Towards Optimal Sorting of 16 Elements

Marcin Peczarski

Institute of Informatics, University of Warsaw, ul. Banacha 2, 02-097 Warszawa, Poland, marpe@mimuw.edu.pl

Abstract. One of the fundamental problem in the theory of sorting is to find the pessimistic number of comparisons sufficient to sort a given number of elements. Currently 16 is the lowest number of elements for which we do not know the exact value. We know that 46 comparisons suffices and that 44 do not. There is an open question if 45 comparisons are sufficient. We present an attempt to resolve that problem by performing an exhaustive computer search. We also present an algorithm for counting linear extensions which substantially speeds up computations.

1 Introduction

We consider sorting by comparisons. One of the fundamental problem in that area is to find the pessimistic number $S(n)$ of comparisons sufficient to sort $n$ elements. Steinhaus posed this problem in [8]. Knuth considered it in [4]. From the information-theoretic lower bound, further denoted by ITLB, we know that $S(n) \geq \lceil \log_2 n! \rceil = C(n)$. Ford and Johnson discovered [2] an algorithm, further denoted by FJA, which nearly and sometimes even exactly matches $C(n)$. Let $F(n)$ be the pessimistic number of comparisons in the FJA. It holds $S(n) = F(n) = C(n)$ for $n \leq 11$ and $n = 20, 21$. The FJA does not achieve the ITLB for $12 \leq n \leq 19$ and infinitely many $n \geq 22$. Carrying an exhaustive computer search, Wells discovered in 1965 [9,10] that the FJA is optimal for 12 elements and $S(12) = F(12) = C(12) + 1 = 30$. Kasai et al. [3] computed $S(13) = F(13) = C(13) + 1 = 34$ in 1994, but that result was not widely known. It was discovered again a few years later [5], independently, extending the Wells method. Further improvement of the method led to show in years 2003–2004 [6,7] that it holds $S(n) = F(n) = C(n) + 1$ for $n = 14, 15, 22$, similarly.

In this paper we consider the case $n = 16$. This is now the lowest number of elements for which we do not know the exact value of $S(n)$. The previous results could suggest that $S(16) = F(16) = C(16) + 1 = 46$. However Knuth conjectures that $S(16) = C(16) = 45$. He does not believe that the FJA is optimal for 16 elements. He wrote [4]: “There must be a way to improve upon this!” We present recently obtained result[4] aiming to compute the value of $S(16)$. It is

---

1 The results presented in this paper are obtained using computer resources of the Interdisciplinary Centre for Mathematical and Computational Modelling (ICM), University of Warsaw.
very unlikely that someone will find it by pure theoretical consideration. It seems that the only promising way leads by performing an exhaustive computer search supported by cleaver heuristic.

The paper is organized as follows. In Sect. 2 we introduce notation used throughout the paper. In Sect. 3 we briefly describe the algorithm we use to resolve if there exists a sorting algorithm for a given number of elements and comparisons. We analyse why the ITLB is not achieved for 13, 14 and 15 elements in Sect. 4. We present the newest results for 16 elements in Sect. 5. In Sect. 6 we compare the computation complexity of the previous cases and the case of 16 elements. Finally, in Sect. 7, we present the algorithm for counting linear extensions which substantially improves the algorithm from Sect. 3.

2 Notation

We denote by $U = \{u_0, u_1, \ldots, u_{n-1}\}$ an $n$-element set to be sorted. Sorting of the set $U$ is represented as a sequence of posets $(P_c = (U, R_c))_{c=0,1,\ldots,C}$, where $R_c$ is a partial order relation over a set $U$. Sorting starts from the total disorder $P_0 = (U, R_0)$, where $R_0 = \{(u, u) : u \in U\}$. After performing $c$ comparisons we obtain a poset $P_c = (U, R_c)$. Sorting should end with a linear order $P_C$. Assume that elements $u_j$ and $u_k$ are being compared in step $c$. Without loss of generality we can assume that $(u_j, u_k) \notin R_{c-1}$ and $(u_k, u_j) \notin R_{c-1}$. Suppose the answer to the comparison is that element $u_j$ is less than element $u_k$. Then we obtain the next poset $P_c = (U, R_c)$, where the relation $R_c$ is the transitive closure of the relation $R_{c-1} \cup \{(u_j, u_k)\}$. We denote this by $P_c = P_{c-1} + u_j u_k$.

