(\ell^2)$-round algorithm is relatively straightforward. It is obtained by iteratively finding the predecessor of each node in an augmenting path by sequential $O(\ell)$ invocations of the verification algorithm. The technical highlight of the proposed algorithm is the design of the $O(s_{\max})$-round algorithm. The $O(s_{\max})$-round algorithm constructs a sparse certificate, which is a sparse (i.e., containing $O(s_{\max})$ edges) subgraph of $G$ preserving the reachability between two nodes by alternating paths. That is, a sparse certificate contains an augmenting path if and only if the original graph admits an augmenting path. By the sparseness property, a node can collect all the information on the sparse certificate within $O(s_{\max})$ rounds, trivially allowing the centralized solution of finding augmenting paths. To establish a highly parallel construction of sparse certificates, we also propose a new characterization of sparse certificates, which might also be of independent interest.

### 1.3 Related Works

In the LOCAL model, it is known that no $o(1/\epsilon)$ algorithm exists for the $(1-\epsilon)$-approximate maximum matching problem [5]. Together with the $\Omega(\sqrt{\log n / \log \log n})$-round lower bound reported by Kuhn et al. [34], the lower bound in the LOCAL model is obtained as $\Omega(1/\epsilon + \sqrt{\log n / \log \log n}) = (\log n)/\epsilon \Omega(1)$. Ghaffari et al. [21] showed a $((\log n)/\epsilon)^{O(1)}$ upper bound for the $(1-\epsilon)$ approximate maximum matching problem. By combining these results, we infer that the time complexity of solving the $(1-\epsilon)$ approximate maximum matching problem is $(\log n)/\epsilon \Theta(1)$ in the LOCAL model. Ben-Basat et al. also proved the lower bound as $\Omega(|M|)$ in the LOCAL model [5].

Many literatures have addressed the maximum matching problem in the CONGEST model (see Table 1). Loker et al. [37] presented the first approximation algorithm in the CONGEST model, which is a randomized algorithm to compute $(1-\epsilon)$-approximate maximum matching in $O(\log n)$ rounds for any constant $\epsilon > 0$. The running time of the algorithm depends exponentially on $1/\epsilon$. Bar Yehuda et al. [4] improved the algorithm and proposed an $O(\log \Delta / \log \log \Delta)$-round algorithm of computing $(1-\epsilon)$-approximate matching for any constant $\epsilon > 0$, where $\Delta$ is maximum degree of the graph. Fabin et al. [34] has shown of $\Omega(\log \Delta / \log \log \Delta)$ rounds if $\log \Delta \leq \sqrt{n}$ holds. Ben-Basat et al. [5] proposed a deterministic $O(s_{\max}^2)$-round CONGEST algorithm. They also proposed a $(1/2-\epsilon)$ approximate algorithm in $O(s_{\max} + (s_{\max}/\epsilon)^2)$ rounds. Ahmadi et al. [2] proposed a deterministic $(2/3-\epsilon)$ approximate maximum matching algorithm in general graphs, which runs in $O(\log \Delta/\epsilon^2 + (\log^2 \Delta + \log^* n)/\epsilon)$ rounds. They also presented an $O(M)$-round algorithm and $O((\log^2 \Delta + \log^* n)/\epsilon)$-round $(1-\epsilon)$ approximate algorithm in bipartite graphs. However, no $o(n^2)$-round algorithm for solving the exact maximum matching problem in the CONGEST model has been proposed so far.

In addition to distributed computing, many studies have considered centralized exact maximum matching algorithms. Edmonds presented the first centralized polynomial-time algorithm for the maximum matching problem [12,13] by following the seminal blossom argument. Hopcroft and Karp proposed a phase-based algorithm of finding multiple augmenting paths [28]. Their algorithm finds a

maximal set of pairwise disjoint shortest augmenting paths in each phase. They showed that \(O(\sqrt{n})\) phases suffice to compute the maximum matching and proposed an algorithm of implementing one phase in \(O(m)\) time for bipartite graphs. Several studies have reported phase-based algorithms for general graphs that attain \(O(\sqrt{nm})\) time [7, 17, 42].

### 2 Preliminaries

#### 2.1 CONGEST Model

The vertex set and edge set of a given graph \(G\) are, respectively, denoted by \(V(G)\) and \(E(G)\). A distributed system is represented by a simple undirected connected graph \(G = (V(G), E(G))\). Let \(n\) and \(m\) be the numbers of nodes and edges, respectively. The diameter of a given subgraph \(H \subseteq G\) is denoted by \(D(H)\). Nodes and edges are uniquely identified by integer values, which are represented by \(O(\log n)\) bits. The set of edges incident to \(v \in V(G)\) is denoted by \(I_G(v)\). In the CONGEST model, the computation follows round-based synchrony. In one round, each node \(v\) sends and receives \(O(\log n)\)-bit messages through the edges in \(I_G(v)\) and executes local computation following its internal state, local random bits, and received messages. It is guaranteed that every message sent in a round is delivered to the destination within the same round. Each node has no prior knowledge of the network topology, except for its neighborhood IDs. We use the labeling of nodes and/or edges for specifying inputs and outputs of algorithms. Each node has information on the label(s) assigned to itself and those assigned to its incident edges. A walk \(W\) of \(G\) is an alternating sequence \(W = v_0, e_1, v_1, e_2, \ldots, e_\ell, v_\ell\) of vertices and edges such that \(e_i = (v_{i-1}, v_i)\) holds for any \(1 \leq i \leq \ell\). A walk \(W\) is often treated as a subgraph of \(G\). A walk \(W = v_0, e_1, v_1, e_2, \ldots, e_\ell, v_\ell\) is called a (simple) path if every vertex in \(W\) is distinct. For any walk \(W = v_0, e_1, v_1, \ldots, v_\ell\) of \(G\), we define \(W \circ u\) as the walk obtained by adding \(u\), satisfying \((v_\ell, u) \in E(G)\), to the tail of \(W\). For any edge \(e = (v_k, u)\), we also define \(W \circ e = W \circ u\). Given a walk \(W\) containing a node \(u\), we denote by \(W_u^p\) and \(W_u^s\) the prefix of \(W\) up to \(u\) and the suffix of \(W\) from \(u\), respectively. We also denote
the inversion of the walk \( W = v_0, e_1, v_1, \ldots, v_{\ell} \) (i.e., the walk \( v_{\ell}, e_{\ell-1}, v_{\ell-1}, \ldots, v_0 \)) by \( \overline{W} \). The length of a walk \( P \) is represented by \(|P|\).

