Abstract

Scaling functions, $F_+ (\omega/\omega_c^+)$ and $F_- (\omega/\omega_c^-)$ for $\phi > \phi_c$ and $\phi < \phi_c$, respectively, are derived from an equation for the complex conductivity of binary conductor–insulator composites. It is shown that the real and imaginary parts of $F_\pm$ display most properties required for the percolation scaling functions. One difference is that, for $\omega/\omega_c < 1$, $\Re F_-(\omega/\omega_c)$ has an $\omega$-dependence of $(1 + t)/t$ and not $\omega^2$ as previously predicted, but never conclusively observed. Experimental results on a Graphite-Boron Nitride system are given which are in reasonable agreement with the $\omega(1+t)/t$ behaviour for $\Re F_-$. Anomalies in the real dielectric constant just above $\phi_c$ are also discussed.

1 Introduction

The ac and dc conductivities of resistor and resistor-capacitor (R-C) networks and continuum conductor-insulator composites have been extensively studied for many years. In systems where there is a very sharp change (metal-insulator transition or MIT) in the dc conductivity at a critical volume fraction or percolation threshold denoted by $\phi_c$, the most successful model, for both the dc and ac properties, has proved to be percolation theory. Early
work concentrated on the dc properties, but since it was realized \cite{1}–\cite{6} that
the percolation threshold is a critical point, and that the percolation equations could be arrived at from a scaling relation, several papers, which are
referenced and discussed in a previous paper \cite{7}, reporting experimental results on the ac conductivity have appeared. Review articles, containing the
theory and some experimental results, on the complex ac conductivity and
other properties of binary metal-insulator systems include \cite{8}–\cite{10}.

In another paper, extensive dc conductivity and low frequency dielectric
constant results on systems based on Graphite (G) and hexagonal Boron Ni-
tride (BN), which have what are probably the cleanest and sharpest dc MITs
yet observed in a continuum system, have been reported \cite{11, 12}. These G-
BN results were found to obey the percolation equations, as a function of
volume fraction in \cite{11, 12}. In \cite{7} it was shown that the experimental disper-
sion results, for samples with various volume fractions of G, can be scaled
onto two curves which are consistent with previously measured percolation
parameters \cite{11, 12}; one curve refers to the real conductivity above and the
other to the imaginary conductivity (real dielectric constant) below the criti-
cal volume. Unfortunately, the parameters $\omega_c^\pm$ that had to be used to achieve
this scaling were found to be different from those expected from the scaling
models (R-C lattice \cite{8} and anomalous diffusion \cite{13}), no matter whether the
$\omega_c^+$ and $\omega_c^-$ were calculated using the accepted universal parameters or the
already reported dc conductivity and low frequency dielectric results \cite{11, 12}.
However, there is agreement between the critical exponents, characterising the frequency dependence of the real conductivity when $\phi > \phi_c$ (where $\phi$ denotes the conducting volume fraction), the imaginary conductivity for $\phi < \phi_c$ and the exponents found from the previously reported dc and low frequency ac results [11, 12].

One measurable scaling function that did not agree with the previous power law predictions [8]–[10] was that for the loss component in the insulating region. As these results were somewhat controversial they were not discussed in [7]. In the meantime further measurements have been made on one of the $G - BN$ systems [11, 12] and other systems, using a recently acquired dielectric spectrometer system which is able to measure far smaller dielectric loss parameters as well as loss and phase angles. Some of these results are presented in this paper.

The present paper introduces scaling functions which can depend on complex conductivities. They closely fit results of the medium conductance $\sigma_M$, in particular the frequency ($\omega$) dependence of the first order real part for $\phi > \phi_c$ and the first order imaginary part for $\phi < \phi_c$ as was shown in [7]. Most of the scaling power laws given in [8]-[10] are obtained, the range of parameters over which these functions can be expected to generate accurate scaling functions is derived. It is also shown that, while the second order terms of the scaling functions have the exponents $t/(s + t)$ for $\phi \approx \phi_c$ and $\omega/\omega_c \gg 1$ as given in [8]-[10], the second order exponents for low frequencies
and $\phi \geq 0$ or $\phi \leq 1$ differ from those of \[8\]-\[10\]. New experimental results for $\sigma_M(\omega, \phi)$ are presented which agree reasonably well with the exponents predicted by the new scaling functions, provided that the complex conductivities of the dielectric components of the continuum systems are taken into account. The measurements for $\sigma_M(\phi < \phi_c)$ in the G-BN systems are definitely not in accord with the $\omega^2$ prediction given in \[8\]-\[10\].

A feature of the new experimental results is that, where measurable, the real dielectric constant continues to increase with $\phi$ for $\phi > \phi_c$ and certainly does not decrease according to $(\phi - \phi_c)^{-s}$ as given in \[8\]-\[10\]. However this increase is qualitatively consistent with the expressions introduced in this paper. The effect is more clearly observed in carbon black–polyethylene compounds \[14\] and in 3D-systems where various conducting powders are distributed on the surfaces of large insulating grains \[15\].

