STOCHASTIC METHODS FOR COMPOSITE AND 
WEAKLY CONVEX OPTIMIZATION PROBLEMS

JOHN C. DUCHI† AND FENG RUAN‡

Abstract. We consider minimization of stochastic functionals that are compositions of a (potentially) non-smooth convex function \( h \) and smooth function \( c \) and, more generally, stochastic weakly-convex functionals. We develop a family of stochastic methods—including a stochastic prox-linear algorithm and a stochastic (generalized) sub-gradient procedure—and prove that, under mild technical conditions, each converges to first-order stationary points of the stochastic objective. We provide experiments further investigating our methods on non-smooth phase retrieval problems; the experiments indicate the practical effectiveness of the procedures.

1. Introduction. Let \( f : \mathbb{R}^d \to \mathbb{R} \) be the stochastic composite function
\[
(1.1) \quad f(x) := \mathbb{E}_P[h(c(x; S); S)] = \int_S h(c(x; s); s) dP(s),
\]
where \( P \) is a probability distribution on a sample space \( S \) and for each \( s \in S \), the function \( z \mapsto h(z; s) \) is closed convex and \( x \mapsto c(x; s) \) is smooth. In this paper, we consider stochastic methods for minimization—or at least finding stationary points—of such composite functionals. The objective (1.1) is an instance of the more general problem of stochastic weakly convex optimization, where \( f(x) := \mathbb{E}_P[f(x; S)] \) and for each \( x_0 \) and \( s \in S \), there is \( \lambda(s, x_0) \) such that \( x \mapsto f(x; s) + \frac{\lambda(s, x_0)}{2} \|x - x_0\|^2 \) is convex in a neighborhood of \( x_0 \). (We show later how problem (1.1) falls in this framework.) Such functions have classical and modern applications in optimization [25, 18, 43, 47], for example, in phase retrieval [23] problems or training deep linear neural networks (e.g. [31]). We thus study the problem
\[
(1.2) \quad \begin{align*}
\text{minimize} \quad & f(x) + \varphi(x) = \mathbb{E}_P[f(x; S)] + \varphi(x) \\
\text{subject to} \quad & x \in X,
\end{align*}
\]
where \( X \subset \mathbb{R}^d \) is a closed convex set and \( \varphi : \mathbb{R}^d \to \mathbb{R} \) is a closed convex function.

Many problems are representable in the form (1.1). Taking the function \( c \) as the identity mapping, classical regularized stochastic convex optimization problems fall into this framework [40], including regularized least-squares and the Lasso [32, 51], with \( s = (a, b) \in \mathbb{R}^d \times \mathbb{R} \) and \( h(x; s) = \frac{1}{2} (a^T x - b)^2 \) and \( \varphi \) typically some norm on \( x \), or supervised learning objectives such as logistic regression or support vector machines [32]. The more general settings (1.1–1.2) include a number of important non-convex problems. Examples include non-linear least squares [cf. 42], with \( s = (a, b) \) and \( b \in \mathbb{R} \), the convex term \( h(t; s) \equiv h(t) = \frac{1}{2} t^2 \) independent of the sampled \( s \), and \( c(x; s) = c_0(x; a) - b \) where \( c_0 \) is some smooth function a modeler believes predicts \( b \) well given \( x \) and data \( a \). Another compelling example is the (robust) phase retrieval problem [8, 49]—which we explore in more depth in our numerical experiments—where the data \( s = (a, b) \in \mathbb{R}^d \times \mathbb{R}_+ \), \( h(t; s) \equiv h(t) = |t| \) or \( h(t; s) \equiv h(t) = \frac{1}{2} t^2 \), and

\( c(x; s) = (a^T x)^2 - b. \) In the case that \( h(t) = |t| \), the form (1.1) is an exact penalty for the solution of a collection of quadratic equalities \((a^T x)^2 = b, \ i = 1, \ldots, N\), where we take \( P \) to be point masses on pairs \((a_i, b_i)\).

Fletcher and Watson [29, 28] initiated work on composite problems, to

\[
\text{(1.3)} \quad \text{minimize} \quad h(c(x)) + \varphi(x), \quad \text{subject to} \ x \in X
\]

for fixed convex \( h \), smooth \( c \), convex \( \varphi \) and convex \( X \). A motivation of this earlier work is nonlinear programming problems with the constraint that \( x \in \{ x : c(x) = 0 \} \), in which case taking \( h(z) = \| z \| \) functions as an exact penalty [33] for the constraint \( c(x) = 0 \). A more recent line of work, beginning with Burke [7] and continued by (among others) Druvyatskiy, Ioffe, Lewis, Pacquette, and Wright [38, 21, 19, 20], establishes convergence rate guarantees for methods that sequentially minimize convex surrogates for problem (1.3).

Roughly, these papers construct a model of the composite function \( f(x) = h(c(x)) \) as follows. Letting \( \nabla c(x) \) be the transpose of the Jacobian of \( c \) at \( x \), so \( c(y) = c(x) + \nabla c(x)^T (y - x) + o(\| y - x \|) \), one defines the “linearized” model of \( f \) at \( x \) by

\[
\text{(1.4)} \quad f_x(y) := h(c(x)) + \nabla c(x)^T (y - x),
\]

which is convex in \( y \). When \( h \) and \( \nabla c \) are Lipschitzian, then \( |f_x(y) - f(x)| = O(\|x - y\|^2) \), so that the model (1.4) is second-order accurate, which motivates the following prox-linear method. Beginning from some \( x_0 \in X \), iteratively construct

\[
\text{(1.5)} \quad x_{k+1} = \arg \min_{x \in X} \left\{ f_{x_k}(x) + \varphi(x) + \frac{1}{2\alpha_k} \| x - x_k \|^2 \right\},
\]

where \( \alpha_k > 0 \) is a stepsize that may be chosen by a line-search. For small \( \alpha_k \), the iterates (1.5) guarantee decreasing \( h(c(x_k)) + \varphi(x_k) \), the sequence of problems (1.5) are convex, and moreover, the iterates \( x_k \) converge to stationary points of problem (1.3) [19, § 5]. The prox-linear method is effective so long as minimizing the models \( f_{x_k}(x) \) is reasonably computationally easy. More generally, minimizing a sequence of models \( f_{x_k} \) of \( f \) centered around the iterate \( x_k \) is natural, with examples including Rockafellar’s proximal point algorithm [46] and general sequential convex programming approaches, such as trust region and other Taylor-like methods [42, 11, 19, 18].

In our problem (1.2) where \( f(x) = E[f(x; S)] \) for \( f(\cdot, s) \) weakly convex or composite, the iterates (1.5) may be computationally challenging. Even in the case in which \( P \) is discrete so that problem (1.1) has the form \( f(x) = \frac{1}{n} \sum_{i=1}^{n} h_i(c_i(x)) \), which is evidently of the form (1.3), the iterations generating \( x_k \) may be prohibitively expensive for large \( n \). When \( P \) is continuous or is unknown, because we can only simulate draws \( S \sim P \) or in statistical settings where the only access to \( P \) is via observations \( S_i \sim P \), then the iteration (1.5) is essentially infeasible. Given the wide applicability of the stochastic composite problem (1.1), it is of substantial interest to develop efficient online and stochastic methods to (approximately) solve it, or at least to find local optima.

In this work, we develop and study stochastic model-based algorithms, examples of which include a stochastic linear proximal algorithm, which is a stochastic analogue of problem (1.5), and a stochastic subgradient algorithm, both of whose definitions we give in Section 2. The iterations of such methods are often computationally simple, and they require only individual samples \( S \sim P \) at each iteration. Consider for concreteness the case when \( P \) is discrete and supported on \( i = 1, \ldots, n \) (i.e.
\( f(x) = \frac{1}{n} \sum_{i=1}^{n} h_i(c_i(x)) \). Then instead of solving the non-trivial subproblem (1.5), the stochastic prox-linear algorithm samples \( i_0 \in [n] \) uniformly, then substitutes \( h_{i_0} \) and \( c_{i_0} \) for \( h \) and \( c \) in the iteration. Thus, as long as there is a prox-linear step for the individual compositions \( h_i \circ c_j \), the algorithm is easy to implement and execute.

The main result of this paper is that the stochastic model-based methods we develop for the stochastic composite and weakly-convex optimization problems are convergent. More precisely, assuming that (i) with probability one, the iterates of the procedures are bounded, (ii) the objective function \( F + \mathbb{1}_X \) is coercive and (iii) second moment conditions on local-Lipschitzian and local-convexity parameters of the random functions \( f(\cdot, s) \), any appropriate model-based stochastic minimization strategy has limit points taking values \( f(x) \) in the set of stationary values of the function. If the image of non-critical points of the objective function is dense in \( \mathbb{R} \), the methods converge to stationary points of the (potentially) non-smooth, non-convex objective (1.2) (Theorem 2.1 in Sec. 2 and Theorem 3.20 in Sec. 3.4). As gradients \( \nabla f(x) \) may not exist (and may not even be zero at stationary points because of the non-smoothness of the objective), demonstrating this convergence provides some challenge. To circumvent these difficulties, we show that the iterates are asymptotically equivalent to the trajectories of a particular ordinary differential inclusion [1] (a non-smooth generalization of ordinary differential equations (ODEs)) related to problem (1.1), building off of the classical ODE method [39, 37, 6] (see Section 3.2). By developing a number of analytic properties of the limiting differential inclusion using the weak convexity of \( f \), we show that trajectories of the ODE must converge (Section 3.3). A careful stability analysis then shows that limit properties of trajectories of the ODE are preserved under small perturbations, and viewing our algorithms as noisy discrete approximations to a solution of the ordinary differential inclusion gives our desired convergence (Section 3.4).

Our results do not provide rates of convergence for the stochastic procedures, so to investigate the properties of the methods we propose, we perform a number of numerical simulations in Section 4. We focus on a discrete version of problem (1.1) with the robust phase retrieval objective \( f(x; a, b) = |(a^T x)^2 - b| \), which facilitates comparison with deterministic methods (1.5). Our experiments extend our theoretical predictions, showing the advantages of stochastic over deterministic procedures for some problems, and they also show that the stochastic prox-linear method may be preferable to stochastic subgradient methods because of robustness properties it enjoys (which our simulations verify, though our theory does not yet explain).

**Related and subsequent work.** The stochastic subgradient method has a substantial history. Early work due to Erroliev and Norkin [25, 26, 27], Gupal [30], and Dorofeyev [17] identifies the basic assumptions sufficient for stochastic gradient methods to be convergent. Ruszczyński [48] provides a convergent gradient averaging-based optimization scheme for stochastic weakly convex problems. Our analytical approach is based on differential equations and inclusions, which have a long history in the study of stochastic optimization methods, where researchers have used a limiting differential equation or inclusion to exhibit convergence of stochastic approximation schemes [39, 1, 36, 6]; more recent work uses differential equations to model accelerated gradient methods [50, 56]. Our approach gives similar convergence results to those for stochastic subgradient methods, but allows us to study and prove convergence for a more general collection of model-based minimization strategies. Our results do not provide convergence rates, which is possible when the compositional structure (1.1) leaves the problem convex [53, 54]; the problems we consider are typically non-smooth and non-convex, so that these approaches do not apply.
Subsequent to the initial appearance of the current paper on the arXiv and inspired by our work, Davis, Drusvyatskiy, and Grimmer have provided convergence rates for variants of stochastic subgradient, prox-linear, and related methods [14, 12, 13]. Here they show that the methods we develop in this paper satisfy non-asymptotic convergence guarantees. To make this precise, let $F_\lambda(x) = \inf_{y \in X} \{f(y) + \varphi(y) + \frac{1}{2} \|y - x\|^2\}$ be the Moreau envelope of the objective (1.2), which is continuously differentiable and for which $\nabla F_\lambda$ being small is a proxy for near-stationarity of $x$ (see [18, 12, 13]). Then they show that, with appropriate stepsizes, they can construct a (random) iterate $\hat{x}_k$ such that $\mathbb{E}[\|\nabla F_\lambda(\hat{x}_k)\|^2] = O(1/\sqrt{k})$. These convergence guarantees extend the with probability 1 convergence results we provide.

Notation and basic definitions. We collect here our (mostly standard) notation and basic definitions that we require. For $x, y \in \mathbb{R}$, we let $x \wedge y = \min\{x, y\}$. We let $\mathbb{B}$ denote the unit $\ell_2$-ball in $\mathbb{R}^d$, where $d$ is apparent from context, and $\|\cdot\|$ denotes the operator $\ell_2$-norm (the standard Euclidean norm on vectors). For a set $A \subset \mathbb{R}^d$ we let $\|A\| = \sup_{a \in A} \|a\|$. We say $f : \mathbb{R}^d \to \mathbb{R} \cup \{+\infty\}$ is $\lambda$-weakly convex (also known as lower-$C^2$ or semiconvex [47, 5]) near $x$ if there exists $\epsilon > 0$ such that for all $x_0 \in \mathbb{R}^d$,

$$y \mapsto f(y) + \frac{\lambda}{2} \|y - x_0\|^2, \quad y \in x + \epsilon \mathbb{B}$$

is convex (the vector $x_0$ is immaterial in (1.6), as holding at one $x_0$ is equivalent) [47, Ch. 10.G]. For a function $f : \mathbb{R}^d \to \mathbb{R} \cup \{+\infty\}$, we let $\partial f(x)$ denote the Fréchet (or regular [47, Ch. 8.B]) subdifferential of $f$ at the point $x$,

$$\partial f(x) := \{g \in \mathbb{R}^d : f(y) \geq f(x) + \langle g, y - x \rangle + o(\|y - x\|) \text{ as } y \to x\}.$$ 

The Fréchet subdifferential and subdifferential coincide for convex $f$ [47, Ch. 8], and for weakly convex $f$, $\partial f(x)$ is non-empty for $x$ in the relative interior of $\text{dom } f$. The Clarke directional derivative of a function $f$ at the point $x$ in direction $v$ is

$$f'(x; v) := \liminf_{t \downarrow 0, v' \to v} \frac{f(x + tv) - f(x)}{t},$$ 

and recall [47, Ex. 8.4] that $\partial f(x) = \{w \in \mathbb{R}^d : \langle v, w \rangle \leq f'(x; v) \text{ for all } v\}$.

We let $C(A, B)$ denote the continuous functions from $A$ to $B$. Given a sequence of functions $f_n : \mathbb{R}_+ \to \mathbb{R}^d$, we say that $f_n \to f$ in $C(\mathbb{R}_+, \mathbb{R}^d)$ if $f_n \to f$ uniformly on all compact sets, that is, for all $T < \infty$ we have

$$\lim_{n \to \infty} \sup_{t \in [0, T]} \|f_n(t) - f(t)\| = 0.$$ 

This is equivalent to convergence in $d(f, g) := \sum_{t=1}^\infty 2^{-t} \sup_{x \in [0, t]} \|f(\tau) - g(\tau)\| \wedge 1$, which shows the standard result that $C(\mathbb{R}_+, \mathbb{R}^d)$ is a Fréchet space. For a closed convex set $X$, we let $\mathbb{I}_X$ denote the $+\infty$-valued indicator for $X$, that is, $\mathbb{I}_X(x) = 0$ if $x \in X$ and $+\infty$ otherwise. The normal cone to $X$ at $x$ is

$$\mathcal{N}_X(x) := \{v \in \mathbb{R}^d : \langle v, y - x \rangle \leq 0 \text{ for all } y \in X\}.$$ 

For closed convex $C$, $\pi_C(x) := \argmin_{y \in C} \|y - x\|$ denotes projection of $x$ onto $C$.

\footnote{based on personal communication with Damek Davis and Dmitriy Drusvyatskiy}
2. Algorithms and Main Convergence Result. In this section, we introduce the family of algorithms we study for problem (1.2). In analogy with the update (1.5), we first give a general form of our model-based approach, then exhibit three examples that fall into the broad scheme. We iterate

\[
\text{Draw } S_k \sim P
\]

\[
x_{k+1} := \arg\min_{y \in X} \left\{ f_{x_k}(y; S_k) + \varphi(y) + \frac{1}{2\alpha_k} \|y - x_k\|^2 \right\}.
\]

In the iteration (2.1), the function \( f_{x_k}(\cdot; s) \) is an approximation, or model, of \( f(\cdot; s) \) at the point \( x_k \), and \( \alpha_k > 0 \) is a stepsize sequence.

For the model-based strategy (2.1) to be effective, we require that \( f_{x_k}(\cdot; s) \) satisfy a few essential properties on its approximation quality.