## 2.2 Matching and Augmenting Path

For a graph \( G = (V, E) \), a matching \( M \subseteq E \) is a set of edges that do not share endpoints. A node \( v \) is called a matched node if \( M \) intersects \( I_G(v) \), or an unmatched node otherwise. A path \( P = v_0, e_0, v_1, e_1, \ldots, v_{\ell} \) is called an alternating path if \( I_M(e_i) + I_M(e_{i+1}) = 1 \) holds for any \( 1 \leq i \leq \ell - 1 \). If the length \(|P|\) of \( P \) satisfies \(|P| \mod 2 = \theta\), \( P \) is called \( \theta \)-alternating. The value \( \theta \) is called the parity of \( P \). By definition, any 0-alternating (1-alternating) path from an unmatched node \( f \) finishes with a non-matching (matching) edge. Due to a technical issue, we regard the path of length zero as a 0-alternating path. For any \( \theta \in \{0, 1\} \) and \( u, v \in V(G) \), we define \( r^\theta(u, v) \) as the length of the shortest \( \theta \)-alternating path between \( u \) and \( v \). An augmenting path is an alternating path connecting two unmatched nodes. We say that \( (G, M) \) has an augmenting path if there exists an augmenting path in \( G \) with respect to \( M \). The following proposition is a well-known fact in the maximum matching problem.

**Proposition 2.** Given a matching \( M \subseteq E(G) \) of graph \( G \), \( M \) is the maximum matching if and only if \( (G, M) \) has no augmenting path.

## 2.3 Approximate Maximum Matching

Our algorithm uses an \( O(1) \)-approximate upper bound for the maximum matching size of the input graph. To obtain the upper bound, we run the \( O(\log n) \)-round randomized maximal matching algorithm [29] as a preprocessing step. Let \( M^* \) be the computed maximal matching. Since any maximal matching is a \( (1/2) \)-approximate maximum matching, one can obtain the bound \( 2|M^*| \geq s_{\text{max}} \). The size \( s_{\text{max}} \) is at least half of the diameter \( D(G) \), and thus we can spend \( O(D(G)) = O(s_{\text{max}}) \) rounds for counting and propagating the number of edges in \( M^* \). That is, it is possible to provide each node with the value of \( 2|M^*| \) by the preprocessing of \( O(D(G) + \log n) = O(s_{\text{max}} + \log n) \) rounds. In the following argument, we denote \( s = 2s^* \), the value of which is available to each node.

## 2.4 Maximum-Matching Verification Algorithm

Our algorithm uses the algorithm by Ahmadi et al.’s [1] for maximum-matching verification as a building block. Although the original algorithm is designed for the verification of maximum matching, it provides each node with information on the length of alternating paths to the closest unmatched nodes. Precisely, the following lemma holds.

**Theorem 2** (Ahmadi et al. [1]). Assume that a graph \( G = (V, E) \) and a matching \( M \subseteq E \) are given, and let \( W \) be the set of all unmatched nodes. There exist two \( O(\ell) \)-round randomized CONGEST algorithms \( \text{MV}(M, \ell, f) \) and \( \text{PART}(M, \ell) \) that output the following information at every node \( v \in V(G) \) with a probability of at least \( 1 - 1/e^c \) for an arbitrarily large constant \( c > 1 \).

1. Given \( M \), a nonnegative integer \( \ell \), and a node \( f \in W \), \( \text{MV}(M, \ell, f) \) outputs the pair \( (\theta, r^\theta(f, v)) \) at each node \( v \) if \( r^\theta(f, v) \leq \ell \) holds (if the condition is satisfied for both \( \theta = 0 \) and \( \theta = 1 \), \( v \) outputs two pairs). The algorithm \( \text{MV}(M, \ell, f) \) is initiated only by the node \( f \) (with the value \( \ell \)), and other nodes do not require information on the ID of \( f \) and value \( \ell \) at the initial stage.

\(^2\)The indicator function \( I_X(x) \) returns one if \( x \in X \) and zero otherwise.
2. The algorithm $\text{PART}(M, \ell)$ outputs a partition $V^1, V^2, \ldots, V^N$ of $V(G)$ (as the label $i$ for each node in $V^i$) such that (a) the subgraph $G^i$ induced by $V^i$ contains exactly two unmatched nodes $f^i$ and $g^i$ as well as an augmenting path between $f^i_1$ and $g^i_2$ of length at most $\ell$ and (b) the diameter of $G^i$ is $O(\ell)$.

While the original paper [1] presents a single algorithm returning the outputs of both $\text{MV}$ and $\text{PART}$, we intentionally separate it into two algorithms with different roles for clarity. Note that our matching-construction algorithm uses random bits only in the runs of these algorithms. As our algorithm activates them in $O(\text{poly}(n))$ time as subroutines, we can guarantee that our algorithm has a high probability of success by taking a sufficiently large $c$. Hence, we do not pay much attention to the failure probability of our algorithm. Any stochastic statement in the following argument also holds with probability $1 - n^c$ for an arbitrary constant $c > 1$.

### 3 Computing the Maximum Matching in CONGEST

As explained in the introduction, the maximum matching problem is reducible to the problem of finding an augmenting path. We first present two key results below.

**Lemma 1.** Let $M$ be a matching of $G$. Provided that $(G, M)$ has exactly two unmatched nodes $f, g \in V_G$ and contains an augmenting path of length at most $\ell$ between $f$ and $g$, there exists an $O(\ell^2)$-round randomized algorithm that outputs an augmenting path connecting $f$ and $g$.

**Lemma 2.** Let $M$ be a matching of $G$. Provided that $(G, M)$ has exactly two unmatched nodes $f, g \in V_G$ and contains an augmenting path between $f$ and $g$, there exists an $O(n)$-round randomized algorithm that outputs an augmenting path that includes $f$.

The outputs of both algorithms are the labels to the edges in the computed augmented path. To prove the lemmas, one can utilize the output of the algorithm $\text{PART}$. We first run the verification algorithm $\text{PART}(M, \ell)$ (for Lemma 1) or $\text{PART}(M, \hat{s})$ (for Lemma 2) as a preprocessing step and then execute the algorithms of Lemma 1 or 2 for each $G^i$ output by $\text{PART}$ independently. Note that each $G^i$ contains only matched nodes and two unmatched nodes; thus, $|V(G^i)| \leq 2|M| + 2$ holds for any $G^i$. Then, the following corollary is deduced:

**Corollary 1.** There exist two randomized algorithms $A(M, \ell)$ and $B(M)$ satisfying the following conditions, respectively:

- For any graph $G = (V, E)$ and matching $M \subseteq E$, $A(M, \ell)$ finds a nonempty set of vertex-disjoint augmenting paths within $O(\ell^2)$ rounds if $(G, M)$ has an augmenting path of length at most $\ell$.
- For any graph $G = (V, E)$ and matching $M \subseteq E$, $B(M)$ finds a nonempty set of vertex-disjoint augmenting paths of $(G, M)$ within $O(|M|)$ rounds if $(G, M)$ has an augmenting path.