2 Theory

The equation

$$\frac{(1 - \phi)(\sigma_I^{1/s} - \sigma_M^{1/s})}{(\sigma_I^{1/s} + A\sigma_M^{1/s})} + \frac{\phi(\sigma_C^{1/t} - \sigma_M^{1/t})}{(\sigma_C^{1/t} + A\sigma_M^{1/t})} = 0$$

(1)

gives a phenomenological relationship between $\sigma_C$, $\sigma_I$ and $\sigma_M$ which are the conductivities of the conducting and insulating component and the mixture of the two components, respectively \[7, 16\]. Results obtained from an earlier version \[17\] of Eq.(1) are reviewed in \[18\] and references therein, where the dc conductivities of some two phase systems are successfully modelled for
s = t. The conducting volume fraction $\phi$ ranges between 0 and 1 with $\phi = 0$ characterising the pure insulator substance ($\sigma_M \equiv \sigma_I$) and $\phi = 1$ the pure conductor substance ($\sigma_M \equiv \sigma_C$). The critical volume fraction, or percolation threshold, is denoted by $\phi_c$, where a transition from an essentially insulating to an essentially conducting medium takes place. We use the notation $A = (1 - \phi_c)/\phi_c$. For $s = t = 1$ the equation is equivalent to the Bruggeman symmetric media equation [16, 17]. The equation yields the two limits

\[ |\sigma_C| \to \infty : \quad \sigma_M = \sigma_I \frac{\phi_c^s}{(\phi_c - \phi)^s} \quad \phi < \phi_c \tag{2} \]

\[ |\sigma_I| \to 0 : \quad \sigma_M = \sigma_C \frac{(\phi - \phi_c)^t}{(1 - \phi_c)^t} \quad \phi > \phi_c \tag{3} \]

which characterise the exponents $s$ and $t$. Note that Eqs. (2) and (3) are the normalised percolation equations. For ac measurements, [8, 9, 10] have given equations for the case where $\sigma_C$ is real and $\sigma_I = -i\omega\epsilon_0\epsilon_I$, which characterizes a lossless dielectric. However, we note that all three quantities $\sigma_I$, $\sigma_C$ and $\sigma_M$ can in principle be complex numbers in Eq.(1). A solution for $\sigma_M$ can be obtained after rewriting Eq.(1) using the variable $z = \sigma_M^{1/t}$, viz.

\[ A z^{1+\alpha} - z^\alpha (A\phi + \phi - 1)\sigma_C^{1/t} - z(A - A\phi - \phi)\sigma_I^{\alpha/t} - (\sigma_I^\alpha\sigma_C)^{1/t} = 0 \tag{4} \]

with $\alpha = t/s$. We note in passing that Eq.(4) has explicit solutions for $\alpha = 1, 2$ and 3, while numerical solutions are easily obtained for larger integer values. Our interest is now focussed on the question as to what extent the solution for $\sigma_M$ can be used to obtain valid scaling functions.
The scaling conditions, which are based on those given in [8, 9, 10], read

\[
\sigma_M = \sigma_C \frac{(\phi_c - \phi)}{\phi_c^t} F_-(x_-), \quad \phi < \phi_c \tag{5}
\]

\[
\sigma_M = \sigma_C \frac{(\phi - \phi_c)}{(1 - \phi_c)^t} F_+(x_+), \quad \phi > \phi_c \tag{6}
\]

where the scaling functions \( F_\pm(x_\pm) \) depend on the scaling parameters

\[
x_- = \frac{\sigma_I}{\sigma_C (\phi_c - \phi)^s} \frac{\phi_c^{s+t}}{\phi_c^{s+t}} = -i \frac{\omega}{\omega_c^-}, \quad \phi < \phi_c \tag{7}
\]

with

\[
\omega_c^- = \frac{\sigma_C }{\epsilon_0 \epsilon_I} \frac{(\phi_c - \phi)^{s+t}}{\phi_c^{s+t}},
\]

and

\[
x_+ = \frac{\sigma_I}{\sigma_C (\phi - \phi_c)^{s+t}} \frac{(1 - \phi_c)^{s+t}}{\phi_c^{s+t}} = -i \frac{\omega}{\omega_c^+}, \quad \phi > \phi_c. \tag{8}
\]

with

\[
\omega_c^+ = \frac{\sigma_C }{\epsilon_0 \epsilon_I} \frac{(\phi - \phi_c)^{s+t}}{(1 - \phi_c)^{s+t}}.
\]

The expressions involving \( \omega_\pm \) assume specifically a purely real \( \sigma_C \) and imaginary \( \sigma_I \). To ensure that curves drawn for \( F_\pm \) fall on top of each other for different \( \phi_c \), the normalisation employed in all the equations used in this paper differs somewhat from the one used in [8, 9, 10]. Using the variable \( u = F_-^{1/t} \) an equation is found for \( u \) by the substitution \( z = u \sigma_C^{1/t} (\phi_c - \phi)/\phi_c \) in Eq. (5). It reads for \( \phi < \phi_c \)

\[
Au^{1+\alpha} + u^\alpha - u \frac{(\phi_c - \phi)(1 - \phi - \phi_c)}{\phi_c^2} x_+ x_- = 0. \tag{9}
\]
In a similar way, the substitution \( z = u \sigma_C^{1/t}(\phi - \phi_c)/(1 - \phi_c) \) leads to an equation for \( F_1^{1/t} \) (again denoted by \( u \)) for \( \phi > \phi_c \)

\[
Au^{1+\alpha} - Au^{\alpha} - u(\phi - \phi_c)(1 - \phi - \phi_c)x_1^{1/s} - x_1^{1/s} = 0. \tag{10}
\]

If the term linear in \( u \) of Eqs.(9) and (10) could be neglected, the scaling functions \( F_\pm \) would manifestly depend only on the respective variables \( x_\pm \).