C.(i) The function \( y \mapsto f_{x_k}(y; s) \) is convex and subdifferentiable on its domain

C.(ii) We have \( f_{x}(x; s) = f(x; s) \)

C.(iii) At \( y = x \) we have the containment

\[
\partial_y f_{x}(y; s)|_{y=x} \subset \partial_x f(x; s).
\]

In addition to conditions C.(i)–C.(iii), we require one additional technical condition on the models, which quantitatively guarantees they locally almost underestimate \( f \).

C.(iv) There exists \( \epsilon_0 > 0 \) such that \( 0 < \epsilon \leq \epsilon_0 \) implies that for all \( x_0 \in X \) there exists \( \delta_\epsilon(x_0; s) \geq 0 \) with

\[
f(y; s) \geq f_{x}(y; s) - \frac{1}{2} \delta_\epsilon(x_0; s) \|y - x\|^2
\]

for \( x, y \in x_0 + \epsilon B \), where \( \mathbb{E}[\delta_\epsilon(x_0; S)] < \infty \).

2.1. Examples. We give four example algorithms for problems (1.1) and (1.2), each of which consists of a local model \( f_{x} \) satisfying conditions C.(i)–C.(iv). The conditions C.(i)–C.(iii) are immediate, while we defer verification of condition C.(iv) to after the statement of Theorem 2.1. The first example is the natural generalization of the classical subgradient method [25].

**Example 1** (Stochastic subgradient method). For this method, we let \( g(x; s) \in \partial f(x; s) \) be a (fixed) element of the Fréchet subdifferential of \( f(x; s) \); in the case of the composite objective (1.1) this is \( g(x; s) \in \nabla c(x; s) \partial h(c(x; s); s) \). Then the model (2.1) for the stochastic (regularized and projected) subgradient method is

\[
f_{x}(y; s) := f(x; s) + \langle g(x; s), y - x \rangle.
\]

The properties C.(i)–C.(iii) are immediate. ◦

The stochastic prox-linear method applies to the structured family of convex composite problems (1.1), generalizing the deterministic prox-linear method [7, 19, 20].

**Example 2** (Stochastic prox-linear method). Here, we have \( f(x; s) = h(c(x; s); s) \), and in analogy to the update (1.4) we linearize \( c \) without modifying \( h \), defining

\[
f_{x}(y; s) := h(c(x; s) + \nabla c(x; s)^T(y - x); s)
\]

Again, conditions C.(i)–C.(iii) are immediate. ◦
Lastly, we have stochastic proximal point methods for weakly-convex functions.

**Example 3 (Stochastic proximal-point method).** We assume that the instantaneous function \( f(\cdot; s) \) is \( \lambda(s) \)-weakly convex over \( X \). In this case, for the model in the update (2.1), we set \( f_x(y; s) = f(y; s) + \frac{\lambda(s)}{2} \| y - x \|^2 \). ☐

**Example 4 (Guarded stochastic proximal-point method).** We assume that for some \( \epsilon > 0 \) and all \( x \in X \), the instantaneous function \( f(\cdot; s) \) is \( \lambda(s, x) \)-weakly convex over \( X \cap \{ x + \epsilon B \} \). In this case, for the model in the update (2.1), we set

\[
(2.2) \quad f_x(y; s) = f(y; s) + \frac{\lambda(s, x)}{2} \| y - x \|^2 + \mathbb{I}_{x + \epsilon B}(y),
\]

which restricts the domain of the model function \( f_x(\cdot; s) \) to a neighborhood of \( x \) so that the update (2.1) does not escape the region of convexity. Again, by inspection, this satisfies conditions C.(i)–C.(iii). ☐

### 2.2. The main convergence result.

The main theoretical result of this paper is to show that stochastic algorithms based on the update (2.1) converge almost surely to the stationary points of the objective function \( F(x) = f(x) + \varphi(x) \) over \( X \). To state our results formally, for \( \epsilon > 0 \) we define the function \( M_\epsilon : X \times \mathcal{S} \to \mathbb{R}_+ \) by

\[
M_\epsilon(x; s) := \sup_{y \in X, \| y - x \| \leq \epsilon} \sup_{g \in \partial f(y; s)} \| g \|.
\]

We then make the following local Lipschitzian and convexity assumptions on \( f(\cdot; s) \).

**Assumption A.** There exists \( \epsilon_0 > 0 \) such that \( 0 < \epsilon \leq \epsilon_0 \) implies that

\[
\mathbb{E}[M_\epsilon(x; S)^2] < \infty \quad \text{for all} \quad x \in X.
\]

**Assumption B.** There exists \( \epsilon_0 > 0 \) such that \( 0 < \epsilon \leq \epsilon_0 \) implies that for all \( x \in X \), there exists \( \lambda(s, x) \geq 0 \) such that

\[
y \mapsto f(y; s) + \frac{\lambda(s, x)}{2} \| y - x_0 \|^2
\]

is convex on the set \( x + \epsilon B \) for any \( x_0, \) and \( \mathbb{E}[\lambda(S, x)] < \infty. \)

As we shall see in Lemma 3.6 later, Assumptions A and B are sufficient to guarantee that \( \partial f(x) \) exists, is non-empty for all \( x \in X \), and is outer semi-continuous. In addition, it is immediate that for any \( \lambda \geq \mathbb{E}[\lambda(S, x)] \), the function \( f \) is \( \lambda \)-weakly convex (1.6) on the \( \epsilon \)-ball around \( x \).

With the assumptions in place, we can now proceed to a (mildly) simplified version of our main result in this paper. Let \( X^* \) denote the set of stationary points for the objective function \( F(x) = f(x) + \varphi(x) \) over \( X \). Lemma 3.6 to come implies that \( \partial F(x) = \partial f(x) + \partial \varphi(x) \) for all \( x \in X \), so we can represent \( X^* \) as

\[
X^* := \{ x \in X \mid \exists g \in \partial f(x) + \partial \varphi(x) \text{ with } \langle g, y - x \rangle \geq 0 \text{ for all } y \in X \}.
\]

Equivalently, \( \partial f(x) + \partial \varphi(x) \cap -N_X(x) \neq \emptyset \), or \( 0 \in \partial f(x) + \partial \varphi(x) + N_X(x) \). Important for us is the *image* of the set of stationary points, that is,

\[
F(X^*) := \{ f(x) + \varphi(x) \mid x \in X^* \}.
\]

With these definitions, we have the following convergence result, which is a simplification of our main convergence result, Theorem 3.20, which we present in Section 3.4.
THEOREM 2.1. Let Assumptions A and B hold and assume $X$ is compact. Let $x_k$ be generated by any model-based update satisfying conditions C.(i)–C.(iv) with stepsizes $\alpha_k > 0$ satisfying $\sum_k \alpha_k = \infty$ and $\sum_k \alpha_k^2 < \infty$. Then with probability 1,
\[
\liminf_k F(x_k), \limsup_k F(x_k) \subset F(X^*).
\]

We provide a few remarks on the theorem, as well as elucidating our examples 1–4 in this context. The limiting inclusion (2.4) is familiar from the classical literature on stochastic subgradient methods [17, 26], though in our case, it applies to the broader family of model-based updates (2.1), including Examples 1–4.

To see that the theorem indeed applies to each of these examples, we must verify Condition C.(iv). For Examples 1, 3, and 4, this is immediate by taking the lower approximation function $\delta_\epsilon(x; s) = \lambda(s, x)$ from Assumption B, yielding the following

OBSERVATION 1. Let Assumption B hold. Then Condition C.(iv) holds for each of Examples 1, 3, and 4.

We also provide conditions on the composite optimization problem (1.1), that is, when $f(x; s) = h(c(x; s); s)$, sufficient for Assumptions A–B and Condition C.(iv) to hold. Standard results [21] show that $\partial f(x; s) = \nabla c(x; s) \partial h(c(x; s); s)$, so Assumption A holds if $\sup_{\|x-x'\| \leq \epsilon} \|\nabla c(x; s) \partial h(c(x; s); s)\|$ is integrable (with respect to $s$). For Assumption B, we assume that there exists $\epsilon_0 > 0$ such that if $0 < \epsilon \leq \epsilon_0$, there exist functions $\gamma_\epsilon : \mathbb{R}^d \times \mathcal{S} \to \mathbb{R}^d \cup \{+\infty\}$ and $\beta_\epsilon : \mathbb{R}^d \times \mathcal{S} \to \mathbb{R}^d \cup \{+\infty\}$ such that $c(\cdot; s)$ has $\beta_\epsilon(x; s)$-Lipschitz gradients in an $\epsilon$ neighborhood of $x$, that is,
\[
\|\nabla c(y; s) - \nabla c(y'; s)\| \leq \beta_\epsilon(x, s) \|y - y'\| \quad \text{for } \|y - x\|, \|y' - x\| \leq \epsilon,
\]
and that $h(\cdot; s)$ is $\gamma_\epsilon(x; s)$-Lipschitz continuous on the compact convex neighborhood
\[
\text{Conv}\left\{c(y; s) + \nabla c(y; s)^T (z - y) + v | y, z \in x + \epsilon \mathbb{B}, \|v\| \leq \frac{\beta_\epsilon(x, s)}{2} ||y - z||^2\right\}.
\]

We then have the following claim; see Appendix B.1 for a proof.

CLAIM 1. If $\mathbb{E}[\gamma_\epsilon(x; s) \beta_\epsilon(x; s)] < \infty$ for all $x \in X$, then Assumption B holds with $\lambda(s, x) = \gamma_\epsilon(x; s) \beta_\epsilon(s)$, and Condition C.(iv) holds with $\delta_\epsilon(x; s) = \gamma_\epsilon(x; s) \beta_\epsilon(x; s)$.

Theorem 2.1 does not guarantee convergence of the iterates, though it does guarantee cluster points of $\{x_k\}$ have limiting values in the image of the stationary set. A slightly stronger technical assumption, which rules out pathological functions such as Whitney’s construction [55], is the following assumption, which is related to Sard’s results that the measure of critical values of $C^d$-smooth $f : \mathbb{R}^d \to \mathbb{R}$ is zero.

ASSUMPTION C. The set $F(X^*)^c$ is dense in $\mathbb{R}$.

If $f$ is convex then $(f + \varphi)(X^*)$ is a singleton. Moreover, if the set of stationary points $X^*$ consists of a (finite or countable) collection of sets $X_1^*, X_2^*, \ldots$ such that $f + \varphi$ is constant on each $X_i^*$, then $F(X^*)$ is at most countable and Assumption C holds. In subsequent work to the first version of this paper, Davis et al. [15] give sufficient conditions for Assumption C to hold (see also [34, 35, 4]). We have

COROLLARY 2.2. In addition to the conditions of Theorem 2.1, let Assumption C hold. Then $f(x_k) + \varphi(x_k)$ converges, and all cluster points of the sequence $\{x_k\}$ belong to $X^*$. 

3. Convergence Analysis of the Algorithm. In this section, we present the arguments necessary to prove Theorem 2.1 and its extensions, beginning with a heuristic explanation. By inspection and a strong faith in the limiting behavior of random iterations, we expect that the update scheme (2.1), as the stepsizes $\alpha_k \to 0$, are asymptotically equivalent to iterations of the form

$$
\frac{x_{k+1} - x_k}{\alpha_k} \approx -[g(x_k) + v_k + w_k], \quad g(x_k) \in \partial f(x_k), \quad v_k \in \partial \varphi(x_{k+1}), \quad w_k \in \mathcal{N}_X(x_{k+1}),
$$

and the correction $w_k$ enforces $x_{k+1} \in X$. As $k \to \infty$ and $\alpha_k \to 0$, we may (again, deferring rigor) treat $\lim_k \frac{1}{\alpha_k} (x_{k+1} - x_k)$ as a continuous time process, suggesting that update schemes of the form (2.1) are asymptotically equivalent to a continuous time process $t \mapsto x(t) \in \mathbb{R}^d$ that satisfies the differential inclusion (a set-valued generalization of an ordinary differential equation)

$$
(3.1) \quad \dot{x} \in -\partial f(x) - \partial \varphi(x) - \mathcal{N}_X(x) = - \int \partial f(x; s) dP(s) - \partial \varphi(x) - \mathcal{N}_X(x).
$$

We develop a general convergence result showing that this limiting equivalence is indeed the case and that the second equality of expression (3.1) holds. As part of this, we explore in the coming sections how the weak convexity structure of $f$ indeed the case and that the second equality of expression (3.1) holds. As part of this, we develop a general convergence result showing that this limiting equivalence is

$$
\lim_k \frac{1}{\alpha_k} (x_{k+1} - x_k) = \mathcal{N}_X(x).
$$

3.1. Preliminaries: differential inclusions and set-valued analysis. We now review a few results in set-valued analysis and differential inclusions we require, which build on standard convergence results [1, 36]. Once we have presented these preliminary results, we show how the stochastic iterations (2.1) eventually approximate solution paths to differential inclusions (Section 3.2), which builds off of a number of stochastic approximation results and the so-called “ODE method” Ljung develops [39], (see also [37, 2, 6]). We develop the analytic properties of the composite objective, which yields the uniqueness of trajectories solving (3.1) as well as a particular Lyapunov convergence inequality (Section 3.3). Finally, we develop stability results on the differential inclusion (3.1), which allows us to prove convergence as in Theorem 2.1 (Section 3.4).

We let $G : X \rightrightarrows \mathbb{R}^d$ denote a set-valued mapping $G$ from $X$ to $\mathbb{R}^d$, and we define $\text{dom } G := \{ x : G(x) \neq \emptyset \}$. Then $G$ is outer semicontinuous (o.s.c.) if for any sequence $x_n \to x \in \text{dom } G$, we have $\limsup_n G(x_n) \subset G(x)$. One says that $G$ is $\epsilon$-$\delta$ outer semicontinuous [1, Def. 1.1.5] if for all $x$ and $\epsilon > 0$, there exists $\delta > 0$ such that $G(x + \delta B) \subset G(x) + \epsilon B$. These notions coincide when $G(x)$ is bounded. Two standard examples of outer-semicontinuous mappings follow.

**Lemma 3.1** (Hiriart-Urruty and Lemaréchal [33, Theorem VI.6.2.4]). Let $f : \mathbb{R}^d \to \mathbb{R} \cup \{+\infty\}$ be convex. Then the subgradient mapping $\partial f : \text{int } \text{dom } f \rightrightarrows \mathbb{R}^d$ is o.s.c.
Lemma 3.2 (Rockafellar and Wets [47], Proposition 6.6). Let $X$ be a closed convex set. Then the normal cone mapping $N_x : X \rightrightarrows \mathbb{R}^d$ is o.s.c. on $X$.

The differential inclusion associated with $G$ beginning from the point $x_0$, denoted
\begin{equation}
\dot{x}(t) \in G(x), \ x(0) = x_0
\end{equation}
has a solution if there exists an absolutely continuous function $x : [0, T] \rightarrow \mathbb{R}^d$ satisfying $\frac{dx}{dt}(t) = \dot{x}(t) \in G(x(t))$ for all $t \geq 0$. For $G : \mathcal{T} \rightrightarrows \mathbb{R}^d$ and a measure $\mu$ on $\mathcal{T}$,
\begin{equation}
\int_{\mathcal{T}} Gd\mu = \int_{\mathcal{T}} G(t)d\mu(t) := \left\{ \int_{\mathcal{T}} g(t)d\mu(t) \mid g(t) \in G(t) \text{ for } t \in \mathcal{T}, \text{ } g \text{ measurable} \right\}.
\end{equation}

With these definitions, the following results (with minor extension) on the existence and uniqueness of solutions to differential inclusions are standard.

Lemma 3.3 (Aubin and Cellina [1], Theorem 2.1.4). Let $G : X \rightrightarrows \mathbb{R}^d$ be outer semicontinuous and compact-valued, and $x_0 \in X$. Assume there is $K < \infty$ such that $\text{dist}(0, G(x)) \leq K$ for all $x$. Then there exists an absolutely continuous function $x : [0, T] \rightarrow \mathbb{R}^d$ such that $\dot{x}(t) \in G(x(t))$ and $x(t) \in x_0 + \int_0^t G(x(\tau))d\tau$ for all $t \in [0, T]$.

Lemma 3.4 (Kunze [36], Theorem 2.2.2). Let the conditions of Lemma 3.3 hold and assume there exists $c < \infty$ such that
\begin{equation}
\langle x_1 - x_2, g_1 - g_2 \rangle \leq c \|x_1 - x_2\|^2 \text{ for } g_i \in G(x_i) \text{ and all } x_i \in \text{dom } G.
\end{equation}
Then the solution to the differential inclusion (3.2) is unique.