We present an $O\left(\frac{3}{2}s_{\text{max}}^{3/2} + \log n\right)$-round algorithm for computing the maximum matching using the algorithms $A(M, \ell)$ and $B(M)$. The pseudocode of the whole algorithm is presented in Algorithm 1. It basically follows the standard idea of centralized maximum matching algorithms, i.e., finding an augmenting path and improving the current matching iteratively. The first $\hat{s} - \sqrt{\hat{s}}$ iterations use $A(M, \ell)$ (lines 1–4), and the remaining $\sqrt{\hat{s}}$ iterations use $B(M)$. In the $i$-th iteration, the algorithm $A(M, \ell)$ runs with $\ell = \left[\frac{2s}{(2\hat{s} - i)}\right]$. This setting comes from Proposition 1. The improvement of the current matching by a given augmenting path is simply a local operation and is realized by flipping the labels of matching edges and non-matching edges on the path. The correctness and running time of Algorithm 1 are analyzed below.
Algorithm 1 Constructing a maximum matching in $O(n^{3/2})$ rounds.

1: for $i = 1; i \leq \hat{s} - \sqrt{\hat{s}}; i++$ do
2: run the algorithm $A(M, \ell)$ with $\ell = [2\hat{s}/(\hat{s} - i)]$ for $O(\ell)$ rounds.
3: if $A(M, \ell)$ finds a nonempty set of vertex-disjoint augmenting paths within $O(\ell)$ rounds, then
4: improve the current matching using the set of vertex-disjoint augmenting paths.
5: for $i = 1; i \leq \sqrt{\hat{s}}; i++$ do
6: run the algorithm $B(M)$ for $O(\hat{s})$ rounds.
7: if $B(M)$ finds a nonempty set of vertex-disjoint augmenting paths within $O(\hat{s})$ rounds, then
8: improve the current matching $M$ using the set of vertex-disjoint augmenting paths.

Lemma 3. Algorithm 1 constructs a maximum matching with high probability in $O\left(\left(s_{\text{max}}^{3/2} + \log n\right)\right)$ rounds.

Proof. Let $s(i)$ be the matching size at the end of $i$ iterations of the algorithm $A(M, \ell)$. We show that $s(\hat{s} - s_{\text{max}} + j) \geq j$ holds for any $0 \leq j \leq s_{\text{max}} - \sqrt{\hat{s}}$. It implies that the matching size is at least $s_{\text{max}} - \sqrt{\hat{s}}$ after the application of $A(M, \cdot)$. Therefore, the maximum matching is constructed by $\sqrt{\hat{s}}$ iterations of the algorithm $B(M)$. The proof of the statement above follows the induction on $j$.

(Basis) If $j = 0$, the statement trivially holds. (Inductive step) As the induction hypothesis, suppose $s(\hat{s} - s_{\text{max}} + j') \geq j'$ holds. If $s(\hat{s} - s_{\text{max}} + j') \geq j' + 1$, then the statement holds. Therefore, we consider the case in which $s(\hat{s} - s + j') = j'$ holds. By Proposition 1, there exists an augmenting path of length at most $2s_{\text{max}}(s_{\text{max}} - j') \leq 2s/(s_{\text{max}} - j') = 2s/(\hat{s} - (\hat{s} - s_{\text{max}} + j')) \leq 2s/(\hat{s} - (\hat{s} - s_{\text{max}} + (j'+1)))$ at the end of $\hat{s} - s_{\text{max}} + j'$ iterations of the algorithm $A(M, \ell)$. Hence, the size of the matching is increased by at least one in the $(\hat{s} - s_{\text{max}} + j' + 1)$-th iteration.

Now, we show the running-time analysis of Algorithm 1. As $A(M, \ell)$ is repeated $\hat{s} - \sqrt{\hat{s}}$ times and $B(M)$ is repeated $\sqrt{\hat{s}}$ times, the running time of Algorithm 1 is as follows.

$$O\left(s_{\text{max}} + \log n\right) + O\left(\sum_{i=1}^{\hat{s} - \sqrt{\hat{s}}} \left(\left\lfloor \frac{2\hat{s}}{\hat{s} - i}\right\rfloor \right)^2\right) + O\left(\hat{s}\sqrt{\hat{s}}\right)$$

$$= O\left(\sum_{i=1}^{\hat{s} - \sqrt{\hat{s}}} \left(\frac{\hat{s}}{\hat{s} - i}\right)^2 + \hat{s} - \sqrt{\hat{s}} + \hat{s}\sqrt{\hat{s}} + \log n\right)$$

$$= O\left(\sum_{i=\sqrt{\hat{s}}}^{\hat{s} - 1} \left(\frac{\hat{s}}{i}\right)^2 + \hat{s}\sqrt{\hat{s}} + \log n\right)$$

$$= O\left(\hat{s}^2 \sum_{i=\sqrt{\hat{s}}}^{\hat{s} - 1} \left(\frac{1}{i}\right)^2 + \hat{s}\sqrt{\hat{s}} + \log n\right)$$

$$= O\left(\hat{s}^2 \frac{1}{\sqrt{\hat{s}}} + \hat{s}\sqrt{\hat{s}} + \log n\right)$$

$$= O\left(\hat{s}^{3/2} + \log n\right)$$

$$= O\left(s_{\text{max}}^{3/2} + \log n\right).$$
The following sections are devoted to proving Lemmas 1 and 2. Since the presented algorithms are intended to run in each $G^i$ returned by the preprocessing run of PART$(M, \cdot)$, without loss of generality, we assume that $G$ has exactly two unmatched nodes $f$ and $g$ with an augmenting path between them. In addition, it is assumed that one of $f$ and $g$ is elected as a primary unmatched node (referred to as $f$ hereafter). This election process is easily implemented in $O(\ell)$ rounds because the distance between $f$ and $g$ is at most $\ell$. When we argue the existence of augmenting or alternating paths in a subgraph $H = (V(H), E(H))$ of $G$, the matching $M \cap E(H)$ of graph $H$ is considered without explicit notice. Given a subgraph $H \subseteq G$, we denote the length of the shortest odd (even) alternating path from $f$ to $v$ in $H$ by $r^1_H(f, v)$ ($r^0_H(f, v)$). If no odd or even alternating path exists from $f$ to $v$ in $H$, then we define $r^1_H(f, v) = \infty$ or $r^0_H(f, v) = \infty$. As sentinels, we also define $r^0_H(f, f)$ as $\infty$ and $r^1_H(f, f)$ as 0.

