Viruses use different strategies to evade the host immune response to establish persistent infection. These strategies include generating antibody and T cell escape variants as well as actively suppressing the immune system (1–5). In addition, neutralizing antibody (nAb) responses to certain viral infections are mounted late and inefficiently (2, 6, 7). Lymphocytic choriomeningitis virus (LCMV) infection in mice is an exemplary model characterized by low titers of nAbs, which are not detected until at least 60 d after infection (2). A similar phenomenon is observed in humans after infection with HIV and hepatitis C virus (references 6, 7). There are several possible reasons for the delayed formation of nAb, including immunopathological and suppressive effects mediated by T cells (5, 8), the prolonged time for affinity and avidity maturation of specific nAbs (9), low precursor frequency of B cells with neutralizing specificity (10), and structural features of the viral surface proteins (11, 12). Despite their late appearance, nAbs may be important in the long-term control of LCMV infection because B cell–deficient mice cannot control LCMV strain WE infection (13).

Neutralizing antibody (nAb) responses to lymphocytic choriomeningitis virus (LCMV) in mice and immunodeficiency virus and hepatitis C virus in humans are usually weak and slow to develop. This may be the result of structural properties of the surface glycoprotein, a low frequency of B cells with neutralizing specificity, and the necessity of prolonged affinity maturation of specific nAbs. In this study, we show that during LCMV infection, CD27 signaling on CD4+ T cells enhances the secretion of interferon-γ and tumor necrosis factor-α. These inflammatory cytokines lead to the destruction of splenic architecture and immunodeficiency with reduced and delayed virus-specific nAb responses. Consequently, infection with the otherwise persistent LCMV strain Docile was eliminated after CD27 signaling was blocked. Our data provide a novel mechanism by which LCMV avoids nAb responses and suggest that blocking the CD27–CD70 interaction may be an attractive strategy to prevent chronic viral infection.
increased the secretion of IFNγ and TNFα, leading to the destruction of the splenic architecture, including the splenic marginal zone. CD27-dependent immunopathological destruction of lymphatic organs correlated with functional immunosuppression and impaired nAb responses. Blocking CD27 interaction with CD70 by infecting CD27-deficient mice or by administering a monoclonal αCD70 antibody after infection reduced immunopathology, and nAb responses were efficiently mounted. As a consequence of the absence of CD27 signaling, infection with the otherwise persistent LCMV strain Docile was eliminated.

RESULTS
nAb responses to viral infections in the absence of CD27 signaling
To analyze the role of CD27 signaling in the induction of specific B cell responses, we first infected CD27−/− mice and C57BL/6 (BL/6) control mice with vesicular stomatitis virus (VSV) Indiana (VSV-IND; Fig. 1 A). After infection with VSV-IND, the neutralizing T-independent IgM antibody response was comparable in CD27−/− and control mice. However, there was a fourfold increase in the T-dependent neutralizing IgG antibody titers 8 and 12 d after infection in BL/6 mice compared with CD27−/− mice. This slightly enhanced switch from IgM to IgG antibodies in BL/6 mice suggests a role for CD27 signaling in CD4+ T helper cells. However, nAbs in CD27−/− mice reached comparable titers with those in BL/6 mice 20 d after infection, and all CD27−/− mice survived VSV infection without developing lethal paralysis. Therefore, in agreement with earlier findings in influenza infection (19), our results indicate that CD4+ T helper cell–dependent and –independent B cell responses are largely independent of CD27.

nAb responses to LCMV infection in mice are low and are only mounted late after infection (2). Surprisingly, CD27−/− mice mounted high nAb responses starting 20–30 d after infection with LCMV-WE, whereas BL/6 mice had antibody titers below the detection limit (Fig. 1 B). In addition to the virus-specific antibody response, LCMV infection polyclonally activates B cells that are not virus specific, leading to hypergammaglobulinemia (20). A recent study suggested an inverse correlation between CD4+ T cell–dependent polyclonal B cell activation and the induction of nAb in LCMV infection (21). However, polyclonal B cell activation and hypergammaglobulinemia was even enhanced in the absence of CD27 signaling when compared with controls (Fig. 1 B).