We recall basic Lyapunov theory for differential inclusions. Let $V : X \rightarrow \mathbb{R}_+$ be a non-negative function and $W : X \times \mathbb{R}^d \rightarrow \mathbb{R}_+$ be continuous with $v \mapsto W(x, v)$ convex in $v$ for all $x$. A trajectory $\dot{x} \in G(x)$ is monotone for the pair $V, W$ if
\begin{equation}
V(x(T)) - V(x(0)) + \int_0^T W(x(t), \dot{x}(t))dt \leq 0 \text{ for } T \geq 0.
\end{equation}
The next lemma gives sufficient conditions for the existence of monotone trajectories.

Lemma 3.5 (Aubin and Cellina [1], Theorem 6.3.1). Let $G : X \rightrightarrows \mathbb{R}^d$ be outer semicontinuous and compact-convex valued. Assume that for each $x$ there exists $v \in G(x)$ such that $V'(x; v) + W(x; v) \leq 0$. Then there exists a trajectory of the differential inclusion $\dot{x} \in G(x)$ such that
\begin{equation}
V(x(T)) - V(x(0)) + \int_0^T W(x(t), \dot{x}(t))dt \leq 0.
\end{equation}

Finally, we present a lemma on the subgradients of $f$ using our set-valued integral definitions. The proof is somewhat technical and not the main focus of this paper, so we defer it to Appendix B.2.

Lemma 3.6. Let $f(\cdot, s)$ satisfy Assumptions A and B. Then
\begin{equation}
\partial f(x) = E_P[\partial f(x; S)]
\end{equation}
and $\partial f(\cdot, s) : \mathbb{R}^d \rightrightarrows \mathbb{R}^d$ and $\partial f(\cdot) : \mathbb{R}^d \rightrightarrows \mathbb{R}^d$ are closed compact convex-valued and outer semicontinuous.
Lemma 3.6 shows that $\partial f(x; s)$ is compact-valued and o.s.c., and we thus define the shorthand notation for the subgradients of $f + \varphi$ as

\begin{equation}
G(x; s) := \partial f(x; s) + \partial \varphi(x) \quad \text{and} \quad G(x) := \int_{S} \partial f(x; s) dP(s) + \partial \varphi(x),
\end{equation}

both of which are o.s.c. in $x$ and compact-convex valued because $\varphi$ is convex.

### 3.2. Functional convergence of the iteration path.

With our preliminaries in place, we now establish a general functional convergence theorem (Theorem 3.7) that applies to stochastic approximation-like algorithms that asymptotically approximate differential inclusions. By showing the generic algorithm (2.1) has the form our theorem requires, we conclude that each of examples 1–4 converge to the appropriate differential inclusion (Sec. 3.2.2).

#### 3.2.1. A general functional convergence theorem.

Let $\{g_k\}_{k \in \mathbb{N}}$ be a collection of set-valued mappings $g_k : \mathbb{R}^d \rightrightarrows \mathbb{R}^d$, $\{\alpha_k\}_{k \in \mathbb{N}}$ be a sequence of positive stepsizes, $\{\xi_k\}_{k = 1}^{\infty}$ be an arbitrary $\mathbb{R}^d$-valued sequence (the noise sequence). Consider the following iteration, which begins from the initial value $x_0 \in \mathbb{R}^d$:

\begin{equation}
x_{k+1} = x_k + \alpha_k[y_k + \xi_{k+1}], \quad \text{where} \quad y_k \in g_k(x_k) \quad \text{for} \quad k \geq 0.
\end{equation}

For notational convenience, define the “times” $t_m = \sum_{k=1}^{m} \alpha_k$ as the partial stepsize sums, and let $x(\cdot)$ be the linear interpolation of the iterates $x_k$:

\begin{equation}
x(t) := x_k + \frac{t - t_k}{t_{k+1} - t_k} (x_{k+1} - x_k) \quad \text{and} \quad y(t) = y_k \quad \text{for} \quad t \in [t_k, t_{k+1}).
\end{equation}

This path satisfies $\dot{x}(t) = y(t)$ for almost all $t$ and is absolutely continuous on compact. For $t \in \mathbb{R}_+$, define the time-shifted process $x^f(\cdot) = x(t + \cdot)$. We have the following convergence theorem for the interpolation (3.5) of the iterative process (3.4), where we recall that we metrize $\mathcal{C}(\mathbb{R}_+, \mathbb{R}^d)$ with $d(f, g) = \sum_{t=1}^{\infty} 2^{-t} \sup_{\tau \in [0, t]} \|f(\tau) - g(\tau)\| \wedge 1$.

**Theorem 3.7.** Let the following conditions hold:

(i) The iterates are bounded, i.e. $\sup_k \|x_k\| < \infty$ and $\sup_k \|y_k\| < \infty$.

(ii) The stepsizes satisfy $\sum_{k=1}^{\infty} \alpha_k = \infty$ and $\sum_{k=1}^{\infty} \alpha_k^2 < \infty$.

(iii) The weighted noise sequence converges: $\lim_n \sum_{k=1}^{n} \alpha_k \xi_k = v$ for some $v \in \mathbb{R}^d$.

(iv) There exists a closed-valued $H : \mathbb{R}^d \rightrightarrows \mathbb{R}^d$ such that for all $\{z_k\} \subset \mathbb{R}^d$ satisfying $\lim_k z_k = z$ and all increasing subsequences $\{n_k\}_{k \in \mathbb{N}}$, we have

$$
\lim_{n \to \infty} \text{dist} \left( \frac{1}{n} \sum_{k=1}^{n} g_{n_k}(z_k), H(z) \right) = 0.
$$

Then for any sequence $\{\tau_k\}_{k=1}^{\infty} \subset \mathbb{R}_+$, the sequence of functions $\{x^{\tau_k}(\cdot)\}$ is relatively compact in $\mathcal{C}(\mathbb{R}_+, \mathbb{R}^d)$. If $\tau_k \to \infty$, all limit points of $\{x^{\tau_k}(\cdot)\}$ are in $\mathcal{C}(\mathbb{R}_+, \mathbb{R}^d)$ and there exists $y : \mathbb{R}_+ \to \mathbb{R}^d$ satisfying $y(t) \in H(x(t))$ for all $t \in \mathbb{R}_+$ where

$$
\bar{x}(t) = \bar{x}(0) + \int_{0}^{t} y(\tau) d\tau \quad \text{for all} \quad t \in \mathbb{R}_+.
$$

The theorem is a generalization of Theorem 5.2 of Borkar [6], where the set-valued mappings $g_k$ are identical for all $k$; our proof techniques are similar. For completeness, we provide a proof in Appendix A.
3.2.2. Differential inclusion for stochastic model-based methods. With Theorem 3.7 in place, we can now show how the update scheme (2.1) is representable by the general stochastic approximation (3.4). To do so, we must verify that any method satisfying Conditions C.(i)–C.(iv) satisfies the four conditions of Theorem 3.7. With this in mind, we introduce a bit of new notation before proceeding. In analogy to the gradient mapping from convex [41] and composite optimization [21], we define a stochastic gradient mapping \( G \) and consider its limits. For fixed \( x \) we define

\[
x^+(s) := \arg \min_{y \in X} \left\{ f_x(y) + \varphi(y) + \frac{1}{2\alpha} \|y - x\|^2 \right\} \quad \text{and} \quad G_\alpha(x; s) := \frac{1}{\alpha} (x - x^+(s)),
\]

For any model \( f_x(\cdot; s) \) we consider, the update is well-behaved: it is measurable in \( s \) [45, Lemma 1], and it is bounded, as the next lemma shows.

**Lemma 3.8.** The update (3.6) guarantees that \( \|G_\alpha(x; s)\| \leq \|G(x; s)\| \), where \( G(x; s) \) is the subgradient (3.3).

**Proof.** For shorthand, write \( x^+ = x^+(s) \) and let \( g \in \partial f_x(x; s) \subset \partial f(x; s) \). By the definition of the optimality conditions for \( x^+ \), there exists a vector \( g^+ \) that \( g^+ \in \partial f_x(x^+; s) \) and another vector \( v^+ \in \partial \varphi(x^+) \) such that

\[
\langle g^+ + \frac{1}{\alpha}(x^+ - x) + v^+, y - x^+ \rangle \geq 0 \quad \text{for all} \; y \in X.
\]

Rearranging, we substitute \( y = x \) to obtain

\[
\langle g^+, x^+ - x \rangle + \frac{1}{\alpha} \|x - x^+\|^2 + \langle v^+, x^+ - x \rangle \leq 0.
\]

The subgradient mapping is monotone for \( f_x(\cdot; s) \) and \( \varphi \), so \( \langle g^+, x - x^+ \rangle \geq \langle g, x - x^+ \rangle \) and \( \langle v^+, x - x^+ \rangle \geq \langle \partial \varphi(x), x - x^+ \rangle \). Thus

\[
\langle g, x^+ - x \rangle + \frac{1}{\alpha} \|x - x^+\|^2 + \langle v, x^+ - x \rangle \leq 0
\]

for all \( v \in \partial \varphi(x) \). Cauchy-Schwarz implies \( \|g + v\| \|x^+ - x\| \geq \frac{1}{\alpha} \|x - x^+\|^2 \), which implies our desired result. \( \square \)

To define the population counterpart of the gradient mapping \( G_\alpha \), we require a result showing that the gradient mapping is locally bounded and integrable. To that end, for \( x \in X \) and \( \epsilon > 0 \), define the Lipschitz constants

\[
L_\epsilon(x; s) := \sup_{x' \in X, \|x' - x\| \leq \epsilon} \|G(x'; s)\| \quad \text{and} \quad L_\epsilon(x) := E_P[L_\epsilon(x; S)]^{\frac{1}{2}}.
\]

The following lemma shows these are not pathological (see Appendix B.3 for a proof).

**Lemma 3.9.** Let Assumptions A and B hold. Then \( x \mapsto L_\epsilon(x; s) \) and \( x \mapsto L_\epsilon(x) \) are upper semicontinuous on \( X \) and \( L_\epsilon(x) < \infty \) for all \( x \in X \).

As a consequence of this lemma and Lemma 3.8, \( G_\alpha(x; S) \) is locally bounded by \( L_\epsilon(x; s) \) and we may define the mean subgradient mapping

\[
\mathcal{G}_\alpha(x) := E_P[G_\alpha(x; S)] = \int_S G_\alpha(x; s) dP(s).
\]
Moreover, any update of the form (2.1) (e.g. Examples 1–4) has representation

\[ x_{k+1} = x_k - \alpha_k G_\alpha(x_k; S_k) = x_k - \alpha_k \mathcal{G}_\alpha(x_k) - \alpha_k \xi_\alpha(x_k; S_k), \]

where the noise vector \( \xi_\alpha(x; s) := G_\alpha(x; s) - \mathcal{G}_\alpha(x) \). Defining the filtration of \( \sigma \)-fields \( \mathcal{F}_k := \sigma(x_0, S_1, \ldots, S_{k-1}) \), we have \( x_k \in \mathcal{F}_k \) and that \( \xi \) is a square-integrable martingale difference sequence adapted to \( \mathcal{F}_k \). Indeed, for \( \alpha \) and \( \epsilon > 0 \) we have

\[ \| G_\alpha(x; s) \| \leq L_\epsilon(x; s) \quad \text{and} \quad \| \mathcal{G}_\alpha(x) \| \leq L_\epsilon(x) \]

by Lemma 3.8 and the definition of the Lipschitz constant, and for any \( x \) and \( \alpha > 0 \),

\[ E_P \left[ \| \xi_\alpha(x; S) \|^2 \right] \leq E_P \left[ \| G_\alpha(x; S) \|^2 \right] \leq E \left[ L_\epsilon^2(x; S) \right] = L_\epsilon(x)^2, \]

because \( E[G_\alpha] = \mathcal{G}_\alpha \). In the context of our iterative procedures, for any \( \alpha > 0 \),

\[ E[\xi_\alpha(x_k; S_k) | \mathcal{F}_k] = 0 \quad \text{and} \quad E[\| \xi_\alpha(x_k; S_k) \|^2 | \mathcal{F}_k] \leq L_\epsilon(x_k)^2. \]

The (random) progress of each iterate of the algorithm \( G \) is now the sum of a mean progress \( \mathcal{G} \) and a random noise perturbation \( \xi \) with (conditional) mean 0 and bounded second moments. The update form (3.7) shows that all of our examples—stochastic proximal point, stochastic prox-linear, and the stochastic gradient method—have the form (3.4) necessary for application of Theorem 3.7.

**Functional convergence for the stochastic updates.** Now that we have the representation (3.7), it remains to verify that the mean gradient mapping \( \mathcal{G} \) and errors \( \xi \) satisfy the conditions necessary for application of Theorem 3.7. That is, we verify (i) bounded iterates, (ii) non-summable but square-summable stepsizes, (iii) convergence of the weighted error sequence, and (iv) the distance condition in the theorem. Condition (ii) is trivial. To address condition (i), we temporarily make the following assumption, noting that the compactness of \( X \) is sufficient for it to hold (we give other sufficient conditions in Section 3.4, showing that it is not too onerous).

**Assumption D.** With probability 1, the iterates (2.1) are bounded,

\[ \sup_k \| x_k \| < \infty. \]

A number of conditions, such as almost supermartingale convergence theorems [44], are sufficient to guarantee Assumption D. Whenever Assumption D holds, we have

\[ \sup_k \sup_{\alpha > 0} \| \mathcal{G}_\alpha(x_k) \| \leq \sup_k L_\epsilon(x_k) < \infty, \]

by Lemmas 3.8 and 3.9, because the supremum of an upper semicontinuous function on a compact set is finite. That is, condition (i) of Theorem 3.7 on the boundedness of \( x_k \) and \( y_k \) holds.

The error sequences \( \xi_\alpha \) are also well-behaved for the model-based updates (2.1). That is, condition (iii) of Theorem 3.7 is satisfied:

**Lemma 3.10.** Let Assumptions A, B, and D hold. Then with probability 1, the limit \( \lim_{n \to \infty} \sum_{k=1}^n \alpha_k \xi_\alpha(x_k; S_k) \) exists and is finite.

**Proof.** Ignoring probability zero events, by Assumption D there is a random variable \( B \), which is finite with probability 1, such that \( \| x_k \| \leq B \) for all \( k \in \mathbb{N} \). As \( L_\epsilon(\cdot) \) is
upper semicontinuous (Lemma 3.9), we know that \( \sup \{ L_\epsilon(x) \mid \|x\| \leq B, x \in X \} < \infty \).

Hence, using inequality (3.8), we have

\[
\sum_{k=1}^{\infty} \mathbb{E} \left[ \alpha_k^2 \| \xi_{\omega_k} (x_k; S_k) \|^2 \mid F_k \right] \leq \sum_{k=1}^{\infty} \alpha_k^2 \sup_{\|x\| \leq B, x \in X} L_\epsilon(x)^2 < \infty.
\]

Standard convergence results for \( \ell^2 \)-summable martingale difference sequences [16, Theorem 5.3.3] immediately give the result. \( \square \)

Finally, we verify the fourth technical condition Theorem 3.7 requires by constructing an appropriate closed-valued mapping \( H : \mathbb{R}^d \rightrightarrows \mathbb{R}^d \) for any update scheme of the form (2.1). Recall the definition (3.3) of the outer semicontinuous mapping \( G(x) = \mathbb{E}_p \{ \partial f(x; S) \} + \partial \varphi(x) \). We then have the following limiting inclusion, which is the key result allowing our limit statements.

**Lemma 3.11.** Let the sequence \( x_k \in X \) satisfy \( x_k \rightarrow x \in X \) and Assumptions A and B hold. Let \( \{i_k\} \subset \mathbb{N} \) be an increasing sequence. Then, for updates (2.1) satisfying Conditions C.(i)–C.(iv),

\[
\lim_{n \rightarrow \infty} \text{dist} \left( \frac{1}{n} \sum_{k=1}^{n} \xi_{\omega_k} (x_k), G(x) + \mathcal{N}_X(x) \right) = 0.
\]

**Proof.** We begin with two intermediate lemmas on the continuity properties of the models \( f_x \). Both lemmas assume the conditions of Lemma 3.11.