## 4 Construction of Augmenting Path in $O(\ell^2)$ Rounds

### 4.1 Outline

Let $P = v_0, v_1, \ldots, v_\ell$ be the shortest augmenting path from $f$ to $g$ (i.e., $f = v_0$ and $g = v_\ell$) and $P_i = P_{v_i}$ for short. The key idea of the algorithm is to find the predecessor of each node $v_i$ along $P$ sequentially. Note that it does not suffice to choose a neighbor $v$ of $v_i$ with $r^0_G(f, v) = i$ and $I_M(v_i, v) = 0$ for $\theta = (i - 1) \mod 2$ as the predecessor. This strategy is problematic in the scenario in which there exists two neighbors $v$ and $u$ such that $r^0_G(f, v) = r^0_G(f, u) = i - 1$ and $I_M(v_i, u) = I_M(v_i, v) = 0$ for $\theta = (i - 1) \mod 2$, where $u$ is the correct successor. While $v$ is guaranteed to have the alternating path $Q$ from $f$ to $v$ of length $i - 1$, it can intersect $P_i$. Then, the concatenation $Q \circ (v_i, v) \circ P_i$ is not simple. That is, it is not an augmenting path. To avoid this scenario, the algorithm finds the predecessor of $v_i$ in the graph $G - P_i$, where $G - P_i$ is the induced graph by $V(G) \setminus V(P_i)$. If some neighbor $v$ of $v_i$ satisfies $r^0_{G - P_i}(f, v) = i - 1$ and $I_M(v_i, v) = 1 - \theta$, the concatenated walk $Q \circ (v_i, v) \circ P_i$ is guaranteed to be simple.

---

**Algorithm 2** Construction of the augmenting path $CAP((G, M), f, g, \ell)$ for node $v_i$.

**Require:** The path $P_0$ is an augmenting path with length $\ell$ from $f$ to $g$.

1: $P_0, P_1, \ldots, P_\ell$: initially $\emptyset$.
2: $\text{target} = g$
3: for $i = 1; i \leq \ell; i += 1$ do
4:   if $h$ is even then
5:     $\text{target}$ chooses the node $v_{\ell-i}$ that satisfies $I_M((\text{target}, v_{\ell-i})) = 1$.
6:     $P_{\ell-i} \leftarrow P_{\ell-i+1} \cup \{(\text{target}, v_{\ell-i})\}$.
7:     $\text{target} \leftarrow v_{\ell-i}$.
8: else
9:   run the algorithm MV($M, \ell - i, f$) with the subgraph $H_{\ell-i+1}$ induced by $V(G - P_{\ell-i+1})$ as the input.
10:   for any $v \in V(G - P_{\ell-i+1})$, the node $v$ sends $r^0_{H_{\ell-i+1}}(f, v)$ to its neighborhood.
11:   $\text{target}$ chooses the node $v_{\ell-i}$ that satisfies $I_M((\text{target}, v_{\ell-i})) = 0$ and $r^0_{H_{\ell-i+1}}(f, v_{\ell-i}) = \ell - i$.
12:   $P_{\ell-i} \leftarrow P_{\ell-i+1} \cup \{(\text{target}, v_{\ell-i})\}$.
13: $\text{target} \leftarrow v_{\ell-i}$.
4.2 Algorithm Details

Algorithm 2 details the algorithm for constructing the augmenting path in $O(\ell^2)$ rounds. The algorithm consists of $\ell$ steps. In the $i$-th step, it finds the predecessor of $v_\ell-1$. Assume that the algorithm has already found $P_{\ell-i+1}$ at the beginning of the $i$-th step. Any node in $V(P_{\ell-i+1}) \setminus \{v_{\ell-i+1}\}$ quits the algorithm (with the information of the predecessor in $P_1$), and thus, the nodes still running the algorithm are given by $V(G - P_{\ell-i+1})$. If $i$ is even, the edge $(v_{\ell-i}, v_{\ell-i+1})$ is the matching edge, and thus, the algorithm determines the neighbor of $v_{\ell-i+1}$ connected by the edge with $M$ as the predecessor. Otherwise, the nodes still participating in the algorithm run $MV(M, \ell - i + 1, f)$ (that is, they run in the graph $G - P_{\ell-i+1}$) The algorithm decides an arbitrary neighbor $v$ of $v_i$ satisfying $r^0_{G-P_{\ell-i+1}}(f, v) = \ell - i - 1$ and $\theta_M(v, v_i) = 0$ as the predecessor of $v_{\ell-i}$.

**Lemma 4.** Algorithm 2 constructs an augmenting path between $f$ and $g$ with high probability in $O(\ell^2)$ rounds.

**Proof.** Let $z_0 = g$ and $z_i$ be the node that satisfies $\text{target} = z_i$ at the end of the $i$-th iteration for $1 \leq i \leq \ell$. Let $H_i$ be a subgraph induced by $V(G - P_i)$. We prove the statement that $P_{\ell-i}$ is a $(h \mod 2)$-alternating path between $z_0$ and $z_h$. As $r^0_G(f, z_\ell) = r^0_{H_0}(f, z_\ell) = 0$, $z_\ell = v$ holds, and thus, we obtain $P_0$ as an augmenting path of length $\ell$ from $f$ to $g$ by setting $h = \ell$. The proof follows the induction on $h$. (Basis) Since $z_0$ chooses the node $z_1$ that satisfies $\theta_{M}\left((\text{target}, v_{\ell-1})\right) = 0$ and $r^0_{H_{\ell}}(f, v_{\ell-1}) = \ell - 1$ in the first iteration of Algorithm 2. $P_{\ell-1} = \{(z_0, z_1)\}$ is a 1-alternating path between $z_0$ and $z_1$. (Inductive Step) As the induction hypothesis, suppose there exists a $(h' \mod 2)$-alternating path between $z_0$ and $z_{h'}$ at the end of the $h'$-th iteration. Because $r^0_{H_{\ell-h'+1}}(f, z_{h'}) = \ell - h'$ holds by the definition of $z_{h'}$, there exists an edge $(z_{h'}, v)$ that satisfies $\theta_{M}(z_{h'}, v) = h' \mod 2$, and $r^0_{H_{\ell-h'+1}}(f, v) = \ell - h' - 1$ holds. Therefore, $z_{h'}$ can choose the node $z_{h'+1}$ that satisfies $\theta_{M}(z_{h'+1}) = h' \mod 2$ and $r^0_{H_{\ell-h'+1}}(f, z_{h'+1}) = \ell - h' - 1$ in the $(h'+1)$-th iteration of Algorithm 2. Hence, $P_{\ell-h'} \circ \{(z_{h'}, z_{h'+1})\}$ is a $(h' + 1 \mod 2)$-alternating path between $z_0$ and $z_{h'+1}$ at the end of the $(h'+1)$-th iteration.