It is due to this term, that scaling is invalidated to a certain degree by the solution for \( \sigma_M \) of Eq.(1). The range and extent to which this is the case is discussed below. An interesting aspect of Eqs.(9) and (10) is exact scaling at \( \phi = \phi_c \) and \( \phi = 1 - \phi_c \). Whether or not exact scaling for \( \phi = 1 - \phi_c \) is merely a coincidence can only be revealed by appropriate experiments. We stress that all results obtained in this section are independent of whether the conductances and hence the scaling functions \( F_\pm \) are genuinely complex or real.

Exact solutions of Eqs.(9) and (10) can be read off at the limit points of the concentration. At \( \phi = 0 \), it is \( u^{\alpha} = x_1^{1/s} \), i.e. \( F_- \equiv x_- \) and at \( \phi = 1 \), it is \( u = 1 \), i.e. \( F_+ \equiv 1 \). From these solutions, Eqs.(2) and (3) are obtained from Eqs.(5) and (6), respectively. In fact, the respective solutions are valid to high accuracy for \( \phi > 0 \) and \( \phi < 1 \) as long as \( |x_\pm| \ll 1 \) or for \( \phi \) very close to either \( \phi_c \) or \( 1 - \phi_c \). Correction terms are given below.

For the opposite limit of the scaling parameters, i.e. \( |x_\pm| \gg 1 \), we obtain for the leading term at \( \phi \approx \phi_c \) the solution \( Au^{1+\alpha} = x^{1/s} \) from both equations,
(11) and (10). This translates into

$$F_{\pm} = (x_{\pm})^{\mp \frac{\alpha}{\gamma}} A^{-\frac{m}{n}}$$  \hspace{1cm} (11)

which gives

$$\sigma_M = \frac{\sigma_C}{A^{\mp \frac{\alpha}{\gamma}}} \left( \frac{\sigma_I}{\sigma_C} \right)^{\mp \frac{\alpha}{\gamma}} \quad \text{at} \quad \phi = \phi_c. \hspace{1cm} (12)$$

Note that Eq.(12) conveniently lends itself for complex values of $\sigma_I$ and $\sigma_C$; in particular, if $\sigma_I$ is purely imaginary and $\sigma_C$ real one obtains

$$\Im \sigma_M = -\frac{\sigma_C}{A^{\mp \frac{\alpha}{\gamma}}} \left| \frac{\omega \epsilon_0 \epsilon_I}{\sigma_C} \right|^{\mp \frac{\alpha}{\gamma}} \sin \left( \frac{\pi t}{2(s + t)} \right), \hspace{1cm} (13)$$

$$\Re \sigma_M = +\frac{\sigma_C}{A^{\mp \frac{\alpha}{\gamma}}} \left| \frac{\omega \epsilon_0 \epsilon_I}{\sigma_C} \right|^{\mp \frac{\alpha}{\gamma}} \cos \left( \frac{\pi t}{2(s + t)} \right). \hspace{1cm} (14)$$

From Eq.(11) it follows that the slope of the real and imaginary part of $\log(F_{\pm})$ is $t/(t+s)$ when plotted against $\log(x_{\pm})$ for $|x_{\pm}| \gg 1$. Equations(13) and (14) show that, with $\sigma_I = -i\omega \epsilon_0 \epsilon_I$, the frequency dependence of both real and imaginary $\sigma_M$ is $\omega^{\pm \frac{\alpha}{\gamma}}$. This dispersion law is given in [7]-[10]. Experimental results validating this power law are found in [7, 12], [20]-[24]. The loss angle $\delta = \arctan[\pi t/(2(s + t))]$ implied by Eqs.(13,14) is also given in [8].

It is of physical interest to determine the correction terms of next order in Eqs.(2) and (3). Note that Eq.(2) yields a purely imaginary result for $\sigma_M$ if $\sigma_I$ is imaginary. However, a loss term should emerge for $\omega > 0$ when $\phi > 0$. This is obtained by expanding the solution of Eq.(4) for $\phi \geq 0$. One finds for
the scaling function

\[ F_- = x_- s \frac{\phi}{\phi_c} x_- \frac{x_+^1}{Ax_+^1 + 1} = \frac{\sigma_I}{\sigma_C} \left( 1 + (s + t) \frac{\phi}{\phi_c} - s \frac{\phi}{\phi_c^2} A \left( \frac{\sigma_I}{\sigma_C} \right)^{\frac{1}{2}} + 1 \right) \]  