By $e(P)$ we denote the number of linear extensions of a poset $P = (U, R)$. We assume that $e(P + u_j u_k) = e(P)$ and $e(P + u_k u_j) = 0$ if elements $u_j$, $u_k$ are in relation, i.e., if $(u_j, u_k) \in R$.

3 The Algorithm

In this section we remember briefly the algorithm which answers if sorting of a given poset $P_0$ can be finished in $C$ comparisons. The algorithm was invented in [9,10] and improved in [5] and later in [6]. We present the next improvement to the algorithm in Sect. 4. The algorithm has two phases: forward steps and backward steps.

In the forward steps we consider a sequence of sets $(S_c)_{c=0,1,\ldots,C}$. The set $S_0$ contains only the poset $P_0$. In step $c$ we construct the set $S_c$ from the set $S_{c-1}$. Every poset $P \in S_{c-1}$ is examined for every unrelated pair $(u_j, u_k)$ in order to verify whether it can be sorted in the remaining $C - c + 1$ comparisons. As the result of the comparison of $u_j$ and $u_k$ one can get one of two posets $P_1 = P + u_j u_k$ or $P_2 = P + u_k u_j$. If the number of linear extensions of $P_1$ or $P_2$ exceeds $2^{C-c}$ then by the ITLB it cannot be sorted in the remaining $C - c$ comparisons. It follows that in this case, in order to finish sorting in $C - c + 1$ comparisons, elements $u_j$ and $u_k$ should not be compared in step $c$. If the number of linear extensions of both $P_1$ and $P_2$ do not exceed $2^{C-c}$ then we store one of them in
the set \( S_c \), namely that with greater number of linear extensions. If both have the same number of linear extensions we choose \( P_1 \) arbitrarily. We do not store isomorphic posets or a poset which dual poset is isomorphic to some already stored poset.

If some set \( S_c \) in the sequence appears to be empty then we conclude that the poset \( P_0 \) cannot be sorted in \( C \) comparisons. Such results are received for 12 and 22 elements and \( C = C(n) \) \( \square \), where the set \( S_{23} \) and \( S_{40} \) is empty, respectively. Wells reported \( [10] \) that for \( n = 12 \) only the set \( S_{24} \) is empty. Those results mean that \( S(n) > C(n) \) for \( n = 12, 22 \). If the set \( S_C \) is not empty after performing forwards steps, we cannot conclude about sorting of the poset \( P_0 \). In that case we continue with backward steps.

In the backward steps we consider the sequence of sets \( (S'_c)_{c=0,1,...,C} \). We start with the set \( S'_C = S_C \) which contains only a linear order of the set \( U \). In step \( c \), where \( c = C - 1, C - 2, \ldots, 0 \), we construct the set \( S'_c \) from the set \( S'_{c+1} \).

The set \( S'_c \) is a subset of the set \( S_c \) and contains only posets which can be sorted in the remaining \( C - c \) comparisons. Poset \( P \in S_c \) is stored in \( S'_c \) iff there exists in \( P \) a pair of unrelated elements (\( u_j, u_k \)) such that poset \( P_1 = P + u_ju_k \) or poset \( P_2 = P + u_ku_j \) belongs to the set \( S'_{c+1} \) (as previously we identify isomorphic and dual posets) and both posets are sortable in \( C - c - 1 \) comparisons. Therefore we store the poset \( P \) in the set \( S'_c \) iff both \( P_1, P_2 \in S'_{c+1} \) or \( P_1 \in S'_{c+1} \) and \( P_2 \) is sortable in \( C - c - 1 \) comparisons or \( P_2 \in S'_{c+1} \) and \( P_1 \) is sortable in \( C - c - 1 \) comparisons.