We show the running-time analysis of Algorithm 2. The algorithm consists of $\ell$ iterations. As each iteration is obliviously implemented in $O(\ell)$ rounds, the running time of Algorithm 2 is $O(\ell^2)$ rounds.

Theorem 3 trivially follows from Lemma 4.

5 Construction of Augmenting Path in $O(n)$ Rounds

5.1 Outline

We first introduce several auxiliary notions and definitions. Given a subgraph $H \subseteq G$ and $\theta \in \{0, 1\}$, a node $v \in V_H$ is called $\theta$-reachable in $H$ if $r^\theta_H(f, v)$ is finite. In addition, $v$ is called $\theta$-reachable in $H$ if it is both $1$-reachable and $0$-reachable in $H$. A node that is neither $1$-reachable nor $0$-reachable in $H$ is called unreachable in $H$. A node that is $\theta$-reachable for some $\theta \in \{0, 1\}$ in $H$ but not $bireachable$ in $H$ is called strictly $\theta$-reachable in $H$. Given two spanning subgraphs $H_1$ and $H_2$ of $G$, we say that a node $v \in V(H_1)$ preserves the reachability of $H_2$ in $H_1$ if for any $\theta \in \{0, 1\}$, the $\theta$-reachability of $v$ in $H_2$ implies that in $H_1$. A graph $H_1$ is said to preserve the reachability of $H_2$ if any node $v \in V(H_1)$ preserves the reachability of $H_2$ in $H_1$, which is denoted by $H_1 \searrow H_2$. We define $r_{H}(f, v) = \min_{\theta \in \{0, 1\}} r^\theta_H(f, v)$ and $\gamma_{H}(v) = \arg\min_{\theta \in \{0, 1\}} r^\theta_H(f, v)$. Note that $r^0_{H}(f, v) = r^1_{H}(f, v)$ does not hold, because $r^0_{H}(f, v)$ is even and $r^1_{H}(f, v)$ is odd. When $r^0_{H}(f, v) = \infty$ and $r^1_{H}(f, v) = \infty$ hold, $\gamma_{H}(v)$ is defined as zero. We assume that any node $v$ unreachable from $f$ in $G$ does not join
Figure 1: Examples of the alternating base tree. Bold lines are matching edges, and thin lines are unmatched edges.

our algorithm. Therefore, without loss of generality, we assume that none of the nodes \( v \in V_G \) are unreachable in \( G \) without loss of generality. In addition, we assume that any node \( v \in V_G \) has information on the values of \( r^0_G(f, v) \) and \( r^1_G(f, v) \) at the beginning of the algorithm. This assumption is realized by activating MV(\( M, n, f \)) as a preprocessing step.

The key idea of our proof is to construct a sparse certificate \( H \), which is a spanning subgraph \( H \subseteq G \) of \( O(n) \) edges satisfying \( H \succ G \). If such a graph is obtained, the trivial centralized approach (i.e., the approach in which \( f \) collects the whole topological information of \( H \)) yields an \( O(n) \)-round algorithm for constructing the augmenting path. For constructing sparse certificates, we first introduce a novel tree structure associated with \( G \), \( M \), and \( f \):

**Definition 1 (Alternating base tree).** An alternating base tree for \( G \), \( M \), and \( f \) is the rooted spanning tree \( T \) of \( G \) satisfying the following conditions:

- \( f \) is the root of \( T \).
- For any \( v \in V(G) \), the edge from \( v \) to its parent in \( T \) is the last edge of the shortest alternating path from \( f \) to \( v \) in \( G \). Formally, letting \( \text{par}_T(v) \) be the parent of \( v \in V(G) \setminus \{f\} \) in \( T \),
  \[
  r_G^{\text{sc}}(f, v) = r_G^{1-\gamma_G(v)}(f, \text{par}_T(v)) + 1 \quad \text{and} \quad I_M((v, \text{par}_T(v))) = 1 - \gamma_G(v) \hold \text{for any } v \in V(G) \setminus \{f\}.
  \]

It is not difficult to check that such a spanning tree always exists. As a node might have two or more shortest alternating paths, \( T \) is not uniquely determined (see Figure 1 (1) and (2) for examples). In the following argument, however, we fix an arbitrarily chosen alternating base tree \( T \). It should be emphasized that the alternating base tree does not necessarily contain an alternating path from \( f \) to each node \( v \). For example, both alternating base trees in Figure 1 have no alternating path from \( f \) to \( v_9 \).

Fixing \( T \), the subscript \( T \) of the notation \( \text{par}_T(v) \) is omitted in the following argument. We define \( \text{ep}(v) \) as the edge from \( v \) to its parent and \( T_v \) as the subtree of \( T \) rooted by \( v \). Any non-tree edge \( e = (u, w) \in E(G) \setminus E(T) \) and the unique path from \( u \) to \( w \) in \( T \) form a simple cycle in \( G \), which is denoted by \( \text{cyc}(e) \).

The sparse certificate is obtained by incrementally augmenting edges to \( T \). For any \( 1 \leq k \leq n \), we define the **level-k edge set** \( F_k \) as \( F_k = \{ (u, v) \mid (u, v) \in E(G) \setminus M \land \max(r^0_G(f, u), r^0_G(f, v)) = 
\]

10
This condition is satisfied. That is, any edge $e$ from $T$ from $\gamma$ concatenated path $r$ the induction hypothesis yields $w$ holds. Therefore any node $G$ tree of $k_1 = 1$, $G$ is a subset of $E(T)$ because $T$ is a spanning tree of $G$. The following lemma is the key technical ingredient of our construction.

Lemma 5. Let $F^c_k \subseteq F_k \setminus E(T)$ be an arbitrary subset of non-tree edges in $F_k$ satisfying $B_{k-1} \setminus B_k \subseteq \cup e \in F^c_k E(cyc(e))$. Then, $(T + \cup_{1 \leq i \leq k} F^c_i) > G_k$ holds. In addition, the edge set $F^c = \cup_{0 \leq i \leq k} F^c_i$ contains at most $n-1$ edges.

This lemma naturally yields the following incremental construction of sparse certificates: each node $v$ identifies $k$ such that $\text{ep}(v) \in B_{k-1} \setminus B_k$ holds, and if $T_v$ has an outgoing edge $e$ belonging to $F_k$, $v$ adds $e$ to $F^c_k$ (if $F_k$ contains two or more outgoing edges, one is chosen arbitrarily). Since $cyc(e)$ obliviously covers $\text{ep}(v)$, the constructed edge set $F^c_k$ satisfies the lemma. Consequently, $H = T + \cup_{1 \leq i \leq n} F^c_i > G_n$ is satisfied, and thus, $H$ is a sparse certificate.