(15)

which can be used for real or complex \( \sigma_I \) or \( \sigma_C \). Combining Eq.(15) with Eq.(3) one obtains for small \( \phi/\phi_c \), as expected, both an enhanced dielectric loss term \( \Re \sigma_I(1 + s\phi/\phi_c) \) and a composite loss term. Taking specifically \( \sigma_I \) purely imaginary and \( \sigma_C \) real, the composite loss term reads explicitly up to terms linear in \( \phi/\phi_c \)

\[ \Re \sigma_M = s \sigma_C \frac{\phi}{\phi_c^2} A \frac{|\frac{\sigma_I}{\sigma_C}|^{\frac{1}{2}} \sin(\frac{\pi}{2t})}{2|\frac{\sigma_I}{\sigma_C}|^{\frac{1}{2}} + 2A|\frac{\sigma_I}{\sigma_C}|^{\frac{1}{2}} \cos(\frac{\pi}{2t}) + 1}. \]  

(16)

An important consequence of Eq.(16) is the small frequency behaviour of the loss term (recall \( \sigma_I = -i\omega\epsilon_0\epsilon_I \)), which implies

\[ \Re \sigma_M \sim \omega^{\frac{1+s}{2}}, \]  

(17)

which differs from the \( \omega^2 \)-behaviour predicted by the expansions used for \( F_- \) in [8]-[10]. We note that these expansions assume analytic behaviour for \( \sigma_M \) around \( \omega = 0 \) which is in contrast to our findings; also we obtain a loss term that vanishes for \( \phi \to 0 \), which is not the case for the expressions in [8]-[10]. The following section presents experimental results which appear to confirm the power law expressed by Eq.(17).

By similar means we obtain the first order correction term in the vicinity of \( \phi \leq 1 \) which reads

\[ F_+ = 1 + t \frac{1 - \phi}{\phi_c(1 - \phi_c)} \frac{x_+^1}{A + x_+^2} = 1 + t \frac{1 - \phi}{\phi_c(1 - \phi_c)} \frac{\left( \frac{\sigma_I}{\sigma_C} \right)^{\frac{1}{2}}}{A + \left( \frac{\sigma_I}{\sigma_C} \right)^{\frac{1}{2}}}. \]  

(18)
Note that this term implies not only a correction to the real part of $\sigma_M$ in Eq.(3) but also a switching on of an imaginary part for complex $\sigma_I$. For purely imaginary $\sigma_I$ this is

$$\Im \sigma_M = -t \frac{1 - \phi}{\phi_c (1 - \phi_c)} \sigma_C \frac{\left| \frac{\sigma_I}{\sigma_C} \right|^2 \left( \frac{\pi}{t s} \right) \sin \left( \frac{\pi}{2s} \right)}{A^2 + 2A \left| \frac{\sigma_I}{\sigma_C} \right|^2 \cos \left( \frac{\pi}{2s} \right) + \left| \frac{\sigma_I}{\sigma_C} \right|^4} \tag{19}$$

which implies in this limit, for $\sigma_I = -i \omega \epsilon_0 \epsilon_I$, that $\Im \sigma_M \sim \omega^{1/s}$.

So far, we have concentrated on regions where scaling is obeyed by the solution of Eq.(3) either exactly or to high accuracy, that is for $0 \leq \phi < \phi_c$ and $\phi_c < \phi \leq 1$, if $|x_\pm| \ll 1$, and for $\phi \approx \phi_c$, if $|x_\pm| \gg 1$. There is an intermediate region $|x_\pm| \sim 1$, where the linear term in $u$ of Eqs.(9) and (10) does invalidate the sole dependence of $F_\pm$ on $x_\pm$ except for $\phi = \phi_c$ or $\phi = 1 - \phi_c$. In fact, it can be shown that, as long as the inequality

$$\frac{\omega}{\omega_0} < \frac{\phi_c}{1 - 2 \phi_c} \quad \text{with} \quad \omega_0 = \left| \frac{\sigma_C}{\epsilon_0 \epsilon_I} \right| \tag{20}$$

is obeyed, the linear term of Eqs.(3) and (10) is immaterial and scaling prevails. As a consequence, the leading behaviour of $F_\pm$, for $x_\pm \gg 1$, is governed by the power law $x_\pm^{t/(t+s)}$ only up to the frequency which obeys the inequality (20), for larger frequencies $F_\pm$ becomes a linear function of $x_\pm$.

Note, however, that the right hand side of Eq.(20) depends on $\phi_c$ in such a way that scaling is expected to be invalidated only for small values of $\phi_c$ and sufficiently large values of $\omega$. In turn, for $\phi_c > 1/3$ the right hand side of (20) is larger than unity, and for $\phi_c \to 1/2$ no bound on $\omega$ prevails. (Note that $\phi_c = 1/3$ is the Bruggeman value for spheres in three dimensions and $\phi_c = 1/2$
for discs in two dimensions [16, 17].) As a consequence, there should be no discernible deviations from scaling for $\phi_c > 1/3$. To what extent these results are physically valid can only be assessed by experiment. No experiments in this region appear to exist and the situation is complicated by the fact that $\sigma_C$ and $\sigma_I$ depend on $\omega$ when $\omega$ becomes sufficiently large.