Our finding suggested an important inhibitory role of CD27 signaling in the generation of LCMV-specific nAb responses.

nAb responses to LCMV infection in mice are low and are only mounted late after infection (2). Surprisingly, CD27−/− mice mounted high nAb responses starting 20–30 d after infection with LCMV-WE, whereas BL/6 mice had antibody titers below the detection limit (Fig. 1 B). In addition to the virus-specific antibody response, LCMV infection polyclonally activates B cells that are not virus specific, leading to hypergammaglobulinemia (20). A recent study suggested an inverse correlation between CD4+ T cell–dependent polyclonal B cell activation and the induction of nAb in LCMV infection (21). However, polyclonal B cell activation and hypergammaglobulinemia was even enhanced in the absence of CD27 signaling when compared with controls (Fig. 1 B).

Our finding suggested an important inhibitory role of CD27 signaling in the generation of LCMV-specific nAb responses.
Therefore, we analyzed the expression of the CD27 ligand (CD70) in the spleen at different time points after infection of BL/6 or CD27-deficient mice with LCMV-WE. CD70 was expressed for a prolonged time on CD4\(^+\) and CD8\(^+\) T cells and on CD19\(^+\) B cells (Fig. 1 C). In addition, CD70 was detectable on a few dendritic cells at days 8 and 15 after infection.

Normal CTL induction and expansion in the absence of CD27

Titers of nAb against LCMV increased when CD8\(^+\) T cell function was absent (2). This increase may be caused by enhanced viral replication. We recently showed that CTL induction after infection with 200 pfu LCMV-WE was independent of CD27 signaling (22). Comparably, primary CTL function after infection with 10\(^6\) pfu LCMV-WE, as analyzed by the direct lysis of peptide-pulsed target cells and the absolute number of gp33-specific T cells, was not impaired in CD27\(^{-/-}\) mice (Fig. 2, A and B). More importantly, both CD27\(^{-/-}\) and control mice eliminated the virus within 12–16 d after infection from the spleen, lung, liver, and kidney (Fig. 2 C and Fig. S1, available at

Figure 3. Spleen architecture after LCMV-WE infection. (A and B) BL/6 and CD27\(^{-/-}\) mice and CD27\(^{-/-}\) mice receiving purified CD4\(^+\) T cells from BL/6, IFN\(\gamma^{-/-}\), or TNF\(\alpha^{-/-}\) mice were infected with LCMV-WE. 8 d after infection, the spleen was analyzed. (A) Cryosections stained for metallophilic marginal zone macrophages (MOMA-1), follicular dendritic cell (4C11) networks, PNA\(^+\) germinal center clusters, surface IgM\(^+\) B cells, and CD21\(^+\)CD35\(^+\) marginal zone B cells. (B) The relative frequency of CD21\(^+\)CD35\(^+\)IgM\(^+\)IgD\(^-\) marginal zone B cells and of CD21\(^-\)CD35\(^-\)IgM\(^+\)IgD\(^-\) T1B cells among total lymphocytes and their absolute number per spleen are shown. (C) The relative frequency of CD19\(^+\) B cells among total lymphocytes and their absolute number per spleen are shown. Horizontal bars indicate gates for CD19\(^+\) B cells. One representative section or dot plot out of \(n = 3–9\) mice per group is shown. Numbers indicate the mean. Numbers of marginal zone B cells and T1B cells in BL/6 mice or CD27\(^{-/-}\) mice receiving CD4\(^+\) T cells from BL/6, IFN\(\gamma^{-/-}\), or TNF\(\alpha^{-/-}\) mice were compared with CD27\(^{-/-}\) mice. *, \(P < 0.05\); ns, \(P \geq 0.05\).
We next compared the production of inflammatory cytokines by LCMV gp33 TCR transgenic P14 and P14 x CD27−/− CD8+ T cells 8 d after infection with LCMV-WE and found similar levels of IFNγ and TNFα (Fig. 2 D). Therefore, CTL responses to LCMV infection were normal in the absence of CD27, and differences in viral control did not explain the more efficient generation of nAb in CD27−/− mice.