Considering the distributed construction of $H$, a useful property of Lemma 5 is that one does not have to wait for the computation of $F^c_k$ to start the computation of $F^c_{k+1}$. As the information on $r^\theta_G(f, v)$ for $\theta \in \{0, 1\}$ is available to $v$, each node can identify the level of each incident edge. Thus, the construction of $F^c_k$ for all $k$ can be executed in parallel. The details of the distributed construction is explained in Section 5.3.

5.2 Proof Details

Before proving Lemma 5 we prove an auxiliary lemma.

Lemma 6. For any $\theta \in \{0, 1\}$ and $v \in V(G) \setminus \{f\}$ such that $r^\theta_G(f, v) \leq k + 1$ holds, $r^\theta_{G_k}(f, v) = r^\theta_G(f, v)$ holds for all $k' \geq k$.

Proof. The proof is based on induction on $k$. (Basis) $k = 0$: Let $v$ be any node satisfying $r^\theta_G(f, v) \leq k + 1$ for some $\theta \in \{0, 1\}$, and let $Q$ be the $\theta$-shortest path from $f$ to $v$ in $G$. This path is contained in $T$ because $v$ chooses $f$ as its parent in $T$. (Inductive Step): As the induction hypothesis, suppose $r^\theta_{G_{k-1}}(f, u) = r^\theta_G(f, u)$ holds (and also $r^\theta_{G_k}(f, u) = r^\theta_G(f, u)$ holds because of $G_{k-1} \subseteq G(k)$ for any $u$ and $\theta$ satisfying $r^\theta_G(f, u) \leq k$). Consider any node $v$ such that $r^\theta_G(f, v) \leq k + 1$ holds. As the case of $r^\theta_G(f, v) < k + 1$ is evidently proved by the induction hypothesis, we assume $r^\theta_G(f, v) = k + 1$. The proof consists of the following two cases.

(Case 1) $\gamma_G(v) = \emptyset$: By the definition of alternating base trees, we have $r^1_{G}(f, \text{par}(v)) = r^1_{G}(f, v) - 1 = k$. In addition, for any $w \in T$, $r^\theta_G(w)(f, w) = r^\gamma_{G}(w)(f, \text{par}(w)) + 1 > r^\gamma_{G}(\text{par}(w))(f, \text{par}(w))$ holds. Therefore any node $w \in T_v$ satisfies $r^\gamma_{G}(w)(f, w) \geq k + 1$. Then, any outgoing non-tree edge of $T_v$ has a level of at least $k + 1$. That is, $\text{ep}(v)$ is the bridge in $G_k$. Since $r^1_{G}(f, \text{par}(v)) = k$ holds, the induction hypothesis yields $r^1_{G}(f, \text{par}(v)) = k$ and thus there exists a $(1 - \theta)$-alternating path $P$ from $f$ to $\text{par}(v)$ in $G_k$. Due to the fact that $\text{ep}(e)$ is a bridge, $P$ does not contain $v$. Hence the concatenated path $P \circ \text{ep}(e)$ is a $\theta$-alternating path from $f$ to $v$ in $G_k$ of length $k + 1$. That is, $r^\theta_{G_k}(f, v) = r^\theta_G(f, v)$ holds.

(Case 2) $\gamma_G(v) = 1 - \theta$: Let $Q = v_0, e_1, v_1, e_2, \ldots, e_{k+1}, v_{k+1}$ be the shortest $\theta$-alternating path from $f$ to $v$ in $G$ ($f = v_0$ and $v = v_{k+1}$). To prove the lemma, it suffices to show that any edge in $Q$ has a level of at most $k$ or is an edge in $E(T)$. Suppose for contradiction that a non-tree edge $e_j$ has the level $k' > k$. Without loss of generality, we assume that $j$ is the highest value for which this condition is satisfied. That is, any edge $e_{j'}$ for $j' > j$ has a level of at most $k$ or an edge in $T$. We define $\rho$ as $I_M(e_j)$. We further divide Case 2 into the following three subcases.
(Case 2a) \( j = k + 1 \): Since \( Q \) is the shortest \( \theta \)-alternating path of length \( k + 1 \), \( \rho = 1 - \theta \) holds, and \( Q^\rho_{v_k} \) is a \((1 - \theta)\)-alternating path from \( f \) to \( v_k \) of length \( k \). From the condition \( \gamma_G(v) = \gamma_G(v_{k+1}) = 1 - \theta \) for Case 2, \( r^1_G(f, v_k) \leq k \) and \( r^1_G(f, v_{k+1}) < r^\theta_G(f, v_{k+1}) = k + 1 \) hold. That is, the level of \( e_j = e_{k+1} \) is at most \( k \), which is a contradiction.

(Case 2b) \( j < k + 1 \) and \( \rho = 1 \): Since the length of \( Q^\rho_{v_j} \) is \( j \), we have \( r^\rho_G(f, v_j) \leq j \). From the induction hypothesis, \( G_{k-1} \) contains a 0-alternating path \( Q' \) from \( f \) to \( v_j \). In other words, \( v_j \) has a 0-alternating path \( Q' \) such that any non-tree edge in \( E(Q') \) has a level of at most \( k \). The assumption of \( \rho = 1 \) implies that \( Q' \) must terminate with a matching edge incident to \( v_j \), i.e., the edge \( e_j \). This is a contradiction because we assume that \( e_j \) is not contained in \( G_{k-1} \).

(Case 2c) \( j < k + 1 \) and \( \rho = 0 \): We denote \( R = Q_{v_j}^\rho \) as shorthand. As the length of \( Q^\rho_{v_j} \) is \( j \), from the induction hypothesis, we have \( r^1_{G^\rho}(f, v_j) = r^1_G(f, v_j) \leq j \), and thus, there exists the shortest 1-alternating path \( P \) from \( f \) to \( v_j \) in \( G_k \). Let \( v_h \in V(R) \cap V(P) \) be the first node in \( P \), which also belongs to \( R \). If \( e_{h+1} \) is a matched edge, \( P^\rho_{v_h} \circ Q_{v_h}^\rho \) is a \( \theta \)-alternating path in \( G_k \) (see Figure 3(a)), the length of which is bounded by \( |P^\rho_{v_h} \circ Q_{v_h}^\rho| \leq |P| + (k + 1 - h) \leq j + (k + 1 - j) \leq k + 1 \). Hence, we obtain \( r^\theta_{G_k}(f, v_k) \leq k + 1 = r^\theta_G(f, v_{k+1}) \), which is a contradiction. If \( e_{h+1} \) is an unmatched edge, \( e_h \) is a matched edge. Therefore, \( P^\rho_{v_h} \circ P^\rho_{v_h} \) is a 0-alternating path from \( f \) to \( v_j \) in \( G_k \) (see Figure 3(b)). But, we consider the case of \( \rho = 0 \), the edge \( e_j \) is an unmatched edge. Therefore, \( v_h \neq v_j \) holds, and thus \( v_h \) is not the last node of \( P \). This implies \( |P^\rho_{v_h}| \leq |P| - 1 \). We obtain \( |P^\rho_{v_h} \circ P^\rho_{v_h}| \leq |P| - 1 + (k + 1 - h) \leq j - 1 + (k + 1 - j) \leq k \), and thus, \( r^0_G(f, v_j) \leq r^0_{G_k}(f, v_j) \leq k \). Since \( Q_{v_j}^\rho \) is a 0-alternating path from \( f \) to \( v_j \), of length \( j - 1 \), we have \( r^0_{G_k}(f, v_{j-1}) \leq j - 1 \leq k \). This implies that the level of \( e_{v_j} \) is at most \( k \), which is a contradiction. \( \square \)