In Fig.1 we illustrate the behaviour of the real and imaginary parts of $F_{\pm}(x_{\pm})$ for $s = 1$, $t = 2$ and $\phi = \phi_c = 0.16$, that is for the situation where scaling holds exactly. As discussed above, deviations are marginal when $\phi$ is near to $\phi_c$ and become noticeable only when the inequality (20) is appreciably invalidated. Note the equal slopes for large $x_{\pm}$ of all four curves in accordance with Eqs.(13,14). Also, since $t > s$, the imaginary parts are larger than the real parts; for $s = t$ all four curves would coincide asymptotically. For $s > t$ the real parts would be larger than the imaginary parts but no such system has been observed or predicted.

We interpret the dependence on $\sigma_I/\sigma_C$ of the percolation loss term as predicted by Eqs.(15-17) as follows: Consider a three dimensional lattice, with ideal capacitors on nearly all the bonds but with a small number of randomly distributed resistors embedded in the capacitor matrix, either as isolated components or as small clusters, and choose $C\omega < 1/R$. If a voltage is applied to two opposite faces of the lattice, the displacement current in the lattice is determined almost entirely by the capacitors. Therefore, as the current in the resistors is evoked by a "fixed current source", which is
determined by the value of $1/(C\omega)$, the dissipation is proportional to $I^2R$, i.e. the larger $R$ the more power is dissipated. This argument can be extended to continuum systems, which qualitatively explains the dependence on $\sigma_I/\sigma_C$ in Eq.(13). The presence of the exponent $t$, which determines the rate of increase of the conductivity beyond $\phi_c$, would therefore appear to have a role in the formation of the conducting clusters, which determine the dissipation below $\phi_c$. However, below $\phi_c$, the behaviour of the complex effective conductivity is dominated by the imaginary component, which is primarily determined by the interconnectivity of the insulating medium, or more specifically its ability of keeping the clusters of the conducting medium disconnected below $\phi_c$, which in turn is characterised by the exponent $s$.

We note that the treatment given in [8]-[10] has no $t$- or $s$-dependence for $x_- < 1$ or $x_+ < 1$, respectively. However, our Eqs.(15) and (18) which are based upon Eqs.(9) and (10) indicate that the exponent $t$, which characterizes the formation of the conducting backbone, continues to play a role for $\phi < \phi_c$; similarly, the real dielectric constant is not independent of $s$ for $\phi > \phi_c$.

3 Experimental Method

The percolation system [7, 11, 12] which best exhibits the $(1+t)/t$ behaviour is a lightly poured powder of 55% Graphite 45% Boron Nitride which is compressed, expelling air, in a capacitive cell through the percolation threshold. As the percolation threshold is at 0.124 (volume fraction of G), the insulator
at and around this point consists of 11.4%BN and 88.6% dry air, which obviously has a $\Re \varepsilon$ close to one and a very low $\Im \varepsilon$ term. The dissipation in more compacted systems, such as compressed pellets of G-BN [7] or polyethylene-carbon black [18], would appear to be dominated by the dissipation in the dielectric component.

As the constructions of the cells and experimental procedures for the G-BN powder have been adequately described for the dc and low frequency ac measurements in [11, 12] as well as the dispersion measurements ($\sigma_M(\omega)$ for fixed $\phi$) in [7, 12], they will not be repeated here. Some experimental results are presented, which are obtained by tumbling various conducting powders with larger wax coated insulating grains. The conductor coated grains are then compressed into discs [19].

The new measurements presented here are results of the real and imaginary parts of the conductivity between $10^{-1}$ and $3 \times 10^6$ Hz, obtained using a newly acquired Novocontrol Dielectric Spectrometer. This instrument is able to measure far smaller loss components of the dielectric or insulating phase (equivalent to a resistor of $10^{18} \Omega$ at $10^{-1}$ Hz and $10^8 \Omega$ at $10^5$ Hz in parallel with a perfect capacitor) and had a better resolution of loss or phase angle (a maximum of $\tan \delta$ of $> 10^3$ and a minimum of $< 10^{-3}$ can be measured) than the instruments used in [7] or measurements of a similar nature [20–24].
4 Results and Discussion

The experimental results for $\Re \epsilon$ and $\Re \sigma_M$ for the 55%G-45%BN powder as function of frequency between $10^{-1}$ and $3.10^6$Hz are given in Figs.2 and 3. The dispersion results for the three highest lying curves in Fig.3 are conducting samples ($\phi > \phi_c$) with dispersion free conductivities at low frequencies [8]–[10]. The dielectric constant of these three samples (upper curves in Fig.2) show a strong dispersion, which should go from $s/(s+t) = 0.47/(0.47+4.8) \approx 0.09$ at $\phi_c$ to $1/s \approx 2$ near to $\phi = 1$. The observed values range from 0.1 to 0.33. The dielectric constant for the conducting samples ($\phi > \phi_c$) will be further discussed below.