**Lemma 3.12.** There exists \( M'_\epsilon(x; s) \) such that \( y \mapsto f_x(y; s) \) is \( M'_\epsilon(x; s) \)-Lipschitz for \( y \in x + (\epsilon/2)B \), and \( \mathbb{E}[M'_\epsilon(x; S)] < \infty \).

**Proof.** Let \( \epsilon > 0 \), and let \( g = g(x; s) \in \partial f_x(x; s) \subset \partial f(x; s) \). We have that

\[
f_x(y; s) \geq f_x(x; s) + \langle g, y - x \rangle \geq f(x; s) - M_\epsilon(x; s) \|y - x\|
\]

by the local Lipschitz condition A on \( f \). Condition C.(iv) and the Lipschitzian assumptions on \( f \) also guarantee that for \( y \in x + \epsilon B \),

\[
f_x(y; s) \leq f(y; s) + \frac{1}{2} \delta_\epsilon(x; s) \|y - x\|^2 \leq f(x; s) + [M_\epsilon(x; s) + \delta_\epsilon(x; s)] \|x - y\| \|y - x\|.
\]

These two boundedness conditions and convexity of the model \( f_x \) imply [33, Lemma IV.3.1.1] that \( y \mapsto f_x(y; s) \) is \( 2M_\epsilon(x; s) + \delta_\epsilon(x; s) \)-Lipschitz for \( y \in x + (\epsilon/2)B \). \( \square \)

**Lemma 3.13.** Let \( x_k, y_k \in X \) satisfy \( x_k \rightarrow x, y_k \rightarrow x \), and let \( g_k \in \partial f_{x_k}(y_k; s) \). Then there exists an integrable function \( M(\cdot) \) such that for large \( k \), \( \text{dist}(g_k, \partial f(x; s)) \leq M(s) \) for all \( s \), and \( \text{dist}(g_k, \partial f(x; s)) \rightarrow 0 \).

**Proof.** By Lemma 3.12, we know that there exists an integrable \( M \) such that \( \|g_k\| \leq M(s) \) for all large enough \( k \). This gives the first claim of the lemma, as \( f(\cdot; s) \) is locally Lipschitz (Assumption A). Let \( g_\infty \) be any limit point of the sequence \( g_k \); by moving to a subsequence if necessary, we assume without loss of generality that \( g_k \rightarrow g_\infty \in \mathbb{R}^d \). Now let \( y \in x + \epsilon B \). Then for large \( k \) we have

\[
f(y; s) \overset{(i)}{\geq} f_{x_k}(y; s) - \frac{\delta_\epsilon(x; s)}{2} \|y - x_k\|^2 \geq f_{x_k}(x_k; s) + \langle g_k, y - x_k \rangle - \frac{\delta_\epsilon(x; s)}{2} \|y - x_k\|^2
\]

\[
\rightarrow f(x; s) + \langle g_\infty, y - x \rangle - \frac{\delta_\epsilon(x; s)}{2} \|y - x\|^2,
\]
where inequality (i) is a consequence of Condition C.(iv). By definition of the Fréchet subdifferential, we have \( g_\infty \in \partial f(x; s) \) as desired.

Now we return to the proof of Lemma 3.11. Let \( x^+_k(s) \) be shorthand for the result of the update (2.1) when applied with the stepsize \( \alpha = \alpha_k \). For any \( \epsilon > 0 \), Lemma 3.8 shows that \( \|x^+_k(s) - x_k\| \leq \alpha_k L_\epsilon(x; s) \). By the (convex) optimality conditions for \( x^+_k(s) \), there exists a vector \( g^+(x_k; s) \) such that

\[
 g^+(x_k; s) \in \partial f_{\epsilon x}(x^+_k(s); s)
\]

and

\[
 G_{\alpha_k}(x_k; s) \in g^+(x_k; s) + \partial \varphi(x^+_k(s)) + \mathcal{N}_\epsilon(x^+_k(s)).
\]

Let \( v^+_k(s) \in \partial \varphi(x^+_k(s)) \) and \( w^+_k(s) \in \mathcal{N}_\epsilon(x^+_k(s)) \) be the vectors such that

\[
 G_{\alpha_k}(x_k; s) = g^+(x_k; s) + v^+_k(s) + w^+_k(s).
\]

The three set-valued mappings \( x \mapsto \partial f(x; s) \), \( x \mapsto \partial \varphi(x) \), and \( x \mapsto \mathcal{N}_\epsilon(x) \) are outer semicontinuous (see Lemmas 3.1, 3.2, and 3.6). Since \( x^+_k(s) \to x \) as \( k \to \infty \) (as \( x_k \to x \)), this outer semicontinuity and Lemma 3.13 thus imply (3.9)

\[
 \text{dist}(g^+(x_k; s), \partial f(x; s)) \to 0, \quad \text{dist}(v^+_k(s), \partial \varphi(x)) \to 0, \quad \text{dist}(w^+_k(s), \mathcal{N}_\epsilon(x)) \to 0
\]
as \( k \to \infty \). Because \( x_k \to x \) and the Lipschitz constants \( L_\epsilon(x; s) \) are upper semicontinuous, Eq. (3.9) and Lemma 3.8 also imply that

\[
 \limsup_k \| g^+(x_k; s) + v^+_k(s) \| \leq L_\epsilon(x; s) \quad \text{and} \quad \limsup_k \| G_{\alpha_k}(x_k; s) \| \leq L_\epsilon(x; s).
\]

By the triangle inequality, we thus obtain \( \limsup_k \| w^+_k(s) \| \leq 2L_\epsilon(x; s) \), and hence,

\[
 \text{dist}(w^+_k(s), \mathcal{N}_\epsilon(x) \cap 2L_\epsilon(x; s) \cdot \mathbb{B}) \to 0.
\]

That \( L_\epsilon(x) = \mathbb{E}[L_\epsilon(x; S)^2]^{\frac{1}{2}} \) yields \( \mathcal{N}_\epsilon(x) \cap 2L_\epsilon(x) \cdot \mathbb{B} \supset \int (\mathcal{N}_\epsilon(x) \cap 2L_\epsilon(x; s) \cdot \mathbb{B}) dP(s) \), and the definition of the set-valued integral and convexity of \( \text{dist}(\cdot, \cdot) \) imply that

\[
 \text{dist}
 \left( \frac{1}{n} \sum_{k=1}^{n} G_{\alpha_{ik}}(x_k), G(x) + \mathcal{N}_\epsilon(x) \cap 2L_\epsilon(x) \cdot \mathbb{B} \right)
\]

\[
 \leq \frac{1}{n} \sum_{k=1}^{n} \int \text{dist}
 \left( G_{\alpha_{ik}}(x_k; s), \partial f(x; s) + \partial \varphi(x) + \mathcal{N}_\epsilon(x) \cap 2L_\epsilon(x; s) \cdot \mathbb{B} \right) dP(s).
\]

We now bound the preceding integral. By the definition of Minkowski addition and the triangle inequality, we have the pointwise convergence

\[
 \text{dist}
 \left( G_{\alpha_{ik}}(x_k; s), \partial f(x; s) + \partial \varphi(x) + \mathcal{N}_\epsilon(x) \cap 2L_\epsilon(x; s) \cdot \mathbb{B} \right)
\]

\[
 \leq \text{dist}(g(x_k; s), \partial f(x; s)) + \text{dist}(v^+_k(s), \partial \varphi(x)) + \text{dist}(w^+_k(s), \mathcal{N}_\epsilon(x) \cap 2L_\epsilon(x; s) \cdot \mathbb{B}) \to 0
\]
as \( k \to \infty \) by the earlier outer semicontinuity convergence guarantee (3.9). For suitably large \( k \), the first term in the preceding sum is bounded by an integrable
function $M'(x; s)$ by Lemma 3.13 and the latter two are bounded by $2L_s(x; s)$, which is square integrable by Lemma 3.9. Lebesgue’s dominated convergence theorem thus implies that the individual summands in expression (3.10) converge to zero, and the analytic fact that the Cesàro mean $\frac{1}{n} \sum_{k=1}^{n} a_k \to 0$ if $a_k \to 0$ gives the result.

With this lemma, we may now show the functional convergence of our stochastic model-based update schemes (2.1). We have verified that each of the conditions (i)–(iv) of Theorem 3.7 hold with the mapping $H(x) = -N_X(x) - G(x)$. Indeed, $H$ is closed-valued and outer-semicontinuous as $G(\cdot)$ is convex compact o.s.c. and $N_X(\cdot)$ is closed and o.s.c. Thus, with slight abuse of notation, let $x(\cdot)$ be the linear interpolation (3.5) of the iterates $x_k$ for either the stochastic prox-linear algorithm or the stochastic subgradient algorithm, where we recall that $x^*(\cdot) = x(t + \cdot)$. We have

**Theorem 3.14.** Let Assumptions A, B, and D hold. With probability one over the random sequence $S$, iid $\mathcal{P}$ we have the following. For any sequence $\{\tau_k\}_{k=1}^{\infty}$, the function sequence $\{x^{\tau_k}(\cdot)\}$ is relatively compact in $C(\mathbb{R}_+, \mathbb{R}^d)$. In addition, for any sequence $\tau_k \to \infty$, any limit point of $\{x^{\tau_k}(\cdot)\}$ in $C(\mathbb{R}_+, \mathbb{R}^d)$ satisfies

$$\bar{x}(t) = \bar{x}(0) + \int_0^t y(\tau)d\tau \text{ for all } t \in \mathbb{R}_+, \text{ where } y(\tau) \in -G(x(\tau)) - N_X(x(\tau)).$$

**3.3. Properties of the limiting differential inclusion.** Theorem 3.14 establishes that the updates (2.1), which include stochastic subgradient methods (Ex. 1), stochastic prox-linear methods (Ex. 2), or stochastic proximal point methods (Exs. 3–4), have sample paths asymptotically approximated by the differential inclusion

$$\dot{x} \in -G(x) - N_X(x) \text{ where } G(x) = \partial f(x) + \partial \varphi(x)$$

for the objective $f(x) = \mathbb{E}[f(x; S)]$. To establish convergence of the iterates $x_k$ themselves, we must understand the limiting properties of trajectories of the preceding differential inclusion.

We define the minimal subgradient

$$g^*(x) := \arg\min_g \left\{ \|g\|^2 \mid g \in \partial f(x) + \partial \varphi(x) + N_X(x) \right\} = \pi_{G(x) + N_X(x)}(0).$$

Before presenting the theorem on the differential inclusion, we need one regularity assumption on the objective function $F(x)$ and the constraint set $X$. Recall that a function $f$ is coercive if $f(x) \to \infty$ as $\|x\| \to \infty$.

**Assumption E.** The function $x \mapsto F(x) + \mathbb{I}_X(x)$ is coercive.

This assumption ensures that the sublevel sets of the objective function $F + \mathbb{I}_X$ are compact. Now we have the following convergence theorem.

**Theorem 3.15.** Let Assumptions A, B, and E hold. Let $x(\cdot)$ be a solution to the differential inclusion $\dot{x} \in -\partial f(x) - \partial \varphi(x) - N_X(x)$ initialized at $x(0) \in X$. Then $x(t)$ exists and is in $X$ for all $t \in \mathbb{R}_+$, sup$_t \|x(t)\| < \infty$, $x(t)$ is Lipschitz in $t$, and

$$f(x(t)) + \varphi(x(t)) + \int_0^t \|g^*(x(\tau))\|^2 d\tau \leq f(x(0)) + \varphi(x(0)).$$

We prove the theorem in Section 3.3.1, giving a few corollaries to show that solutions to the differential inclusion converge to stationary points of $f + \varphi$. 
Corollary 3.16. Let \( x(\cdot) \) be a solution to \( \dot{x} \in -G(x) - \mathcal{N}_X(x) \) and assume that for some \( t > 0 \) we have \( f(x(t)) = f(x(0)) \). Then \( g^*(x(\tau)) = 0 \) for all \( \tau \in [0, t] \).

Proof. By Theorem 3.15, we have that \( \int_0^t \|g^*(x(\tau))\|^2 \, d\tau = 0 \), so that \( g^*(x(\tau)) = 0 \) for almost every \( \tau \in [0, t] \). The continuity of \( x(\cdot) \) and outer semi-continuity of \( G \) extend this to all \( \tau \).

In addition, we can show that all cluster points of any trajectory solving the differential inclusion (3.1) are stationary. First, we recall the following definition.

Definition 3.17. Let \( \{x(t)\}_{t \geq 0} \) be a trajectory. A point \( x_\infty \) is a cluster point of \( x(t) \) if there exists an increasing sequence \( t_n \to \infty \) such that \( x(t_n) \to x_\infty \).

We have the following observation.

Corollary 3.18. Let \( x(\cdot) \) be the trajectory of \( \dot{x} \in -G(x) - \mathcal{N}_X(x) \) and let \( x_\infty \) be a cluster point of \( x(\cdot) \). Then \( x_\infty \) is stationary, meaning that \( g^*(x_\infty) = 0 \).

Proof. For \( \epsilon > 0 \), define \( T_\epsilon(x_\infty) = \{ t \in \mathbb{R}_{+} \mid \|x(t) - x_\infty\| \leq \epsilon \} \), and let \( \mu \) denote Lebesgue measure on \( \mathbb{R} \). Because the trajectory \( x(\cdot) \) is Lipschitz, we have that \( \mu(T_\epsilon(x_\infty) \cap [T, \infty)) = 0 \) for all \( \epsilon > 0 \) and \( T < \infty \) (cf. [1, Proposition 6.5.1]). Let \( \epsilon_n, \delta_n \) be sequences of positive numbers converging to 0. Because \( f(x(t)) + \varphi(x(t)) \) converges to \( f(x_\infty) + \varphi(x_\infty) \) (the sequence is decreasing and \( f + \varphi \) is continuous), we have \( \int \|g^*(x(t))\|^2 \, dt < \infty \). Moreover, there exist increasing \( T_n \) such that

\[
\int_{T_n(x_\infty) \cap [T_n, \infty)} \|g^*(x(t))\|^2 \, dt \leq \delta_n.
\]

As \( \mu(T_{\epsilon_n}(x_\infty) \cap [T_n, \infty)) = \infty \), there must exist an increasing sequence \( t_n \geq T_n, \)

\[
t_n \in T_{\epsilon_n}(x_\infty),
\]

such that \( \|g^*(x(t_n))\|^2 \leq \delta_n \). By construction \( x(t_n) \to x_\infty \), and we have a subsequence \( g^*(x(t_n)) \to 0 \). The outer semi-continuity of \( x \mapsto G(x) + \mathcal{N}_X(x) \) implies that \( 0 \in G(x_\infty) + \mathcal{N}_X(x_\infty) \).

3.3.1. Proof of Theorem 3.15. Our argument proceeds in three main steps. For shorthand, we define \( F(x) = f(x) + \varphi(x) \). Our first step shows that the function \( V(x) := F(x) + \mathbb{I}_X(x) - \inf_{y \in X} F(y) \) is a Lyapunov function for the differential inclusion (3.1), where we take the function \( W \) in Lemma 3.5 to be \( W(x, v) = \|v\|^2 \). Once we have this, then we can use the existence result of Lemma 3.3 to show that a solution \( x(\cdot) \) exists in a neighborhood of \( 0 \). The uniqueness of trajectories (Lemma 3.4) then implies that the trajectory \( x \) is non-increasing for \( V \), which then—combined with the assumption of coercivity of \( F + \mathbb{I}_X \)—implies that the trajectory \( x \) is bounded and we can extend uniquely it to all of \( \mathbb{R}_{+} \).

Part 1: A Lyapunov function. To develop a Lyapunov function, we compute directional derivatives of \( f + \varphi \).

Lemma 3.19 ([33], Chapter VI.1). Let \( h \) be convex and \( g^* = \arg\min_{g \in \partial h(x)} \{\|g\|\} \). Then the directional derivative satisfies \( h'(x; -g^*) = -\|g^*\|^2 \).