Now, we present the proof of Lemma 5.

Proof. Let \( F^c_{\leq k} = \cup_{1\leq i\leq k} F^c_i \) and \( H_k = T + F^c_{\leq k} \). We prove the lemma inductively. For \( k = 0 \), \( H_0 = T \supseteq G_0 = T \) evidently holds. Thus, it suffices to show \( H_k \supseteq G_k \), assuming \( H_{k'} \supseteq G_{k'} \) for all \( 0 \leq k' < k \). For any \( 0 \leq h \leq n \), we define \( U_h = \{ (v, \theta) \mid v \in V(G) \land r^\theta_G(f, v) = h \} \). If \( v \) is \( \theta \)-reachable in \( H_k \) for all \( 0 \leq h \leq n \) and \( (v, \theta) \in U_h \), we can conclude that \( H_k \supseteq G_k \). The proof of this statement follows the (nested) induction on \( h \). (Basis) As \( U_0 \) contains only \((f, 1)\), the statement evidently holds. (Inductive Step) As the induction hypothesis, suppose \( v \) is \( \theta \)-reachable for any \( (v, \theta) \in \cup_{0\leq h\leq n} U_h \), and consider any pair \((v, \theta)\) in \( U_{h+1} \). Then, we consider the following two cases.

(Case 1) \( ep(v) \) is a bridge in \( G_k \): We have \( r^{1-\theta}_G(f, \text{par}(v)) = h \) from the definition of alternating base trees. Since the induction hypothesis guarantees that \( \text{par}(v) \) preserves the reachability of \( G_k \) in \( H_k \), there exists a \((1 - \theta)\)-alternating path \( P \) from \( f \) to \( \text{par}(v) \) in \( H_k \). In addition, \( P \) does not
contain $\mathbf{ep}(e)$, because $\mathbf{ep}(e)$ is a bridge in $H_k \subseteq G_k$. From $I_M(\mathbf{ep}(v)) = 1 - \theta$, which directly follows from the definition of alternating base trees, the concatenated path $P \circ \mathbf{ep}(v)$ becomes a $\theta$-alternating path from $f$ to $v$ in $H_k$ (see Figure 4(1)). Then, $v$ is $\theta$-reachable in $H_k$.

**Case 2** $\mathbf{ep}(v)$ is not a bridge in $G_k$: As $G_0 \subseteq G_1 \subseteq \ldots \subseteq G_k$ holds, there exists $1 \leq j \leq k$ such that $\mathbf{ep}(G) \in B_{j-1} \setminus B_j$ holds. Then, $P_j^c$ contains an outgoing edge $e$ of $T_v$ belonging to $F_j$. Let $e = (u, w)$ and $u$ be the side contained in $T_v$. We assume that $e$ is not a matching edge. By symmetry, the case of $e \in M$ is proved similarly. From the definition of $F_j$, we have $\max\{r_G^1(f, u), r_G^1(f, w)\} = j \leq k$. Lemma 4 implies that both $u$ and $w$ have 1-alternating paths from $f$ in $G_{j-1}$; from the induction hypothesis $H_{j-1} \supseteq G_{j-1}$, they have 1-alternating paths from $f$ also in $H_{j-1}$, which we refer to as $P$ and $Q$, respectively. Since $\mathbf{ep}(v)$ is a bridge of $G_{j-1} \supseteq H_{j-1}$, the suffix $P_v^c$ is a subgraph of $T_v$. In addition, $Q$ does not intersect $V(T_v)$, because both $f$ and $w$ are outside $T_v$. Thus, $P_v^c$ and $Q$ are mutually disjoint, and the concatenated path $Q' = Q \circ (w, u) \circ P_v^c$ is simple. It is easy to check that $Q'$ is an alternating path from $f$ to $v$. As $Q$, $e$, and $P_v^c$ are all contained in $H_{j-1} + F_j^c = H_j$, $P_v^c$ and $Q'$ are contained in $H_j$ (see Figure 4(2)). The alternating paths $P_v^c$ and $Q'$ have different parities because their last edges are adjacent in $P$. Hence, we conclude that $v$ is bireachable in $H_j$.

The remaining matter in the proof is to provide a bound on the size of $\cup_{0 \leq i \leq n-1} F_i^c$. Because $G_k \subseteq G_{k+1}$ holds for any $0 \leq k \leq n - 1$, we have $B_{k+1} \subseteq B_k$, which implies that $B_k \setminus B_{k+1}$ for all $k$ are mutually disjoint. Then, $\sum_{0 \leq i \leq n-1} |B_k \setminus B_{k+1}| = |B_0| = n - 1$ holds. Since at most one edge is augmented for each edge in $B_k \setminus B_{k+1}$, the size $|\cup_{0 \leq i \leq n-1} F_i^c|$ is also bounded by $n - 1$. \hfill \Box
5.3 Distributed Implementation

This section explains how to implement the centralized sparse certificate algorithm, presented in Section 5.1, in the CONGEST model to obtain the algorithm of Theorem 2. It is relatively straightforward to construct the alternating base tree $T$. From the preprocessing run of $MV(M, n, f)$, each node $v$ has information on the values of $r_G^1(f, v)$ and $r_G^0(f, v)$; thus, it has information on $\gamma_G(v)$ as well. Then, $v$ chooses an arbitrary neighbor $u$ of $v$ satisfying the second condition of the alternating base tree as its parent (i.e., it chooses $(v, u)$ as an edge of $T$). Algorithm 3 presents the pseudocode of the alternative base tree construction. This algorithm is a local algorithm, which is implemented in zero round.