The sample marked by plus signs in Fig.3, ($\phi - \phi_c = -0.0004 \pm 0.001$) is actually metallic, as its conductivity breaks away from a constant slope at sufficiently low frequencies, as predicted for metallic samples in this paper and [8]–[10]. Note too that the larger exponent 0.15 for the higher frequencies shown by this sample in Fig.2 also indicates that it is not an insulator ($x_- < 1$). When compared to the results in Fig.1 in [7], this observation illustrates the necessity of making measurements at lower frequencies than previously done in any experiments of this nature.

In Fig.2, the exponent of $\Re \epsilon$ drops form -0.10 to -0.02 for the next four samples. While, from the results given in [7], a dispersion exponent of -0.10 could indicate a sample still in the $x_- > 1$ region, the fact that the sum of the absolute values of the exponents for the dispersion in $\Re \epsilon$ and $\Re \sigma_M$ are
greater than one, precludes this possibility [7]–[10]. This, combined with the ever decreasing magnitude of the $\Re \epsilon$ exponents, going down to 0.02 from the lowest lying curve, allows us to conclude that these four samples lie in the dielectric or $x_- < 1$ region. Note that the lowest measured values for $s/(s+t)$ recorded in the literature [7],[19]–[23] are 0.07 for 50%G-50%BN and 0.10 for 55%G-45%BN [7].

Based on the arguments given above, the four lowest lying plots of the conductivity against frequency in Fig.3 are the conductivities for samples in the insulating or dielectric state ($x_- < 1$). There is a very slight upward curvature of the results between 10 and $3 \times 10^6$Hz, but the mean slopes in this region are 1.06 and 1.09. The slope decreases below 3Hz. According to Eq.(15) the conductivity is made up of both a dielectric and percolation loss term, the relative contributions of which must now be examined.

In order to evaluate Eqs.(15,16),(18) and (19), an expression for $\sigma_I$ is required. Unfortunately the loss term in the Boron Nitride-Air system is too small to measure directly on the dielectric spectrometer, which also meant that the percolation parameters for this system could not be measured directly. Therefore, the complex conductivity of Boron Nitride-Air mixture had to be calculated, using effective media theories, from measurements made on a compressed disc with a porosity of 0.19. When plotted against the frequency, in the range $10^{-1}$ to $3 \times 10^6$Hz, $\Re \epsilon$ for this disc was found to be virtually constant, and that the $\Re \sigma_M$ term could be fitted to $\Re \sigma_M = \sigma_{dc} + D\omega^{0.9}$.
with $\sigma_{dc}$ being sensitive to how dry the BN in the disc was (and therefore also how dry the BN in the G-BN powder was). By pumping on the discs long enough the dc component became unmeasurable (i.e. $< 10^{-18}\, (\Omega\text{m})^{-1}$ at $10^{-1}\text{Hz}$). $D$ was independent of $\sigma_{dc}$ and had a value of $9.0 \times 10^{-16}$. Unfortunately, the powders could not be pumped to lower values of $\sigma_{dc}$ as this caused them to collapse.

Although the system is anisotropic [7], if measurements are made in the axial (compression) and radial directions, it is probably still valid to use the Hashim-Strickman (H-S) upper and lower bounds [26] for measurements made in the radial direction only. Therefore, $\Re \sigma_M$ and $\Im \sigma_M$ for ”bulk” BN where determined using the upper bound, as the BN grains are obviously in contact at low volume fractions, which makes the system closer to one where the BN surrounds the air [27]. The bulk parameters are $\Re \epsilon = 4.1$ and $D = 1.2 \times 10^{-15}$. As the critical volume fraction for the 55%G-45%BN system is 0.124, the upper limit for dilute systems was taken to be $\phi = 0.02$. At this volume fraction of G the volume fraction of BN was 0.0164 and of air 0.9636. Therefore the parameters determining $\sigma_M$ for a system with 0.017 volume fraction of BN and 0.983 for air were calculated, again using the formula for the H-S upper bound, which gave a $\Re \epsilon = 1.03$ and a $D = 1.41.10^{-17}$ with $\sigma_{dc}$ selected to fit the experimental results. The calculated $\Re \sigma_M$ at $\phi = 0.02$ is then used to evaluate the enhanced dielectric loss term, the percolation contribution and the combination of these, using Eqs.(3) and (13).
are all shown in Fig.3. The computed value of $\Re\sigma_M$ for the Air-BN insulator is not shown but lies below the enhanced curve by a factor of $s\phi/\phi_c$. The other values $s = 0.47, t = 4.8$ and $\sigma_C = 3126(\Omega m)^{-1}$, used to calculate these curves, have all been determined by dc percolation measurements\textsuperscript{11} \textsuperscript{12} and $\sigma_{dc}$ was chosen to match the curvature at low frequencies. The mean slopes of 1.05 for the squares and 1.09 for the crosses are lower than the value of $(1+4.8)/4.8 = 1.21$, as is predicted by Eq.(17). The discrepancy is explained by the comparatively large values of $\phi$ in the experimental results; in fact numerical solutions of Eq.(4) show that the $\omega^{1/(1+t)}$ behaviour is flattening out for increasing $\phi$ as it has to attain the $\omega^{t/(s+t)}$ behaviour for $\phi \rightarrow \phi_c$.