Now, take \( g^*(x) \) as in the statement of the theorem and define the Lyapunov-like function \( V(x) = f(x) + \varphi(x) + \mathbb{I}_X(x) - \inf_{y \in X} \{f(y) + \varphi(y)\} \); we claim that

\[
V'(x; -g^*(x)) \leq -\|g^*(x)\|^2.
\]

Before proving (3.11), we note that it is identical to that in Lemma 3.5 on monotone trajectories of differential inclusions. Thus there exists a solution \( x(\cdot) \) to the differential inclusion \( \dot{x} \in -G(x) - \mathcal{N}_X(x) \) defined on \([0, T] \) for some \( T > 0 \), where \( x(\cdot) \)
satisfies
\begin{equation}
(3.12) \quad f(x(t)) + \varphi(x(t)) + \mathbb{I}_X(x(t)) \leq f(x(0)) + \varphi(x(0)) - \int_0^t \|g^*(x(\tau))\|^2 d\tau
\end{equation}
for all \( t \in [0, T] \). We return now to prove the claim (3.11). Let \( x \in X \) and recall by Assumption B that for all \( \lambda \geq \mathbb{E}[\lambda(S,x)] \) that \( f + \frac{\lambda}{2} \| \cdot - x_0 \|^2 \) is convex in an \( \epsilon \)-neighborhood of \( x \). Now, define \( F_x(y) = f(y) + \varphi(y) + \frac{\lambda}{2} \| y - x \|^2 \), so that for \( v \) with \( \|v\| = 1 \) and \( t \leq \epsilon \), we have
\[
|F(x + tv) - F(x)| \leq |F_x(x + tv) - F(x)| + \frac{t^2\lambda^2}{2} \| v \|^2.
\]
Because \( \varphi \) is convex and the error in the approximation \( f_x \) of \( f \) is second-order, taking limits as \( u \to v, t \to 0 \), we have for any fixed \( x \in X \) that
\[
\liminf_{t \downarrow 0, u \to v} \frac{F(x + tu) + \mathbb{I}_X(x + tu) - F(x)}{t} = \liminf_{t \downarrow 0} \frac{F_x(x + tv) + \mathbb{I}_X(x + tv) - F_x(x)}{t} = \sup_{g \in \partial f(x) + \partial \varphi(x) + N_X(x)} \langle g, v \rangle,
\]
where \( F(x) = f(x) + \varphi(x) \), and we have used that the subgradient set of \( y \mapsto F_x(y) \) at \( y = x \) is \( \partial f(x) + \partial \varphi(x) \). Applying Lemma 3.19 with \( v = -g^*(x) \) gives claim (3.11).

Part 2: Uniqueness of trajectories. Lemma 3.4 shows that solutions to \( \dot{x} \in -G(x) - N_X(x) \) have unique trajectories almost immediately. By Assumption B, for any \( x \in X \), \( f + \varphi + \frac{\lambda}{2} \| \cdot \|^2 \) is convex on the set \( X \cap \{ x + \epsilon \mathbb{B} \} \) for all \( \lambda \geq \mathbb{E}[\lambda(S,x)] \). Thus for points \( x_1, x_2 \) satisfying \( \| x_1 - x \| \leq \epsilon \) and \( g_i \in \partial f(x_i) + \partial \varphi(x_i) + N_X(x_i) \),
\[
\langle g_1 + \lambda x_1 - g_2 - \lambda x_2, x_1 - x_2 \rangle \geq 0 \quad \text{or} \quad \langle -g_1 + g_2, x_1 - x_2 \rangle \leq \lambda \| x_1 - x_2 \|^2
\]
because subgradients of convex functions are increasing [33, Ch. VI]. Now, suppose that on an interval \([0, T]\) the trajectory \( x(t) \) satisfies \( \| x(t) \| \leq B \), that is, it lies in a compact subset of \( X \). Then by taking a finite subcovering of \( B \mathbb{B} \cap X \) as necessary, we may assume \( f + \varphi + \frac{\lambda}{2} \| \cdot \|^2 \) is convex over \( B \mathbb{B} \cap X \). This preceding display is equivalent to the condition of Lemma 3.4, so that for any \( B \) and any interval \([0, T]\) for which the trajectory \( x(t) \) satisfies \( \| x(t) \| \leq B \) on \( t \in [0, T] \), the trajectory is unique. In particular, the Lyapunov inequality (3.12) is satisfied on the interval over which the trajectory \( \dot{x} \in -G(x) - N_X(x) \) is defined.

Part 3: Extension to all times. We argue that we may take \( T \to \infty \). For any fixed \( T < \infty \), we know that \( f(x(T)) + \varphi(x(T)) \leq f(x(0)) + \varphi(x(0)) \), and the coercivity of \( f + \varphi \) over \( X \) implies that there exists \( B < \infty \) such that \( \| x(t) \| \leq B \) on this trajectory (i.e. \( t \in [0, T] \)). The compactness of \( \partial f(x) + \partial \varphi(x) \) for \( x \in X \cap \{ y : \| y \| \leq B \} \) implies that \( \inf_x \{ \| g \| : g \in \partial f(x) + \partial \varphi(x) + N_X(x) \} \) is bounded (because \( 0 \in N_X(x) \)). The condition on existence of paths for all times \( T \) in Lemma 3.3 applies.

The Lipschitz condition on \( x(t) \) is an immediate consequence of the boundedness of the subgradient sets \( \partial f(x) + \partial \varphi(x) \) for bounded \( x \).

3.4. Almost sure convergence to stationary points. Thus far we have shown that the limit points of the stochastic model-based iterations (2.1) are asymptotically equivalent to the differential inclusion (3.1) (Theorem 3.14) and that solutions to the differential inclusion have certain uniqueness and convergence properties (Theorem 3.15). Based on those asymptotic equivalence results and convergence properties,
this section shows that cluster points of the iterates $x_k$ are stationary. To provide a starting point, we state the main theorem of the section, which applies to any sequence $x_k$ generated by a model update (2.1) satisfying Conditions C.(i)–C.(iv).

**Theorem 3.20.** Let Assumptions A, B, D, and E hold. Then with probability 1,

\[(3.13) \quad \left( \lim \inf_k F(x_k), \lim \sup_k F(x_k) \right) \subseteq F(X^*) = \{ f(x) : x \in X^* \}.\]

Let us discuss the theorem briefly. Theorem 2.1 is an immediate consequence of the theorem, as Assumptions D and E are trivial when $X$ is compact. To illustrate the theorem, we also establish convergence of the iterates of $x_k$ to the stationary set $X^*$ under the weak Sard-type Assumption C, giving Corollary 2.2 as a consequence.

**Corollary 3.21.** Let Assumptions A–E hold. With probability 1, all cluster points of the sequence $(x_k)_{k=1}^\infty$ belong to the stationary set $X^*$, and $F(x_k) = f(x_k) + \varphi(x_k)$ converges.

**Proof.** By Assumption C (that $(F(X^*))^c$ is dense), Theorem 3.20 implies that $F(x_k)$ converges. That all cluster points of $x_k$ belong to $X^*$ follows from Lemma 3.23 to come.

**Conditions for boundedness of the iterates.** Key to our theorems is the boundedness of the iterates $x_k$, so it is important to give sufficient conditions that Assumption D holds even when $X$ is unbounded. We may develop examples by considering the joint properties of the regularizer $\varphi$ and objectives $f(x;S)$ in the stochastic updates of our methods. We mention two such examples, focusing for simplicity on the stochastic subgradient method (Ex. 1, using subgradient $g(x; s) \in \partial f(x; s)$) in the unconstrained case $X = \mathbb{R}^d$. We first assume that $\varphi(x) = \frac{\lambda}{2} \|x\|^2$, i.e. $\ell_2$ or Tikhonov regularization, common in statistical learning and inverse problems. In addition, let us assume that $f(x; s)$ is $L(s)$-Lipschitz in $x$, where $L := \mathbb{E}[L(S)]^{\frac{1}{2}} < \infty$, so that $\|g(x; s)\| \leq L(s)$. This regularization is sufficient to guarantee boundedness:

**Observation 2.** Let the conditions of the preceding paragraph hold. Assume that $\mathbb{E}[L(S)]^{\frac{1}{2}} < \infty$. Then with probability 1, $\sup_k \|x_k\| < \infty$.

We provide the proof of Observation 2 in Appendix B.4. More quickly growing regularization functions $\varphi$ also yield bounded iterates. We begin with a definition.

**Definition 3.22.** A function $\varphi$ is $\beta$-coercive if $\lim_{\|x\| \to \infty} \varphi(x)/\|x\|^\beta = \infty$, and it is $(\lambda, \beta)$-regularly coercive if it is $\beta$-coercive and $\varphi(x) \geq \varphi(\lambda x)$ for $\|x\|$ large.

**Observation 3.** Let $\varphi$ be $(\beta, \lambda)$-coercive with $\lambda \in [0, 1)$. Assume that for all $s \in S$, $x \mapsto f(x; s)$ is $L(1 + \|x\|^\nu)$-Lipschitz in a neighborhood of $x$, where $L < \infty$ is some constant, and $\nu < \beta - 1$. Then $\sup_k \|x_k\| < \infty$.

We provide the proof of Observation 3 in Appendix B.5.

**3.4.1. Proof of Theorem 3.20.** We prove the theorem using two intermediate results: in the first part (Lemma 3.23), we show that if a cluster point $x_\infty$ of the sequence $x_k$ is non-stationary, then the iterates $F(x_k)$ must decrease through $F(x_\infty)$ infinitely often. A consequence we show is that $\limsup_k F(x_k)$ and $\liminf_k F(x_k)$ belong to $F(X^*)$. We then show (Lemma 3.24) that the interpolated path $x(\cdot)$ of the iterates $x_k$ (recall definition (3.5)) cannot move too quickly (Lemma 3.24). We finally use this to show that all limiting values of $f(x_k) + \varphi(x_k)$ belong to $F(X^*)$. In the statements of the lemmas, we implicitly assume all of the conditions of the theorem (i.e. Assumptions A, B, D, and E).
We start with a result on the boundaries of the sequences $F(x_k)$ and the growth of the path $x(t)$ interpolating the iterates $x_k$ (recall the definition (3.5)).

**Lemma 3.23.** With probability one, $\liminf_k F(x_k) \in F(X^*)$ and $\limsup_k F(x_k) \in F(X^*)$. For any increasing sequence $\{h_k\} \subseteq \mathbb{R}$ satisfying $h_k \to \infty$ and $\lim_k x(h_k) = x_\infty \not\in X^*$ and any sequence $\tau_k \to \tau > 0$,

$$\liminf_k F(x(h_k - \tau_k)) > F(x_\infty) > \limsup_k F(x(h_k + \tau_k)).$$  \hfill (3.14)

**Proof.** We begin with the second claim (3.14) of the lemma, as the first is a nearly immediate consequence of the second. Let the probability 1 events of Theorem 3.14 hold, that is, the limit points of the shifted sequences $\{x^\tau(\cdot)\}$ satisfy the differential inclusion (3.1). We introduce the left and right-shifted times

$$h^-_k = h_k - \tau_k \quad \text{and} \quad h^+_k = h_k + \tau_k \quad \text{for} \quad k \in \mathbb{N}.$$

To show the lemma, it suffices to show that, for any subsequence $\{h_{k(m)}\}$ of the sequence $\{h_k\}$, there exists a further subsequence $\{h_{k(m(n))}\}_{n \in \mathbb{N}}$ such that

$$\lim_{n \to \infty} F(x_{h^-_{k(m(n))}}) > F(x_\infty) > \lim_{n \to \infty} F(x_{h^+_{k(m(n))}}).$$

Now, fix a subsequence $\{h_{k(m)}\}_{m \in \mathbb{N}}$. By Assumption D, both sequences $\{x(h^-_{k(m)})\}$ and $\{x(h^+_{k(m)})\}$ are relatively compact in $\mathbb{R}^d$, and Theorem 3.14 implies that the sequence of shifted functions $\{x^{h^-_{k(m)}}(\cdot)\}_{m \in \mathbb{N}}$ is relatively compact in $\mathcal{C}(\mathbb{R}_+, \mathbb{R}^d)$. As a consequence, there exists a further subsequence $\{h_{k(m(n))}\}_n$ such that for $u_n = x(h^-_{k(m(n)})$ and $v_n = x(h^+_{k(m(n)})$, there are points $u_\infty$ and $v_\infty$ and a function $\overline{\tau} \in \mathcal{C}(\mathbb{R}_+, \mathbb{R}^d)$ such that

$$\lim_n u_n = u_\infty, \quad \lim_n v_n = v_\infty, \quad \text{and} \quad \lim_{n \to \infty} x^{h^-_{k(m(n)}}(\cdot) = \overline{\tau}(\cdot).$$

By this equation, that $\tau_k \to \tau$ as $k \to \infty$, and the assumption in the lemma that $\lim_k x(h_k) = \lim_k x^{h^-}(\tau_k) = x_\infty$, we have $\overline{\tau}(0) = u_\infty$, $\overline{\tau}(\tau) = x_\infty$, and $\overline{\tau}(2\tau) = v_\infty$. Theorem 3.14 shows that $\overline{\tau}$ satisfies the differential inclusion (3.1), which has a monotone trajectory by Theorem 3.15. As $\overline{\tau}(\tau) = x_\infty \not\in X^*$, Corollary 3.16 implies the strict decrease

$$F(u_\infty) = F(\overline{\tau}(0)) > F(\overline{\tau}(\tau)) > F(\overline{\tau}(2\tau)) = F(v_\infty),$$

yielding inequality (3.15) and thus inequality (3.14).

Now we show the first claim of the lemma. Let $y = \liminf_k F(x_k)$ (the proof for case $y = \limsup_k F(x_k)$ is, mutatis mutandis, identical). As the sequence $\{x_k\}_k$ is bounded and the function $F$ is continuous on $X$, there is a subsequence $\{x_{k(m)}\}_{m \in \mathbb{N}}$ with $x_{k(m)} \to x_\infty$ and $\lim_m F(x_{k(m)}) = F(x_\infty) = y$. Recall that $x_k = x(t_k)$ for $t_k = \sum_{i=1}^k \alpha_i$. If $x_\infty \not\in X^*$, then for any $\tau > 0$ and for $h_k = t_k$, inequality (3.14) implies $F(x_\infty) > \limsup_m F(x(h_k(m)) + \tau)) \geq \liminf_k F(x_k)$, an absurdity, so we must have $x_\infty \in X^*$.

Our second intermediate result shows that the interpolated paths $x(\cdot)$ cannot move too quickly.
Lemma 3.24. For any two sequences \( \{h_k^0\}_{k=1}^\infty \) and \( \{h_k'\}_{k=1}^\infty \) satisfying \( h_k' > h_k \), \( \lim_k h_k' = \lim_k h_k = \infty \) and \( \liminf_k \|x(h_k') - x(h_k)\| > 0 \), we have with probability 1 that \( \liminf_k (h_k' - h_k) > 0 \).

Proof. As in the proof of Lemma 3.23, fix the sample \( S_1, S_2, \ldots \) so that the probability 1 conclusions of Theorem 3.14 hold. Now, for \( h \in \mathbb{R}_+ \) define

\[
k_<(h) = \max\{k \in \mathbb{N} : t_k \leq h\} \quad \text{and} \quad k_>(h) = \min\{k \in \mathbb{N} : t_k \geq h\},
\]

where we recall the interpolation times \( t_k = \sum_{i=1}^k \alpha_i \). As \( \alpha_k \to 0 \), the statement \( \liminf_{k \to \infty} (h_k - h_k') > 0 \) is equivalent to the statement \( \liminf_{k \to \infty} (t_{k_>(h_k)} - t_{k_<(h_k')} > 0 \). For any \( m \leq n \in \mathbb{N} \), we have

\[
\|x(t_n) - x(t_m)\| = \left\| \sum_{i=m+1}^n \alpha_i \mathcal{G}_{\alpha_i}(x_i) + \sum_{i=m+1}^n \alpha_i \xi_i \right\|
\leq (t_n - t_m) \sup_i \|\mathcal{G}_{\alpha_i}(x_i)\| + \left\| \sum_{i=m+1}^n \alpha_i \xi_i \right\|.
\]

Let \( M = \sup_i \|\mathcal{G}_{\alpha_i}(x_i)\| < \infty \) (use Lemmas 3.8 and 3.9 to see that \( M < \infty \)). Lemma 3.10 implies that \( \lim_{m \to \infty} \sup_{n \geq m} \|\sum_{i=m+1}^n \alpha_i \xi_i\| = 0 \). Thus, we obtain that for any \( \epsilon > 0 \), there exists \( N \in \mathbb{N} \) such that for all \( m, n \geq N \),

\[
(t_n - t_m)M \geq \|x(t_n) - x(t(m))\| - \left\| \sum_{i=m+1}^n \alpha_i \xi_i \right\| \geq \|x(t_n) - x(t(m))\| - \epsilon.
\]

As \( x(\cdot) \) are linear interpolations of \( x_k = x(t_k) \) and \( h_k, h'_k \to \infty \), for any \( \epsilon > 0 \) there exists \( K \in \mathbb{N} \) such that \( k \geq K \) implies

\[
\|x(h_k') - x(h_k)\| \leq \max\{\|x(t_n) - x(t(m))\| : n, m \in [k_<(h_k'), k_>(h_k')]\}
\leq (t_{k_>(h_k)} - t_{k_<(h_k')} + M + \epsilon.
\]

Since \( \liminf_k \|x(h_k') - x(h_k)\| > 0 \), inequality (3.16) gives the result.