The main idea of constructing the edge set $F_c = \bigcup_{1 \leq i \leq n} F_i^c$ in the distributed manner is implemented by the CONGEST algorithm $\text{ConstF}(k)$, where each node $v$ outputs an outgoing edge of $T_v$ of level $k$ if it exists (or $\perp$ otherwise). Let $d$ be the height of the constructed alternating base tree $T$. Given a non-tree edge $e = (u, w) \in E(G) \setminus E(T)$, the depth of the lowest common ancestor of $u$ and $w$ is denoted by $\text{lca}(e)$. In addition, we introduce the ordering relation $\leq_{\text{lca}}$ over all non-tree edges as $e_1 \leq_{\text{lca}} e_2$ if and only if $\text{lca}(e_1) \leq \text{lca}(e_2)$. The algorithm $\text{ConstF}$ works under the assumption that for any non-tree edge $e = (u, v)$, $u$ and $v$ have information on the value of $\text{lca}(e)$. This assumption is realized by the following $O(d)$-round preprocessing.

1. Each node $v$ computes its depth $d_v$ in $T$ through a downward message propagation from $f$ along $T$. The root $f$ first sends to its children the value one. The node $v$ receiving message $i$ decides $d_v = i$ and sends the value $i + 1$ to its children.

2. Each node $v$ broadcasts the pair of its ID and depth $(v, d_v)$ to all the nodes in $T_v$. First, each node sends the pair to its children. In the following rounds, each node forwards the message from its parents to the children. This task finishes within $O(d)$ rounds.

3. The broadcast information of the previous step allows each node $v$ to identify the path $p_T(v)$ from $v$ to $f$ in $T$. For all non-tree edges $e = (u, v)$, $u$ and $v$ exchange $p_T(v)$ (taking $O(d)$ rounds) and compute the value of $\text{lca}(e)$.

The pseudocode of Algorithm $\text{ConstF}(k)$ is presented in Algorithm 4. Let $E^*(T_v)$ be the set of non-tree edges $e$ such that at least one endpoint of $e$ belongs to $V(T_v)$. Each node $v$ computes the minimum edge $e_v \in E^*(T_v) \cap F_k$ with respect to $\leq_{\text{lca}}$. This task is implemented through a standard...
Algorithm 3 Construction of the alternating base tree for $v_i$: ABT($(G, M)$)

Require: The graph induced by the edge set $\bigcup_{v_i \in V} E_i$ is an alternating base tree.
1: $E_i$: initially $\emptyset$.
2: if $v \neq f$ then
3: choose edge $(u, v)$ that is incident on the vertex $v$ and satisfies $r^\gamma(v)(f, v) = r^\gamma(v)(f, u)$ and $I((u, v)) = 1 - \gamma(v)$ (if multiple edges satisfy these conditions, the node arbitrarily chooses one).
4: $E_i \leftarrow E_i \cup (u, v)$.

Algorithm 4 Construction of $F^c_k$ for $v_i$: ConstF($k$)

Require: The edge $e_i$ is an outgoing edge of $T_{v_i}$ if node $v_i$ outputs $e_i$; otherwise, $T_{v_i}$ does not have an outgoing edge.
1: for $i = 1; i \leq d; i + +$ do
2: if $v_i$ is a leaf node then
3: if $I(v_i) \cap F_k \cap E^*(T_v) = \emptyset$ then
4: $e_{v_i} \leftarrow$ dummy edge $e$ such that $lca(e) = \infty$.
5: else
6: $e_{v_i} \leftarrow \min_{e \in I(v_i) \cap F_k \cap E^*(T_{v_i})} e$ w.r.t. $\leq_{lca}$.
7: if $v_i \neq f$ then
8: send $e_{v_i}$ to its parent.
9: else
10: if $v_i$ receives the set of edges $X$ from all its children then
11: $e_{v_i} \leftarrow \min_{e \in X \cup (I(v_i) \cap F_k \cap E^*(T_{v_i}))} e$ w.r.t. $\leq_{lca}$.
12: if $lca(e_{v_i}) \leq d(v_i)$ then
13: output $e_{v_i}$.
14: else
15: output $\bot$.

aggregation over $T$. Each leaf node $v$ sends the minimum edge $e$ in $F_k \cap E^*(T_v)$. If $F_k \cap E^*(T_v) = \emptyset$ holds, the leaf sends a dummy edge $e$ such that $lca(e) = \infty$ holds (the edge sent to the parent is implicitly associated with the value of $lca(e)$ to admit the comparison based on $\leq_{lca}$). Let $X$ be the set of edges a non-leaf node $v$ received from its children. Then, $v$ chooses $e_v$ as the minimum edge in $X \cup (I(v) \cap F_k \cap E^*(T_v))$ with respect to $\leq_{lca}$ and sends the chosen edge to $\par(v)$. Finally, $v$ outputs $e_v$ if $lca(e_v) < d_v$ holds or $\bot$ otherwise. The correctness of ConstF($k$) follows the proposition below.

Proposition 3. Let $e$ be the minimum edge in $E^*(T_v)$ with respect to $\leq_{lca}$. Then, $e$ is an outgoing edge of $T_v$ if and only if $lca(e) < d_v$ holds (thus, $ep(v)$ is a bridge if $lca(e) \geq d_v$ holds).

The edge set $F^c_k$ is constructed by running ConstF($k$) for all $1 \leq k \leq n$. As this algorithm is implemented by one-shot aggregation over $T$, one can utilize the standard pipelining technique for completing ConstF($k$) for all $1 \leq k \leq n$, which takes $O(n)$ rounds in total (including the preprocessing step of computing $lca(e)$). The result of ConstF provides node $v$ with the information of the minimum $k$, such that $ep(v) \in B_{k-1} \setminus B_k$, as well as an outgoing edge of $T_v$ in $F_k$. Following Lemma each node $v$ can decide the edge $e$ that should be added to $F^c = \bigcup_{1 \leq i \leq n} F^c_i$.

6 Conclusion

We proposed the randomized $O(s_{\text{max}}^{3/2} + \log n)$-rounds (i.e. $O(n^{3/2})$-rounds) algorithm for computing a maximum matching in the CONGEST model, which is the first one of attaining $o(n^2)$-round complexity for general graphs. Our algorithm follows the standard augmenting-path approach, and the technical core lies two fast algorithms of finding augmenting paths respectively running in $O(\ell^2)$ and $O(s_{\text{max}})$ rounds.

While we believe that our result is a big step toward the goal of revealing the tight round complexity of the exact maximum matching problem, the gap between the upper and lower bounds are still large. It should be noted that we leave the possibility of much faster augmenting path algorithms. Once an $o(\ell^2)$-round or $o(s_{\text{max}})$-round algorithm of finding an augmenting path is invented, the upper bound automatically improves. This direction is still promising.