The only data that claims an $\omega^2$ dependence for $\sigma_M, \phi < \phi_c$, is that of Benguigui\textsuperscript{21}. However there are problems with his data in a mixture of iron balls and glass beads. His sample contains only $10^5$ particles (about $10^8$ in the present experiments not even counting the air volume) and only 30 particles between the capacitor plates (nearly 300 plus air in the present experiments). Although Benguigui mentions the dc conductivity of the glass, it would appear that neither this nor the dielectric loss term in the glass is taken into account. The authors are also at a loss to explain how the very low frequency dispersion observed for $\Re\epsilon(\omega)$ in an insulating 20.0% iron balls sample (Fig.2 in \textsuperscript{21}) can give a $\Re\epsilon(\omega) \omega \sim \Im\sigma_M(\omega)$ which varies as $\omega^2$ when plotted against the frequency (Fig.8 in \textsuperscript{21}). Therefore we do not regard these experiments as definitive.
In Fig.2 the dielectric results for the conducting samples are terminated at 1 KHz as for lower frequencies $\tan \delta$ exceeds $10^3$ and the dielectric spectrometer gives spurious results. However, the results at 1 KHz (a frequency commonly used in low frequency experiments to measure $\Re \epsilon$) clearly show that $\Re \epsilon$ continues to increase with $\phi$ below and above $\phi_c$. This is in sharp disagreement with the predictions given in [8]-[10], where it is claimed that $\Re \epsilon$ should decrease as $(\phi - \phi_c)^{-s}$ for $\phi > \phi_c$.

The smooth behaviour of $\Re \epsilon$ as a function of $\phi$ passing and extending beyond $\phi_c$ has also recently been observed in carbon black-polyethylene composites [18] and a number of systems where various fine conducting powders are impregnated onto the surface of almost spherical insulator grains before the coated grains are compressed into a three dimensional continuum [19]. Therefore there is now strong experimental evidence that the second order term for $\phi > \phi_c$ given in [8]-[10] is in disagreement with experimental evidence. Their second order percolation term also fails to vanish for $\phi \to 1$ in contrast to our result in Eq.(18).

However, Eqs.(1) and (4) show a $\Re \epsilon$ that continues to increase above $\phi_c$. Unfortunately, the agreement with the experimental results is qualitative, at best, if the parameters obtained from dc experiments are substituted into Eq.(4), as is shown in Figs.4 and 5.

Figure 4 shows the experimental $\Re \epsilon$ results at 1 KHz and 1 Mhz, plotted against $\phi$, for the G-BN powder. All theoretical curves, calculated from Eq.
are for \( t = 4.8 \). The solid curves are for \( \sigma_C = 3.1 \cdot 10^3 (\Omega m)^{-1} \), \( \Re \epsilon = 1.18 \) (calculated \( \phi_c \) value), \( \phi_c = 0.124 \) and \( s = 0.96 \). The upper solid curve is for 1 KHz and the lower one for 1 Mhz. The dotted curves use the same parameters except that \( s = 0.6 \). As the experimental results all lay above the theoretical curves, we display the dashed curve where \( \sigma_C \) has been changed to \( 3.1 \cdot 10^5 (\Omega m)^{-1} \). From this figure and the behaviour of the theoretical plots it is apparent that the experimental results can be better fitted, if some or all of the above parameters are varied to get the best fit. In this case it would not be necessary to change \( \phi_c \) from its dc value of \( 0.124 \pm 0.001 \). As the dc conductivity changes by nine orders of magnitude between 0.120 and 0.130, one cannot argue that the incorrect \( \phi_c \) has been identified.

Of the six powders that were coated onto the wax coated insulating grains, as previously described, only the Nickel powder did not show an increasing \( \Re \epsilon \) above the dc value for \( \phi_c \); this was because the conductivity at and above \( \phi_c \) was too high to measure \( \Re \epsilon \). This combined with the results for carbon black-polyethylene, both as a function of \( \phi \), and \( \phi_c \) (as a function of temperature) for fixed \( \phi \), show that this could well be the usual behaviour for continuum systems. The reason that this has not been previously reported is probably due to the limitations of \( \tan \delta \) in the instruments previously used, and the fact that for \( t \approx 2 \) and large \( \sigma_C/(\omega \epsilon_0 \epsilon) \) ratios the solution of Eq.(4) is sharply peaked just above \( \phi_c \). To observe this difference accurate
measurements of both the dc and the apparent ac value of $\phi_c$ (delayed peak in $\Re \epsilon$) would have had to be made. This has never been done except for the G-BN system, the coated grain system [19] and to some extent the carbon black - polyethylene system [18, 28]. In all the coated grain systems sharp changes in the dc curves of $\sigma_M$ give unambiguous $\phi_c$ values [19]. With a poor conductor (magnetite) $\Re \epsilon$ increases sharply near $\phi_c$ and then smoothly up to $3\phi_c$ [19].