Sortability of \( P_1 \) or \( P_2 \) can be checked recursively using the same algorithm.

If some set \( S'_c \) in the sequence appears to be empty then we conclude that the poset \( P_0 \) cannot be sorted in \( C \) comparisons. On the other hand, if the set \( S'_0 \) is not empty, it contains the poset \( P_0 \) and we conclude that the poset \( P_1 \) can be sorted in \( C \) comparisons. For \( n = 13, 14, 15 \) and \( C = C(n) \) we received that the set \( S'_{15} \) is empty \( \square \), which means that \( S(n) > C(n) \) for \( n = 13, 14, 15 \). We analyze those results in detail in the next section.

### 4 The Previous Cases

The computer experiment for \( n = 13 \) and \( C = C(n) \) returns that the set \( S'_{15} \) is empty, which means that \( S(13) = F(13) = C(13)+1 = 34 \) \( \square \). In that experiment the set \( S'_{16} \) contains only one poset \( P_{16} \), whose Hasse diagram is shown in Fig. \( \square \). The poset \( P_{16} \) can be obtained from a poset contained in the file \( S_{15} \) in two ways:

- we compare elements \( u_0 \) and \( u_{10} \) in the poset \( P'_{15} \in S_{15} \) shown in Fig. \( \square \)
  - if \( u_0 > u_{10} \) we obtain the poset \( P_{16} \); if \( u_0 < u_{10} \) we obtain the poset \( Q'_{16} \) shown in Fig. \( \square \)
- we compare elements \( u_0 \) and \( u_6 \) in the poset \( P''_{15} \in S_{15} \) shown in Fig. \( \square \)
  - if \( u_0 < u_6 \) we obtain the poset \( P_{16} \); if \( u_0 > u_6 \) we obtain the poset \( Q''_{16} \) shown in Fig. \( \square \)

Neither the poset \( P'_{15} \) nor the poset \( P''_{15} \) can be stored in the file \( S_{15} \), because neither the poset \( Q'_{16} \) nor the poset \( Q''_{16} \) can be sorted in the remaining \( C - 16 = \)
Fig. 1. The poset $P_{16}$, $e(P_{16}) = 113400$

Fig. 2. The poset $P'_{15}$, $e(P'_{15}) = 222750$

Fig. 3. The poset $Q'_{16}$, $e(Q'_{16}) = 109350$
Towards Optimal Sorting of 16 Elements

17 comparisons. It is quite surprising that the posets $Q'_{16}$, $Q''_{16}$ cannot be sorted. The poset $Q'_{16}$ has less linear extensions than the poset $P_{16}$, which intuitively should make it easier to sort. Indeed, the poset $Q''_{16}$ has more linear extensions than the poset $P_{16}$, which intuitively makes it harder to sort. On the other hand, there are known the two largest elements of the poset $Q''_{16}$, which intuitively makes it easier to sort. The poset $P_{16}$ is sortable in 17 comparisons because of its symmetry.

Fig. 4. The poset $P''_{15}$, $e(P''_{15}) = 238140$

Fig. 5. The poset $Q''_{16}$, $e(Q''_{16}) = 124740$

Similar results were received in the computer experiments for $n = 14, 15$ and $C = C(n)$, i.e., $S(14) = F(14) = C(14) + 1 = 38$ and $S(15) = F(15) = C(15) + 1 = 42$. In both cases the file $S_{16}$ contains only one poset, namely the poset $P_{16}$ extended by one isolated element $u_{13}$ (for $n = 14$) or two isolated elements.
6 Marcin Peczarski

$u_{13}, u_{14}$ (for $n = 15$), respectively. In both cases the file $S^*_n$ is empty and the reason is the same. The posets $P_{15}', Q''_{15}, Q'_{16}$ extended by $u_{13}$ or $u_{13}, u_{14}$ are observed, respectively, and neither $Q'_{16}$ nor $Q''_{16}$ is sortable in the remaining $C - 16$ comparisons. Note that for $n = 14$ we have $C - 16 = C(n) - 16 = 21$ and for $n = 15$ we have $C - 16 = C(n) - 16 = 25$.