To prove the theorem, we assume (\( \liminf_k F(x_k), \limsup_k F(x_k) \)) is non-empty, as otherwise the result is trivial. As in the proof of Lemma 3.23, fix the sample \( S_1, S_2, \ldots \) so that the probability 1 conclusions of Theorem 3.14 hold.

Suppose for the sake of contradiction that \( y^{hi} \in (\liminf_k F(x_k), \limsup_k F(x_k)) \) satisfies \( y^{hi} \notin F(X^*) \). Let \( y^{lo} < y^{hi} \), \( y^{lo} \in (\liminf_k F(x_k), \limsup_k F(x_k)) \). We claim we may choose sequences \( \{h_k^{lo}\} \) and \( \{h_k^{hi}\} \) with \( h_k^{lo} < h_k^{hi} \), \( \lim_k h_k^{lo} = \lim_k h_k^{hi} = \infty \), and

\[
F(x(h_k^{lo})) = y^{lo}, \quad F(x(h_k^{hi})) = y^{hi}, \quad \text{and} \quad y^{lo} < F(x(t)) < y^{hi} \quad \text{for} \quad t \in (h_k^{lo}, h_k^{hi}).
\]

To see this, consider traversals of the interval \( [y^{lo}, y^{hi}] \) (see Figure 3.1). As \( \liminf_k F(x_k) < y^{lo} < y^{hi} < \limsup_k F(x_k) \), there exist increasing sequences \( h_k^{lo} \) and \( h_k^{hi} \) with

\[
F(x(h_k^{lo})) = y^{lo}, \quad F(x(h_k^{hi})) = y^{hi} \quad \text{and} \quad h_k^{lo} < h_k^{hi}.
\]

Then we define the last entrance and first subsequent exit times

\[
h_k^{lo} := \sup\{h \in [h_k^{lo}, t_k] : f(x(h)) \leq y^{lo}\} \quad \text{and} \quad h_k^{hi} := \inf\{h \in [h_k^{hi}, t_k] : f(x(h)) \geq y^{hi}\}.
\]
The continuity of $F$ and $x(\cdot)$ show that the conclusion (3.17) holds.

By taking a subsequence if necessary, we assume w.l.o.g. that $x(h^hi_k) \to x_{\infty}$. By continuity, we have $y^h = F(x_{\infty})$ and $x_{\infty} \notin X^*$ as $y^h \notin F(X^*)$. Now, fix some $\tau > 0$, and take $y_\tau = \liminf_k F(x(h^hi_k - \tau))$, which satisfies $y_\tau > F(x_{\infty}) = y^h$ by Lemma 3.23, because $x_{\infty} \notin X^*$. Consider the value gap $\Delta = \frac{1}{2}\min\{|y_\tau - y^h|, |y^h - y^{lo}|\} > 0$. The continuity of $F$ implies for some $\delta > 0$, we have $|F(x) - y^h| \leq \Delta$ for $x \in X \cap \{x_{\infty} + \delta B\}$. As $\liminf_k |F(x(h^hi_k)) - F(x_{\infty})| = |y^{lo} - y^h| > \Delta$ and $\liminf_k |F(x(h^hi_k) - \tau) - F(x_{\infty})| = |y_\tau - y^h| \leq \Delta$, by continuity of $F$ and our choice of $\delta$, we must have the separation

$$
\liminf_k \|x(h^lo_k) - x_{\infty}\| > \delta, \quad \text{and} \quad \liminf_k \|x(h^hi_k) - x_{\infty}\| > \delta.
$$

For this value $\delta > 0$, consider the sequence $\{h^\delta_k\}_{k=1}^\infty$ defined by

$$
\delta_k = \max\{t \mid t < h^hi_k, \|x(t) - x(h^hi_k)\| = \delta\}.
$$

Then using $x(h^hi_k) \to x_{\infty}$, we have $\liminf_k \|x(h^lo_k) - x(h^hi_k)\| > \delta$ and so

$$
\delta_k \in [h^lo_k, h^hi_k] \text{ eventually, and } F(x(h^\delta_k)) \in [y^{lo}, y^h]
$$

by definition (3.17) of the upcrossing times.

By Eq. (3.18) and that $x(h^hi_k) \to x_{\infty}$, we have $h^\delta_k > \max\{h^lo_k, h^hi_k - \tau\}$ for large enough $k$. In particular, this implies that $\limsup_k (h^hi_k - h^lo_k) \leq \tau$. Because the paths $x(\cdot)$ cannot move too quickly by Lemma 3.24, the quantity $\tau(\delta) := \liminf_k (h^hi_k - h^lo_k) \in (0, \tau]$. By taking subsequences if necessary, we may assume w.l.o.g. that the sequence $h^\delta_k - h^lo_k \to \tau_\infty \in [\tau(\delta), \tau]$, so that $h^lo_k = h^hi_k - \tau_k$ for $\tau_k \to \tau_\infty > 0$. As $x(h^hi_k) \to x_{\infty} \notin X^*$, Lemma 3.23 implies that $\liminf_k F(x(h^hi_k)) > y^h$, contradicting the containments (3.19). This is the desired contradiction, which gives the theorem.

4. Experiments. The asymptotic results in the previous sections provide somewhat limited guidance for application of the methods. To that end, in this section we present experimental results explicating the performance of the methods as well as comparing their performance to the deterministic prox-linear method (1.5) (adapted
from [19, Section 5]). Drusvyatskiy and Lewis [19] provide a convergence guarantee for the deterministic method that after $O(1/\epsilon^2)$ iterations, the method can output an $\epsilon$-approximate stationary point, that is, a point $\hat{x}$ such that there exists $x_0$ with $\|\hat{x} - x_0\| \leq \epsilon$ and $\min\{\|g\| : g \in \partial f(x_0)\} \leq \epsilon$. These comparisons provide us a somewhat better understanding of the practical advantages and disadvantages of the stochastic methods we analyze.

We consider the following problem. We have observations $b_i = \langle a_i, x^* \rangle^2$, $i = 1, \ldots, n$, for an unknown vector $x^* \in \mathbb{R}^d$, and we wish to find $x^*$. This is a quadratic system of equations, which arises (for example) in phase retrieval problems in imaging science as well as in a number of combinatorial problems [10, 9]. The natural exact penalty form of this system of equations yields the minimization problem

\[(4.1) \quad \text{minimize} \quad f(x) := \frac{1}{n} \sum_{i=1}^{n} |\langle a_i, x \rangle^2 - b_i|,\]

which is certainly of the form (1.1) with the function $h(t) = |t|$ and $c_i(x) = \langle a_i, x \rangle^2 - b_i$, so we may take the sample space $\mathcal{S} = \{1, \ldots, n\}$. In somewhat more general noise models, we may also assume we observe $b_i = \langle a_i, x^* \rangle^2 + \xi_i$ for some noise sequence $\xi_i$; in this case the problem (4.1) is a natural robust analogue of the typical phase retrieval problem, which uses the smooth objective $(\langle a_i, x \rangle^2 - b_i)^2$. While there are a number of specialized procedures for solving such quadratic equations [10], we view problem (4.1) as a natural candidate for exploration of our algorithms’ performance.

The stochastic prox-linear update of Example 2 is reasonably straightforward to compute for the problem (4.1). Indeed, as $\nabla_x (\langle a_i, x \rangle^2 - b_i) = 2 \langle a_i, x \rangle a_i$, by rescaling by the stepsize $\alpha_k$ we may simplify the problem to minimizing $|b + \langle a, x \rangle| + \frac{1}{2} \|x - x_0\|^2$ for some scalar $b$ and vectors $a, x_0 \in \mathbb{R}^d$. A standard Lagrangian calculation shows that

$$\arg\min_x \left\{ |b + \langle a, x \rangle| + \frac{1}{2} \|x - x_0\|^2 \right\} = x_0 - \pi(\lambda)a \quad \text{where} \quad \lambda = \frac{\langle x_0, a \rangle + b}{\|a\|^2}$$

and $\pi(\cdot)$ is the projection of its argument into the interval $[-1, 1]$. The full proximal step (Example 3) is somewhat more expensive, and for general weakly convex functions, it may be difficult to estimate $\rho(s)$, the weak-convexity constant; nonetheless, in Section 4.3 we use it to evaluate its merits relative to the prox-linear updates in terms of robustness to stepsize. Each iteration $k$ of the deterministic prox-linear method [7, 19] requires solving the quadratic program

\[(4.2) \quad x_{k+1} = \arg\min_x \left\{ \frac{1}{n} \sum_{i=1}^{n} |\langle a_i, x_k \rangle^2 + 2 \langle a_i, x_k \rangle \langle a_i, x - x_k \rangle - b_i| + \frac{1}{2\alpha} \|x - x_k\|^2 \right\},\]

which we perform using Mosek via the Convex.jl package in Julia [52].

Before we present our results, we describe our choices for all parameters in our experiments. In each experiment, we let $n = 500$ and $d = 50$, and we choose $x^*$ uniformly from the unit sphere $S^{d-1}$. The noise variables $\xi_i$ are i.i.d. Laplacian random variables with mean 0 and scale parameter $\sigma$, which we vary in our experiments. We construct the design matrix $A \in \mathbb{R}^{n \times d}$, $A = [a_1 \cdots a_n]^T$, where each row is a measurement vector $a_i$, as follows: we choose $U \in \mathbb{R}^{n \times d}$ uniformly from the orthogonal matrices in $\mathbb{R}^{n \times d}$, i.e., $U^T U = I_{d \times d}$. We then make one of two choices for $A$, the first of which controls the condition number of $A$ and the second the regularity of the norms.
of the rows $a_i$. In the former case, we set $A = UR$, where $R \in \text{diag}(\mathbb{R}^d) \subset \mathbb{R}^{d \times d}$ is diagonal with linearly spaced diagonal elements in $[1, \kappa]$, so that $\kappa \geq 1$ gives the condition number of $A$. In the latter case, we set $A = RU$, where $R \in \text{diag}(\mathbb{R}^n) \subset \mathbb{R}^{n \times n}$ is again diagonal with linearly spaced elements in $[1, \kappa]$. Finally, in each of our experiments, we set the stepsize for the stochastic methods as $\alpha_k = \alpha_0 k^{-\beta}$, where $\alpha_0 > 0$ is the initial stepsize and $\beta \in (\frac{1}{2}, 1)$ governs the rate of decrease in stepsize.

We present three experiments in more detail in the coming subsections: (i) basic performance of the algorithms, (ii) the role of conditioning in the data matrix $A$, and (iii) an analysis of stepsize sensitivity for the different stochastic methods, that is, an exploration of the effects of the choices of $\alpha_0$ and $\beta$ in the stepsize choice.

4.1. Performance for well-conditioned problems. In our first group of experiments, we investigate the performance of the three algorithms under noiseless and noisy observational situations. In each of these experiments, we set the condition number $\kappa = \kappa(A) = 1$. We consider three experimental settings to compare the procedures: in the first, we have noiseless observations $b_i = \langle a_i, x^\star \rangle^2$; in the second, we set $b_i = \langle a_i, x^\star \rangle^2 + \xi_i$ where $\xi_i$ are Laplacian with scale $\sigma = 1$; and in the third, we again have noiseless observations $b_i = \langle a_i, x^\star \rangle^2$, but for a fraction $p = .1$ of the observations, we replace $b_i$ with an independent $N(0, 25)$ random variable, so that $n/10$ of the observations provide no information. Within each experimental setting, we perform $N = 100$ independent tests, and in each individual test we allow the stochastic methods to perform $N = 200n$ iterations (so approximately 200 loops over the data).
For the deterministic prox-linear method (4.2), we allow 200 iterations. Each deterministic iteration is certainly more expensive than \( n \) (sub)gradient steps or stochastic prox-linear steps, but it provides a useful benchmark for comparison. The stochastic methods additionally require specification of the initial stepsize \( \alpha_0 \) and power \( \beta \) for \( \alpha_k = \alpha_0 k^{-\beta} \), and to choose this, we let \( \alpha_0 \in \{1, 10, 10^2, 10^3\} \) and \( \beta \in \{0.6, 0.7, 0.8, 0.9\} \), perform 3n steps of the stochastic method with each potential pair \((\alpha_0, \beta)\), and then perform the full \( N = 200n \) iterations with the best performing pair. We measure performance of the methods within each test by plotting the gap \( f(x_k) - f(x^\star) \), where we approximate \( x^\star \) by taking the best iterate \( x_k \) produced by any of those methods.

While the problem is non-convex and thus may have spurious local minima, these gaps provide a useful quantification of (relative) algorithm performance.

We summarize our experimental results in Figure 4.1. In each plot, we plot the median of the excess gap \( f(x_k) - f(x^\star) \) as well as its 10% and 90% confidence intervals over our \( N = 100 \) tests. In order to compare the methods, the horizontal axis scales as iteration \( k \) divided by \( n \) for the stochastic methods and as iteration for the deterministic method (4.2). Each of the three methods is convergent in these experiments, and the stochastic methods exhibit fast convergence to reasonably accurate (say \( \epsilon \approx 10^{-4} \)) solutions after a few passes through the data. Eventually (though we do not always plot such results) the deterministic prox-linear algorithm achieves substantially better accuracy, though its progress is often slower. This corroborates substantial experience from the convex case with stochastic methods [c.f. 40, 24].

There are differences in behavior for the different methods, which we can heuristically explain. In Fig. 4.1(a), the stochastic prox-linear method (Ex. 2) converges substantially more quickly than the stochastic subgradient method. Intuitively, we expect this behavior because each data point \((a_i, b_i)\) should have \( \langle a_i, x \rangle^2 = b_i \) exactly, and the precise stepping of the prox-linear method achieves this more easily. In Fig. 4.1(b), where \( b_i = \langle a_i, x^\star \rangle^2 + \xi_i \) the two methods have similar behavior; in this case, the population expectation \( f_{\text{pop}}(x) = \mathbb{E}[\langle b - \langle a, x^\star \rangle \rangle^2] \) is smooth, because the noise \( \xi \) has a density, so gradient methods are likely to be reasonably effective. Moreover, with probability 1 we have \( \langle a_i, x^\star \rangle^2 \neq b_i \), so that the precision of the prox-linear step is unnecessary. Finally, Fig. 4.1(c) shows that the methods are robust to corruption, but because we have \( \langle a_i, x^\star \rangle^2 = b_i \) for the majority of \( i \in \{1, \ldots, n\} \), there is still benefit to using the more exact (stochastic) prox-linear iteration. We note in passing that the gap in function values \( f(x_k) \) between the stochastic prox-linear method and stochastic subgradient method (SGM) is statistically significantly positive at the \( p = 10^{-2} \) level for iterations \( k = 1, \ldots, 20 \), and that at each iteration \( k \), the prox-linear method outperforms SGM for at least 77 of the \( N = 100 \) experiments (which is statistically significant for rejecting the hypothesis that each is equally likely to achieve lower objective value than the other at level \( p = 10^{-6} \)).

**4.2. Problem conditioning and observation irregularity.** In our second set of experiments, we briefly investigate conditioning of the problem (4.1) by modifying the condition number \( \kappa = \kappa(A) \) of the measurement matrix \( A \in \mathbb{R}^{n \times d} \) or by modifying the relative norms of the rows \( \|a_i\| \) of \( A \). In each of the experiments, we choose the initial stepsize \( \alpha_0 \) and power \( \beta \) in \( \alpha_k = \alpha_0 k^{-\beta} \) using the same heuristic as the previous experiment for the stochastic methods (by considering a grid of possible values and selecting the best after 3n iterations). We present four experiments, whose results we summarize in Figure 4.2. As in the previous experiments, we plot the gaps \( f(x_k) - f(x^\star) \) versus iteration \( k \) (for the deterministic prox-linear method) and versus iteration \( k/n \) for the stochastic methods. In the first two, we use observations
Fig. 4.2. Experiments with $A$ matrices of varying condition number and irregularity in row norms.