Figure 5 shows the experimental results for $\Re \epsilon$ for a system of insulating grains coated with NbC [19]. All theoretical curves, calculated from Eq.(4) are for $t = 4.8$. The solid curves are for $\sigma_C = 7000(\Omega m)^{-1}, \Re \epsilon = 7.45, \phi_c = 0.065$ and $s = 0.8$. The upper solid curve is for 1 KHz and the lower one 1 Mhz. The lower dotted curves are for the same parameters but $s = 0.4$, which is the measured dc value. The low value for $\sigma_C$ could be due to the resistance of the system being largely determined by contacts between the extremely hard and angular NbC grains. All the above parameters, except for $s = 0.8$, are close to those obtained from the dc conductivity fit using Eq.(4). Except for the fact that the drop in $\epsilon$ for larger values of $\phi$ is not observed the results could be called qualitatively correct.

The curves selected do not show that the theoretical curves widen considerably as $t$ is increased, i.e. the conductivity exponent plays a large role in determining $\Re \epsilon$. An explanation may be that as the conductivity of a percolating system above $\phi_c$ increases more slowly with $\phi$ for high $t$ values,
this means that a smaller fraction of the conducting component is on the backbone of a system with a higher $t$ value than a system with a lower $t$. This "off the backbone" conducting material then creates nearly conducting links between different sections of the backbone, which are broken by the insulating component. It would then be the effect of these inter dead end capacitances that continues to increase $\Re \epsilon$ above $\phi_c$, until these capacitances are shorted out by an ever more conductive backbone.

5 Summary and Conclusions

In this paper we have shown analytically that Eq.(1) in conjunction with Eqs.(5) and (6) gives complex scaling functions for continuum percolation type systems with the following results:

i) $\Re F_+(x_+)$ has zero slope for $x_+ < 1$ (first order term), and a slope of $t/(s+t)$ for $x_+ > 1$,

ii) $\Im F_-(x_-)$ has slope unity for $x_- < 1$ (first order term), and a slope of $t/(s+t)$ for $x_- > 1$.

iii) A slope of $t/(s+t)$ for $\Im F_\pm$ and $\Re F_\pm$ for $x_+$ and $x_- > 1$.

Note that for $x_+$ and $x_- > 1$ one cannot clearly distinguish between first and second order terms. All of these limiting slopes agree with those given in \[8\] - [10]. However the $F_\pm$ in this paper are analytic functions with no unspecified constants. The functions $\Re F_+$ and $\Im F_-$ have been shown to continuously fit the first order dispersion data for the G-BN systems over
the whole range of values for $x_\pm$ [7], and $F_\pm$ the dc conductivity results for $Al_xGe_{1-x}$ [13].

The slopes for $\Im F_+$ and $\Re F_-$ for $x_\pm < 1$ (second order terms) differ from those given in [8] - [10], which are based on the plausible assumptions made in [1] - [6]. However, no definitive experimental verification of these two terms seems to exist and the new experimental work given here strongly favours the second order term for $\Re F_-$ given by Eqs.(1) and (5). The experimentally observed increases in $\Re \epsilon$ with $\phi$ above $\phi_c$, some of which are given in Figs.4 and 5, is completely incompatible with the percolation equations, as given in [8] - [10], but is qualitatively in agreement with Eq.(1) if the separately measured dc parameters are used. Better agreement between Eq.(1) and experiment could be obtained if best fit parameters were used.

From the above evidence Eq.(1) may well be a better description of the ac and dc conductivity (dielectric constant) of percolative type systems than the standard percolation equations given in [8] - [10]. However, as Eq.(1) is a phenomenological equation its validity may need to be further tested by experiment as must the standard percolation equations.

Figure Captions.

Fig. 1

Plots of $F_+$ and $F_-$ against $x_+ (\omega/\omega_c^+)$ and $x_- (\omega/\omega_c^-)$, respectively. The parameters used are $\phi \approx \phi_c = 0.16$, $s = 1$ and $t = 2$. As $\phi \approx \phi_c$ the values used for $\sigma_C$ must be accordingly large to yield a finite $\omega_c^\pm$. The upper solid curve is $\Re F_+$ and the lower one $\Re F_-$ (the second order dielectric loss term). The dashed line is $\Im F_-$ (the first order term below $\phi_c$), and the dotted line is $\Im F_+$. Note how this term rises above $\Im F_-$ in the region where $x_\pm$ is between 1 and 100.

Fig. 2

A plot of the real part of the dielectric constant against frequency for a 55%-45% G-BN powder on a log log scale for various values of $\phi$ ($\phi = 0.1309$ (open circles), 0.1290 (triangles), 0.1272 (open squares), 0.1236 (plus), 0.1219 (crosses), 0.1203 (dots), 0.1187 (asteriks), 0.1171 (solid squares)). These are relative volume fractions, as the absolute error is about ±0.001.

Fig. 3
A plot of the real part of the conductivity against frequency for a 55%-45% G-BN powder on a log log scale for various values of \( \phi \) \( (\phi = 0.1309 \text{ (open circles)}, 0.1290 \text{ (triangles)}, 0.1272 \text{ (open squares)}, 0.1236 \text{ (plus)}, 0.1219 \text{ (crosses)}, 0.1203 \text{ (dots)}, 0.1187 \text{ (asteriks)}, 0.1171 \text{ (solid squares)} ) \). These are relative volume fractions as the absolute error is about \( \pm 0.001 \).