5 The Case of 16 Elements

In this section we describe an attempt to find for $n = 16$ a sorting algorithm better than the FJA or to exclude existence of such algorithm. Before starting a long time computation it was checked if the scenario from the previous section repeats for $n = 16$. The posets $Q'_{16}, Q''_{16}$ were extended by three isolated elements $u_{13}, u_{14}, u_{15}$. As previously, the experiment returned that neither the poset $Q'_{16}$ nor the poset $Q''_{16}$ can be sorted in the remaining $C - 16 = C(n) - 16 = 29$ comparisons. Of course, this result does not exclude the existence of the desired algorithm.

To find the exact value of $S(16)$ the algorithm from Sect. 3 with improvement from Sect. 7 is applied. Because the search space is very reach, the problem is divided into smaller subproblems. Let $T(k)$ be the number of elements which were compared (touched) by a sorting algorithm in the first $k$ comparisons. Observe that $T(k_1) \leq T(k_2)$ for $k_1 < k_2$. A sorting algorithm for 16 elements, using at most $C(16) = F(16) - 1 = 45$ comparisons, is examined for possible values of $T(k)$.

The first experiment returned that if $S(16) = 45$ then it holds $T(15) < 16$. Note that for the FJA we have $T(k) = 16$ for $k \geq 8$. Hence a hypothetical algorithm, using for 16 elements pessimistically less comparisons than the FJA, must be complete different from the FJA. It must differ from the FJA already before the 9th comparison. This is quite surprising, when we look at regular structure of the first 15 comparisons in the FJA. The next experiment showed that if $S(16) = 45$ then $T(15) > 11$, which is already not surprising.

6 Computation Complexity

Computation complexity of the method groves exponentially. The case $S(13)$ needed in year 2002 [5] more than 10 hours of CPU time. The value of $S(14)$ was computed one year later (published in 2004 [5]) and took about 392 hours on faster computer and using improved algorithm, which could solve $S(13)$ in about 40 minutes. Further progress in hardware allowed to compute the value of $S(15)$ in year 2004 (published only in 2007 [7]) using about 17500 hours of CPU time. Each next case required significant improvements in the algorithm or hardware. The progress is presented in Table 1. One can argue that the comparison is not fair, because the machines used in the experiments are different. The purpose of this table is to show an overall improvement in software and hardware, and to give a filling, how difficult the case of 16 elements could be. The about 10 times improvement observed between the second last and the last column is due
mainly to the algorithm described in the next section. Note that for Core 2 Duo processor both cores were used in parallel.

Table 1. Computation times

| n   | Pentium II | Pentium III | Opteron 246 | Core 2 Duo |
|-----|------------|-------------|-------------|------------|
| 13  | 10 hr. 30 min. | 41 min. | 10 min. 44 sec. | 46 sec. |
| 14  | 391 hr. 37 min. | 44 hr. 10 min. | 4 hr. 31 min. |
| 15  |              |           | 17554 hr. |

A few years of CPU time was used up to now to search for an algorithm achieving the ITLB for \( n = 16 \). The computation that \( T(15) < 16 \) and \( T(15) > 11 \) took about 20000 and 7000 hours, respectively. Computation for the next case \( T(15) = 12 \) is currently in progress. It used up to now more than 11000 hours.

7 Counting Linear Extensions

The most time consuming part of the algorithm presented in Sect. 3 is counting linear extensions of a given poset. In this section we describe the algorithm for counting linear extensions which is inspired by [1] and which substantially improves computations. For a given poset \( P = (U, \prec) \) the algorithm computes \( e(P) \) and the table \( t[j,k] = e(P + u_ju_k) \) for \( j \neq k \).