$b_i = \langle a_i, x^* \rangle^2 + \xi_i$, where the noise variables are i.i.d. Laplacian with scale $\sigma = 1$, and we set $A = UR$ where $R$ is diagonal, in the first (Fig. 4.2(a)) scaling between 1 and $\kappa = 10$ and in the second (Fig. 4.2(b)) scaling between 1 and $\kappa = 100$. Each method’s performance degrades as the condition number $\kappa = \kappa(A)$ increases, as one would expect. The performance of SGM degrades substantially more quickly with the conditioning of the matrix $A$, in spite of the fact that noisy observations improve its performance relative to the other methods (in the case $\sigma = 0$, SGM’s relative performance is worse).

In the second two experiments, we set $A = RU$, where $R$ is diagonal with entries linearly spaced in $[1,\kappa]$ for $\kappa = 10$, so that the norms $\|a_i\|$ are irregular (varying by approximately a factor of $\kappa = 10$). In the first of the experiments (Fig. 4.2(c)), we set the observations $b_i = \langle a_i, x^* \rangle^2$ with no noise, while in the second (Fig. 4.2(d)) we set $b_i = \langle a_i, x^* \rangle^2 + \xi_i$ for $\xi_i$ i.i.d. Laplacian with scale $\sigma = 1$. In both cases, the stochastic prox-linear method has better performance—this is to be expected, because its more exact updates involving the linearization $h(c(x_k; s) + \nabla c(x_k; s)^T(x - x_k); s)$ are more robust to scaling of $\|a_i\|$. As we explore more carefully in the next set of experiments, one implication of these results is that the robustness and stability of the stochastic prox-linear algorithm with respect to problem conditioning is reasonably good, while the behavior of stochastic subgradient methods can be quite sensitive to conditioning behavior of the design matrix $A$. 

\begin{align*}
(b) & A = UR, \ k(A) = 100 \\
(c) & A = RU, \ b_i = \langle a_i, x^* \rangle^2 \\
(d) & A = RU, \ b_i = \langle a_i, x^* \rangle^2 + \xi_i
\end{align*}
4.3. Robustness of stochastic methods to stepsize. In our final experiment, we investigate the effects of stepsize parameters for the behavior of our stochastic methods. For stepsizes $\alpha_k = \alpha_0 k^{-\beta}$, the stochastic methods require specification of both the parameter $\alpha_0$ and $\beta$, so it is interesting to investigate the robustness of the stochastic prox-linear method and SGM to various settings of $\alpha_0$ and $\beta$. In each of these experiments, we set the condition number $\kappa(A) = 1$ and have no noise, i.e. $b_i = \langle a_i, x^* \rangle^2$. We vary the initial stepsize $\alpha_0 \in \{2^{-1}, 2^1, 2^3, \ldots, 2^{11} \}$ and the power $\beta \in \{0.5, 0.55, 0.6, \ldots, 1 \}$. In this experiment, we have $f(x^*) = 0$, and we investigate the number of iterations

$$T(\epsilon) := \inf \{ k \in \mathbb{N} | f(x_k) \leq \epsilon \}$$

required to find and $\epsilon$-optimal solution. (In our experiments, the stochastic methods always find such a solution eventually.) We perform $N = 250$ tests for each setting of the pairs $\alpha_0, \beta$, and in each test, we implement all three of the stochastic gradient (Ex. 1), prox-linear (Ex. 2), and proximal-point (Ex. 3) methods, each for $k = 200n$ iterations, setting $T(\epsilon) = 200n$ if no iterate $x_k$ satisfies $f(x_k) \leq \epsilon$.

Figure 4.3 illustrates the results of these experiments, where the vertical axis gives the median time $T(\epsilon)$ to $\epsilon = 10^{-2}$-accuracy over all the $N = 250$ tests. The left plot demonstrates convergence time of the stochastic prox-linear and subgradient methods versus the initial stepsize $\alpha_0$ and power $\beta$, indicated on the horizontal axes. The solid white-to-blue surface, with thin lines, corresponds to the iteration counts for the stochastic prox-linear method; the transparent surface with thicker lines corresponds to the iteration counts for the stochastic subgradient method. Figure 4.3 shows that the stochastic prox-linear algorithm consistently has comparable or better performance than SGM for the same choices of parameters $\alpha_0, \beta$. The right plot shows convergence of the stochastic proximal-point method (see Example 3 in Sec 2.1), stochastic prox-linear method, and stochastic subgradient method versus stepsize on a log-plot of initial stepsizes, with $\beta = \frac{1}{2}$ fixed. The most salient aspect of the figures is that the stochastic prox-linear and proximal-point methods are more robust to stepsize (mis-)specification than is SGM. Indeed, Fig. 4.3 makes apparent, the range of stepsizes yielding good performance for SGM is a relatively narrow valley.
while the prox-linear and proximal-point methods enjoy reasonable performance for broad choices of (often large) stepsizes $\alpha_0$, with less sensitivity to the rate of decrease $\beta$ in the stepsize as well. This behavior is expected: the iterations of the stochastic prox-linear and proximal-point methods (Exs. 2–3) guard more carefully against wild swings that result from aggressive stepsize choices, yielding more robust convergence.

**Appendix A. Proof of Theorem 3.7.**

To prove the theorem, we require a few pieces of additional notation. Define the indices

$$k_<(t) = \max\{k \in \mathbb{N} : t_k \leq t\} \quad \text{and} \quad k_>(t) = \min\{k \in \mathbb{N} : t_k \geq t\} \quad \text{for} \quad t \in \mathbb{R}_+.$$  

For $t \in \mathbb{R}_+$, let $x_t(\cdot)$ denote the solution to the differential equation

$$\dot{x}_t(\cdot) = y(\cdot) \quad \text{and} \quad x_t(t) = x(t),$$  

which is evidently $x_t(\tau) = x(t) + \int_t^\tau y(u)du$. We divide the proof into two main parts: first, we show that the function family $x^\tau(\cdot)$ is relatively compact in $C(\mathbb{R}_+, \mathbb{R}^d)$ using the Arzelà-Ascoli theorem. In the second part, we apply a few functional-analytic results on weak convergence to establish that $x^\tau(\cdot)$ has the limiting differential inclusion properties claimed in the theorem.

**Part I: Relative compactness.** We begin with a lemma that shows an equivalence between the time-shifted and interpolated \((3.5)\) sequence $x^t(\cdot) = x(t + \cdot)$ and the differential sequence $x_t(\cdot)$ as $t \to \infty$, showing that the noise and discretization effects in the iteration \((3.4)\) are essentially negligible. As we show presently, the relative compactness of $x_t(\cdot)$ is reasonably straightforward, so this equivalence simplifies our arguments.

**Lemma A.1.** For any $T \geq 0$, we have

$$\lim_{T \to \infty} \sup_{\tau \in [t, t+T]} \|x(\tau) - x_t(\tau)\| = 0.$$

**Proof.** Fix $\tau \in [t, t+T]$ and let $p = k_>(t)$ and $q = k_<(\tau)$. Then by definition of $x_t$ we have

$$\begin{align*}
  x_t(\tau) &= x(t) + \int_t^{t_p} y(u)du + \int_{t_p}^{t_q} y(u)du + \int_{t_q}^\tau y(u)du \\
  &= x(t_p) + \sum_{i=p}^{q-1} \alpha_i y_i + \left( x(t) + \int_t^{t_p} y(u)du - x(t_p) \right) + \int_{t_q}^\tau y(u)du \\
  &= x(t_q) - \sum_{i=p}^{q-1} \alpha_i \xi_i + \left( x(t) + \int_t^{t_p} y(u)du - x(t_p) \right) + \int_{t_q}^\tau y(u)du \\
  &= x(\tau) - \sum_{i=p}^{q-1} \alpha_i \xi_i + \left( x(t) + \int_t^{t_p} y(u)du - x(t_p) \right) \\
  &\quad + \left( x(t_q) + \int_{t_q}^\tau y(u)du - x(\tau) \right).
\end{align*}$$  

**(A.2)**
Taking norms and applying the triangle inequality, we have
\[
\left\| x(t) + \int_t^{t_p} y(u)du - x(t_p) \right\| \leq \left\| x(t_p) - x(t_{p-1}) \right\| + \int_t^{t_p} \| y(u) \| du
\]
and similarly
\[
\left\| x(t_q) + \int_{t_q}^{\tau} y(u)du - x(\tau) \right\| \leq \left\| x(t_{q+1}) - x(t_q) \right\| + \int_{t_q}^{\tau} \| y(u) \| du
\]
The convergence of the sum \( \sum_{k=1}^{\infty} \alpha_k \xi_k \) implies the uniform guarantees
\[
\lim_{p \to \infty} \sup_{q \geq p} \left\| \sum_{i=p}^{q-1} \alpha_i \xi_i \right\| = 0 \quad \text{and} \quad \lim_{p \to \infty} \sup_{q \geq p} \alpha_q (\| \xi_q \| + \| y_q \|) = 0.
\]
Substituting these into the bound (A.2) gives the result.

Now we may show the relative compactness of the function sequence \( x^{t_k}(\cdot) \) for any sequence \( t_k \). Using that \( \sup_{t} \| y(t) \| = \sup_{k} \| y_k \| < \infty \) by assumption, we have that \( \{ x_{t_k}(\cdot) \}_{t \in \mathbb{R}^+} \) is a family of uniformly equicontinuous (even Lipschitz) and pointwise bounded functions. The Arzelà-Ascoli theorem implies it is therefore relatively compact in \( C(\mathbb{R}^+, \mathbb{R}^d) \). In turn, this implies that the family of shifted interpolant functions \( \{ x^{t_k}(\cdot) \}_{t \in \mathbb{R}^+} \subset C(\mathbb{R}^+, \mathbb{R}^d) \) is also relatively compact. Indeed, pick an arbitrary sequence \( \{ t_k \}_{k=1}^{\infty} \); then one of the following two cases must occur.

1. The sequence \( \{ t_k \}_{k=1}^{\infty} \) has a bounded subsequence. Pick any cluster point \( t \) of \( t_k \) (w.l.o.g. we may assume \( t_k \to t \)). Then by the uniform (even Lipschitz) continuity of \( x(\cdot) \) on \([0, t + T]\) for any \( T \geq 0 \), we have that \( x^{t_k}(\cdot) \to x^{t}(\cdot) \) in \( C(\mathbb{R}^+, \mathbb{R}^d) \).

2. The sequence \( \{ t_k \}_{k=1}^{\infty} \) satisfies \( t_k \to \infty \). Since \( x_{t_k}(\cdot) \) is relatively compact in \( C(\mathbb{R}^+, \mathbb{R}^d) \), it has a convergence subsequence \( x_{t_k_n}(\cdot) \to \varphi(\cdot) \) for some limit function \( \varphi(\cdot) \). Lemma A.1 shows that \( x^{\tau_{t_n}}(\cdot) \to \varphi(\cdot) \) as well.

These cases combined yield that \( \{ x^{t_k}(\cdot) \}_{t \in \mathbb{R}^+} \) is relatively compact.

**Part II: Limiting differential inclusion.** We now establish the remainder of the theorem. Following our notational conventions, we define the shifts \( y(\cdot)(\cdot) = y(t^{+}\cdot) \). Let \( \{ u_k \}_{k \in \mathbb{N}} \) satisfy \( u_k \to \infty \) and fix \( T > 0 \), and w.l.o.g. assume that \( x^{u_k}(\cdot) \to \varphi(\cdot) \) in \( C(\mathbb{R}^+, \mathbb{R}^d) \) for some continuous \( \varphi(\cdot) \). Viewing \( \mathcal{Y}_T := \{ y^{u_k}(\tau), \tau \in [0, T]\}_{k \in \mathbb{N}} \) as a subset of the Hilbert space \( L^2([0, T]) \), \( \mathcal{Y}_T \) is bounded and thus weakly sequentially compact by the Banach-Alaoglu theorem. Thus the sequence \( \{ u_k \} \) has a subsequence \( u_{k_n} \) such that \( y^{u_{k_n}}(\cdot) \to \varphi(\cdot) \) weakly in \( L^2([0, T]) \) for some \( \varphi(\cdot) \in L^2([0, T]) \). Lemma A.1 also implies that the integrated sequence \( x_{u_{k_n}}(u_k + \cdot) \to \varphi(\cdot) \) in \( C(\mathbb{R}^+, \mathbb{R}^d) \). Using the definition (A.1) of \( x_{t}(t + \cdot) \), we have for all \( t, \tau \in \mathbb{R}^+ \) that
\[
x_{t}(t + \tau) = x_{t}(t) + \int_{0}^{\tau} y^{u_k}(u)du.
\]
Substituting \( t = u_{k_n} \), and taking limits as \( k_n \to \infty \) on both sides of this equality, we obtain that for \( \tau \leq T \) we have
\[
(A.3) \quad \varphi(\tau) = \varphi(0) + \int_{0}^{\tau} \varphi(\cdot)du
\]
by the weak convergence of $y_{uk_n}$. It remains to show that $\overline{y}(u) \in H(\overline{\pi}(u))$ for (almost)
all $u \leq T$.

As the set $\mathcal{Y}_T \subset L^2([0, T])$ is bounded, the Banach-Saks theorem implies the
existence of a further subsequence $\{k_{n_j}\}_{j \in \mathbb{N}}$, which to simplify notation we now assume
without loss of generality is simply the original sequence $k$, such that

$$\frac{1}{N} \sum_{k=1}^{N} y_{uk}(\cdot) \to \overline{y}(\cdot)$$

in $L^2([0, T])$ as well as almost everywhere. (We could replace the original sequence $u_k$
with $u_{k_n}$ and repeat, mutatis mutandis, our preceding argument.) For $t \in \mathbb{R}_+$, define
the left values $l_k(t) := k_<(u_k + t)$. Then we have by definition of the interpolated
sequence $y(\cdot)$ and the sequence of mappings $g_k : \mathbb{R}^d \to \mathbb{R}^d$ that

$$y_{uk}(\tau) \in g_{l_k(\tau)}(x(t_{l_k(\tau)}))$$

where we recall that $t_i = \sum_{k=1}^{i} \alpha_k$. By the definition $x(t) = x(t + \tau)$, the triangle
inequality, and the left indices $l_k(\tau)$, for any fixed $\tau$ we find that

$$\|x(t_{l_k(\tau)}) - \overline{\pi}(\tau)\| \leq \|x(t_{l_k(\tau)}) - x(u_k + \tau)\| + \|x_{uk}(\tau) - \overline{\pi}(\tau)\|$$

$$\leq \|x(t_{l_k(\tau)+1}) - x(t_{l_k(\tau)})\| + \|x_{uk}(\tau) - \overline{\pi}(\tau)\|$$

$$\leq \alpha_{l_k(\tau)} \|\delta_{l_k(\tau)}\| + \alpha_{l_k(\tau)} \|y_{l_k(\tau)}\| + \|x_{uk}(\tau) - \overline{\pi}(\tau)\|,$$

and this quantity converges to zero as $k \to \infty$ because $y(\cdot)$ is bounded by con-

dition ((ii)) of the theorem, $\alpha_k \|\xi_k\| \to 0$ by the convergence condition ((iii)), and

$x_{uk}(\tau) \to \overline{\pi}(\tau)$ by the assumption that $x_{uk} \to \overline{\pi}$ in $C(\mathbb{R}_+, \mathbb{R}^d)$. That is, $x(t_{l_k(\tau)}) - \overline{\pi}(\tau) \to 0$ for all $\tau$ as $k \to \infty$.

Lastly, we apply item ((iv)) in the conditions for the theorem. Using $y_{uk}(\tau) \in g_{l_k(\tau)}(x(t_{l_k(\tau)}))$, we have

$$\text{dist}(\overline{y}(\tau), H(\overline{\pi}(\tau))) \leq \left\langle \frac{1}{N} \sum_{k=1}^{N} y_{uk}(\tau) - \overline{y}(\tau) \right\rangle + \text{dist} \left( \frac{1}{N} \sum_{k=1}^{N} y_{uk}(\tau), H(\overline{\pi}(\tau)) \right)$$

$$\leq \text{dist} \left( \frac{1}{N} \sum_{k=1}^{N} g_{l_k(\tau)}(x(t_{l_k(\tau)})), H(\overline{\pi}(\tau)) \right) + o(1) \to 0$$

as $N \to \infty$ by item ((iv)). As $H(\overline{\pi}(\tau))$ is closed, we obtain $\overline{y}(\tau) \in H(\overline{\pi}(\tau))$ for almost
every $\tau \in [0, T]$, as desired. Modifying $\overline{y}(\tau)$ on a suitable null set and recognizing that
$T$ is arbitrary then yields the theorem.