![Fig. 6. A poset and the graph of its downsets](image-url)
Let \( P = (U, \preceq) \) be a poset. A subset \( D \subseteq U \) is called a down set of the poset \( P \) if for each \( x \in D \) all elements \( y \in U \) preceding \( x \) (i.e., \( y \prec x \)) also belong to \( D \). We consider a directed acyclic graph \( G \) whose nodes are all downsets of \( P \). For two nodes \( D_1 \) and \( D_2 \) there is an edge \((D_1, D_2)\) if there exists \( x \in U \setminus D_1 \) such that \( D_2 = D_1 \cup \{x\} \). An example of a poset and its graph of downsets is shown in Fig. 6, where \( U = \{u_0, u_1, u_2, u_3\} \).

Let \( d(D) \) denote the number of linear extensions of the poset \((D, \preceq)\) which is the poset \( P \) reduced to the down set \( D \). Let \( u(D) \) denote the number of linear extensions of the poset \((U \setminus D, \preceq)\) which is the poset \( P \) reduced to the complementary set of the down set \( D \). We have

\[
d(D) = \sum_{(X,D)} d(X),
\]

where the sum is taken over all edges \((X,D)\) in the graph \( G \) incoming to the node \( D \). We assume \( d(\emptyset) = 1 \). Observe that \( d(U) = e(P) \). All values of \( d(D) \) are computed using the DFS in the graph \( G \), starting at the node \( U \) and going down, i.e., in the opposite direction to the edges. Similarly, it holds

\[
u(D) = \sum_{(D,X)} u(X),
\]

where the sum is taken over all edges \((D,X)\) in the graph \( G \) outgoing from the node \( D \). We assume \( u(\emptyset) = 1 \). Observe that \( u(U) = e(P) \). All values of \( u(D) \) are computed using the second DFS in the graph \( G \), starting at the node \( \emptyset \) and going up. Values of \( d(D) \) and \( u(D) \) for the graph in Fig. 6 are shown in Fig. 7.

The curly braces are omitted for clarity, e.g., instead of \( d(\{u_0\}) \) we write \( d(u_0) \).

The table \( t \) can be computed from the equation

\[
t[j,k] = \sum_{(V,W)} d(V)u(W),
\]
Table 2. The values of $t[j, k]$

| $k$ | 0 | 1 | 2 | 3 |
|-----|---|---|---|---|
| 0   | – | 2 | 5 | 4 |
| 1   | 3 | – | 5 | 5 |
| 2   | 0 | 0 | – | 2 |
| 3   | 1 | 0 | 3 | – |

where the sum is taken over all edges $(V, W)$ in the graph $G$ such that $W = V \cup \{u_j\}$ and $u_k \in U \setminus W$. For a proof see [1]. This computation is done altogether with the second DFS. For the graph in Fig. 6 the values $t[j, k]$ are included in Table 2.

For a given poset on an $n$-element set its graph of downsets can have up to $2^n$ nodes. We implemented the graph as a table of the size $2^n$. The table is indexed by downsets. The index is the characteristic function of the set $D$, i.e., the index is the $n$-bit number, where bit $j$ is set iff $u_j \in D$. Graph $G$ is not constructed explicitly. When we proceed a node $D$ all incoming and outgoing edges are easily computable from a poset representation. We hold at position $D$ in the table only two numbers $d(D)$, $u(D)$ and visited time stamp $v(D)$ needed to implement the DFS. We initialize the table only once at the beginning of the program by setting all $v(D) = 0$. We also hold the global visited time stamp $v_t$ initialized to 0. Starting a new DFS we increment the time stamp $v_t$. If we proceed a node $D$ and $v_t > v(D)$ then it means that the node $D$ was not yet visited in the current DFS run. If $v_t = v(D)$ then the node was already visited. We do not need to reinitialize the table before the next DFS. This is very important and decreases running time. The algorithm is very efficient for small $n$, because with a high probability the whole graph resides in a processor cache memory.