**Appendix B. Technical Proofs and Results.**

**B.1. Proof of Claim 1.** Fix $s \in \mathcal{S}$; we let $h = h(\cdot; s)$ and $c = c(\cdot; s)$ for
notational simplicity. Then for any $y, z$ with $\|y - x\| \leq \epsilon$ and $\|z - x\| \leq \epsilon$ and some
vector $v$ with $\|v\| \leq \beta_{\epsilon} \|y - z\|^2 / 2$, we have

$$h(c(y)) = h(c(z) + \nabla c(z)^T (y - z) + v)$$

$$\geq h(c(z) + \nabla c(z)^T (y - z)) - \gamma_{\epsilon}(x) \|v\|$$

$$\geq h(c(z)) + \partial h(c(z))^T \nabla c(z)^T (y - z) - \gamma_{\epsilon}(x) \beta_{\epsilon}(x) \|z - y\|^2,$$
where inequality (i) follows from the local Lipschitz continuity of $h$ and (ii) because $h$ is subdifferentiable. Let $\lambda \geq \gamma_c(x)\beta_c(x)$. Then adding the quantity $\frac{\lambda}{2} \|y - x_0\|^2$ to both sides of the preceding inequalities, we obtain for any $g \in \partial h(c(x))$ that

$$h(c(y)) + \frac{\lambda}{2} \|y - x_0\|^2 \geq h(c(z)) + (\nabla c(z)g)^T(y - z) - \frac{\lambda}{2} \|z - y\|^2 + \frac{\lambda}{2} \|y - x_0\|^2$$

$$= h(c(z)) + \frac{\lambda}{2} \|z - x_0\|^2 + (\nabla c(z)g, y - z) + \lambda(z - x_0, y - z).$$

That is, the function $y \mapsto h(c(y)) + \frac{\lambda}{2} \|y - x_0\|^2$ has subgradient $\nabla c(z)g + \lambda(z - x_0)$ at $y = z$ for all $z$ with $\|z - x\| \leq \epsilon$; any function with non-empty subdifferential everywhere on a compact convex set must be convex on that set [33]. In particular, we see that $y \mapsto f(y; s)$ is $\lambda(s, x) = \gamma_c(x)\beta_c(x, s)$-weakly convex in an $\epsilon$-neighborhood of $x$, giving the result.

The final result on Condition C.(iv) is nearly immediate: we have

$$h(c(y); s) \geq h(c(x; s) + \nabla c(x; s)^T(y - x); s) - \frac{\gamma_c(x; s)\beta_c(x; s)}{2} \|y - x\|^2$$

for $y$ in an $\epsilon$-neighborhood of $x$ by the Lipschitz continuity of $h$ and $\nabla c$.

**B.2. Proof of Lemma 3.6.** Recall Assumption B that for all $x \in X$ and some $\epsilon > 0$, there exists $\lambda(s, x)$ such that $y \mapsto f(y; s) + \frac{\lambda(s, x)}{2} \|y - x\|^2$ is convex for $\|y - x\| \leq \epsilon$, and $E[\lambda(S, x)] < \infty$ for all $x$. Then $f(\cdot; s)$ has a Fréchet subdifferential $\partial f(x; s)$ and the directional derivative of $f(\cdot; s)$ in the direction $v$ is $f'(x; s; v) = \sup_{g \in \partial f(x; s)} \langle g, v \rangle$ (cf. [47, Ch. 8]). Let $\lambda(s) = \lambda(s, x)$ for shorthand, as $x$ is fixed throughout our argument. Fix $v \in \mathbb{R}^d$, and let $u$ be near $v$ with $t < \epsilon/(\|u\| + \|v\|)$. Then

$$f(x + tu) = \int \left[ f(x + tu; s) + \frac{\lambda(s)t^2}{2} \|u\|^2 \right] dP(s) - \frac{t^2}{2} \|u\|^2 E[\lambda(S)].$$

Because $u \mapsto f(x + tu; s) + \frac{\lambda(s)}{2} \|tu\|^2$ is a normal convex integrand [47, Ch. 14], the dominated convergence theorem implies that

$$\frac{f(x + tu) - f(x)}{t} = \int \left[ \frac{f(x + tu; s) - f(x; s)}{t} + t \frac{\lambda(s)}{2} \|u\|^2 \right] dP(s) - \frac{t \|u\|^2}{2} E[\lambda(S)]$$

$$\to \int f'(x; s; v) dP(s) \quad \text{as } t \to 0, u \to v.$$

That is, $f'(x; v) = \int f'(x, s; v) dP(s)$. An argument parallel to that of Bertsekas [3, Propositions 2.1–2.2] yields that $\partial f(x) = \int \partial f(x; s)dP(s)$ and that $\partial f(x)$ is compact.

Now we show that $\partial f(\cdot)$ is outer semi-continuous. Because the support function of the subdifferential $\partial f(x)$ is the directional derivative of $f$, the outer semi-continuity of $\partial f$ is equivalent to

$$\limsup_{k \to \infty} f'(x_k; v) \leq f'(x; v) \quad \text{for all } \|v\| = 1 \text{ and } x_k \to x \in X$$

(cf. [33, Proposition V.3.3.9]). The sets $\partial g(f(y; s) + (\lambda(s)/2) \|y - x\|^2)$ are bounded for $y$ in a neighborhood of $x$ because the function $f$ is weakly convex, where $\lambda(\cdot)$ is
\( P \)-integrable. Let \( \lambda = \mathbb{E}_P[\lambda(S, x)] < \infty \), and define \( g(y) = f(y) + \frac{1}{2} \| y - x \|^2 \). Then \( g \) is convex and continuous near \( x \) [3], and we have [33, Corollary VI.6.2.5] that

\[
g'(x; v) = \limsup_{y \to x} g'(y; v)
\]

for all \( v \in \mathbb{R}^d \). But for convex \( g \), we have \( g'(x; v) = \lim_{t \downarrow 0}(g(x + tv) - g(x))/t \), and so the preceding display implies that as \( y \to x \) we have

\[
-o(1) \leq g'(x; v) - g'(y; v)
\]

\[
\lim_{t \downarrow 0} \left[ \frac{f(x + tv) - f(x)}{t} + \frac{\lambda t \| v \|^2}{2} \right] - \lim_{t \downarrow 0} \left[ \frac{f(y + tv) - f(y)}{t} + \frac{\lambda t \| v \|^2}{2} \right] = \lim_{t \downarrow 0} \left[ \frac{f(x + tv) - f(x)}{t} - \frac{f(y + tv) - f(y)}{t} \right] - \lambda \langle v, y - x \rangle.
\]

In particular, the preceding limits exist, we have \( f'(x; v) = \lim_{t \downarrow 0}(f(x + tv) - f(x))/t \), and inequality (B.1) holds by taking \( y \to x \). The preceding argument works, of course, for any weakly convex function, and so applies to \( f(\cdot; s) \) as well.

The final claim of the lemma is a standard calculation [19, 21].

**B.3. Proof of Lemma 3.9.** That \( L_e(x; s) < \infty \) for all \( x \) is immediate, as \( G(x; s) = \partial \varphi(x) + \partial f(x; s) \), and subdifferentials of convex functions \( (\varphi) \) are compact convex sets.

We first show the upper semicontinuity of the function \( L_e(\cdot; s) \). Suppose for the sake of contradiction that for some \( x \in X \) and for some sequence \( \{x_k\}_{k=1}^{\infty} \subset X \) converging to \( x \), we have \( \lim_{k \to \infty} L_e(x_k; s) \) exists and there is some \( \delta > 0 \) such that

\[
\lim_{k \to \infty} L_e(x_k; s) \geq L_e(x; s) + \delta.
\]

By definition of \( L_e \) we may choose \( x'_k \in X \) such that \( \|x_k - x'_k\| \leq \epsilon \) and subgradient vectors \( p_k(s) \in \partial f(x_k; s) \) and \( q_k(s) \in \partial \varphi(x'_k) \) satisfying

\[
L_e(x_k; s) \leq \|p_k(s) + q_k(s)\| + \delta/2 \text{ for all } k.
\]

Since the sequence \( \{x'_k\} \subset X \) is bounded, it has accumulation points and we may assume w.l.o.g. that \( x'_k \to x' \in X \), where \( x' \) satisfies \( \|x' - x\| \leq \epsilon \). The outer semicontinuity of the subdifferential for weakly convex functions (Lemmas 3.1 or 3.6) shows that there must be a subsequence \( \{n_k\} \) satisfying \( p_{n_k}(s) \to p(s) \in \partial f(x'; s) \) and \( q_{n_k}(s) \to q(s) \in \partial \varphi(x') \). In particular,

\[
\lim_{k \to \infty} L_e(x_k; s) = \limsup_{k \to \infty} L_e(x_{n_k}; s) \leq \limsup_{k \to \infty} \|p_{n_k}(s) + q_{n_k}(s)\| + \delta/2 = \|p(s) + q(s)\| + \delta/2 \leq L_e(x; s) + \delta/2,
\]

which is a contradiction. Thus \( L_e(\cdot; s) \) and \( L^2_e(\cdot; s) \) are upper semicontinuous.

To see that \( L_e(\cdot) \) is upper semicontinuous, we construct an integrable envelope for the function and then apply Fatou’s lemma. Indeed, using the assumed \( M_e(x; s) \)-local Lipschitz continuity of \( y \to f(y; s) \) for \( y \) near \( x \), we have

\[
\|G(y; s)\| \leq M_e(x; s) + \|\partial \varphi(y)\|
\]
for $y$ with $\|y - x\| \leq \epsilon$. This quantity is integrable, and we may apply Fatou’s lemma and Assumption $A$ to obtain
\[
\limsup_{y \to x} L_{\epsilon}(y) \leq E \left( \limsup_{y \to x} L_{\epsilon}(y) \right) \leq E[L_{\epsilon}(x; S)] \leq \sqrt{E[L_{\epsilon}(x; S)^2]}.
\]

**B.4. Proof of Observation 2.** In the case that $\varphi(x) = \frac{1}{2} \|x\|^2$, the stochastic update in Ex. 1 becomes $x_{k+1} = \frac{1}{1 + \alpha_k} x_k - \frac{\alpha_k}{1 + \alpha_k} g_k$, and we have the recursion
\[
\|x_{k+1}\| \leq \frac{\|x_k\|}{1 + \alpha_k} + \frac{\alpha_k}{1 + \alpha_k} L(S_k) \leq \prod_{i=1}^{k} (1 + \alpha_i \lambda)^{-1} \|x_1\| + \sum_{i=1}^{k} \alpha_i L(S_i) \prod_{j=i}^{k} (1 + \alpha_j \lambda)^{-1}.
\]

Let $L_i = L(S_i)$ for shorthand and define $\xi_i = L_i - E[L(S_i)]$, noting $\xi_i$ are i.i.d. and mean zero. Assume that $\lambda = 1$ and $E[L(S)]^2 = 1$ without loss of generality. Defining $Z_k = \sum_{i=1}^{k} \alpha_i L_i \prod_{j=i}^{k} (1 + \alpha_j \lambda)^{-1}$, so that $Z_k - E[Z_k] = \sum_{i=1}^{k} \alpha_i \xi_i \prod_{j=i}^{k} (1 + \alpha_j \lambda)^{-1}$ and noting that
\[
E[Z_{k+1}] = \frac{E[Z_k] + \alpha_{k+1}}{1 + \alpha_{k+1}} = \begin{cases} 
\leq E[Z_k] & \text{if } E[Z_k] > 1 \\
1 & \text{if } E[Z_k] \leq 1
\end{cases}
\]
we have that $\sup_k E[Z_k] < \infty$. Moreover, if we let $M_k = \sum_{i=1}^{k} \alpha_i \prod_{j=1}^{i-1} (1 + \alpha_j) \xi_i$, then $Z_k - E[Z_k] = \prod_{j=1}^{k} (1 + \alpha_j)^{-1} M_k$, and $M_k$ is a martingale adapted to the filtration $F_k = \sigma(S_1, \ldots, S_k)$. Noting that $M_{k+1} - M_k = \alpha_{k+1} \prod_{j=1}^{k} (1 + \alpha_j) \xi_{k+1}$, we have
\[
\sum_{k=1}^{\infty} \frac{1}{\prod_{j=1}^{k} (1 + \alpha_j)^2} E[(M_{k+1} - M_k)^2 | F_k] = \sum_{k=1}^{\infty} \alpha_{k+1}^2 E[\xi_{k+1}^2] < \infty.
\]

Applying standard $L_2$-martingale convergence results (e.g. [16, Exercise 5.3.35]) gives that $M_k / \prod_{j=1}^{k} (1 + \alpha_j) \xrightarrow{a.s.} 0$, and thus $Z_k \xrightarrow{a.s.} E[Z_k]$, while certainly $\limsup_k \|x_k\| \leq \limsup_k Z_k$.

**B.5. Proof of Observation 3.** The standard first-order optimality conditions for minimization of (strongly) convex problems immediately yield
\[
(B.2) \quad \frac{1}{\alpha_k} \|x_k - x_{k+1}\|^2 + \langle g_k, x_{k+1} \rangle + \varphi(x_{k+1}) \leq \langle g_k, x_k \rangle + \varphi(x_k),
\]
and as the iterations are unconstrained, we have $x_{k+1} - x_k = -\alpha_k g_k - \alpha_k v_k$ for some $v_k \in \partial \varphi(x_{k+1})$. We first assume that the regularizer $\varphi$ increases in iteration $k$, so $\varphi(x_k) \leq \varphi(x_{k+1})$. Then inequality (B.2) implies that
\[
\|x_{k+1} - x_k\| \|g_k + v_{k+1}\| = \frac{1}{\alpha_k} \|x_{k+1} - x_k\|^2 \leq \langle g_k, x_{k+1} - x_k \rangle \leq \|g_k\| \|x_k - x_{k+1}\|,
\]
or $\|g_k + v_{k+1}\| \leq \|g_k\|$ and we have $\|v_{k+1}\| \leq 2 \|g_k\|$. The local Lipschitz assumption on $b(c(x; s); s)$ guarantees $\|g_k\| \leq L(1 + \|x_k\|^\nu)$. Choose the constant $1 \leq B < \infty$ such that if $\|y\| \geq B$ then $\|v\| \geq 4L \|y\|^\beta - 1$ for all $v \in \partial \varphi(y)$, which must exist by our coercivity assumption, and $B^{\frac{1}{\nu - 1}} \geq (1/\lambda)B$, where $\lambda \in (0, 1]$ is the regularity parameter of $\varphi$ for which $\varphi(\lambda x) \leq \varphi(x)$ for all $x$ with $\|x\| \geq B$ (recall $\beta - 1 > \nu$).
STOCHASTIC METHODS FOR COMPOSITE OPTIMIZATION PROBLEMS

Then we have that

\[ 4L \| x_{k+1} \|^{\beta - 1} \leq 2 \| g_k \| \leq 2L (1 + \| x_k \|^{\nu}) \leq 4L \cdot \begin{cases} \| x_k \|^{\nu} & \text{if } \| x_k \| \geq 1 \\ 1 & \text{otherwise} \end{cases} \]

if \( \| x_{k+1} \| \geq B \). Otherwise, we have \( \| x_{k+1} \| < B \), so our assumptions on \( B \) guarantee

\[ \| x_{k+1} \| \leq \max \left\{ B, 1, \| x_k \|^{\frac{\nu}{\beta - 1}} \right\} \leq \max \left\{ B, \| x_k \|^{\frac{\nu}{\beta - 1}} \right\} \leq \max \{ B, \lambda \| x_k \| \} . \]

We assumed that \( \varphi(x_{k+1}) \geq \varphi(x_k) \), so we see that (because of the \( \lambda \) term above)

(B.3) \[ \varphi(x_{k+1}) \leq \varphi(x_k) \text{ or } \| x_{k+1} \| \leq B. \]

As \( \varphi \) is continuous (it is convex and defined on \( \mathbb{R}^d \)), there exists \( B' \) such that \( \varphi(x) \leq B' \) for all \( \| x \| \leq B \), and thus inequality (B.3) implies

\[ \varphi(x_{k+1}) \leq \varphi(x_k) \vee B'. \]

We may assume w.l.o.g. that \( \varphi(x_1) \leq B' \), because otherwise we could simply increase \( B' = \varphi(x_1) \). An inductive argument implies that \( \varphi(x_{k+1}) \leq B' \) for all \( k \), which implies the result.