CD27-dependent immunopathology

The induction of antibody and T cell responses against viral infections requires that the anatomical structures of secondary lymphoid organs are intact (23). During LCMV infection, the splenic architecture is disrupted, and the marginal zone and germinal centers are destroyed (8). Therefore, we analyzed the splenic architecture 8 d after infection with LCMV-WE in CD27−/− and BL/6 mice. Naive BL/6 (Fig. 3, A and B) and CD27−/− mice (not depicted but identical to naive BL/6 mice) had a normal splenic architecture with an intact marginal zone and germinal centers. LCMV infection of BL/6 mice induced the destruction of the marginal zone and germinal centers and a complete absence of follicular dendritic cells (Fig. 3 A). Flow cytometry analysis further revealed that marginal zone B cell (CD21+CD35+IgM+IgD−) numbers were decreased in LCMV-infected BL/6 mice when compared with noninfected BL/6 mice (Fig. 3 B). Surprisingly, the splenic architecture remained largely intact after LCMV infection of CD27−/− mice, and infected mice had clearly identifiable germinal centers containing follicular dendritic cells and a preserved marginal zone (Fig. 3 A).

In addition, flow cytometry analysis demonstrated that relative (percentage) and absolute numbers of marginal zone B cells (CD21+CD35+IgM+IgD−) were higher in LCMV-infected CD27−/− than in BL/6 mice (Fig. 3 B). The frequency (percentage) and absolute numbers of transitional type 1 B cells (T1B; CD21−CD35−IgM+IgD+) were higher in LCMV-infected CD27−/− mice. However, this only reached statistical significance if analyzed as the percentage of total lymphocytes (Fig. 3 B). In contrast, relative and absolute numbers of CD19+ B cells (Fig. 3 C) and mature IgM+IgD+ B cells in the spleen (16.4 × 106 for CD27−/− vs. 17.4 × 106 for BL/6) were similar in LCMV-infected CD27−/− and BL/6 mice. In summary, LCMV-induced immunopathology is dependent on CD27 signaling.

CD27 signaling on CD4+ T cells induces immunopathology and suppression of nAbs

To identify the cell population responsible for the CD27−/− reduction in nAb responses, purified BL/6 CD8+ or CD4+ T cells were adoptively transferred to CD27−/− recipient mice before infection with LCMV-WE. The adoptive transfer of CD8+ T cells to CD27−/− mice did not affect the nAb response (Fig. 4 A). In contrast, the transfer of purified CD27−/−expressing CD4+ T cells to CD27−/− mice resulted in a reduction and delay in the nAb response when compared with CD27−/− controls (Fig. 4 A). Likewise, the adoptive transfer of CD4+ T cells from BL/6 to CD27−/− mice resulted in immunopathology comparable with BL/6 mice as analyzed by immunohistochemistry and flow cytometry (Fig. 3, A and B).

The constitutive expression of CD70 on B cells in transgenic mice induced IFNγ production by T cells, which led to a depletion of the CD70−expressing B cells (24). Thus, we analyzed the role of CD27 signaling on the secretion of inflammatory cytokines by LCMV gr13 TCR transgenic SMARTA and SMARTA × CD27−/− CD4+ T cells 8 d after infection with LCMV-WE (Fig. 4 B). The production of
IL-6, -1β, and -10 was independent of CD27, whereas the secretion of IFNγ and TNFα was decreased in the absence of CD27 signaling on specific CD4+ T cells. To determine whether the secretion of IFNγ and TNFα by CD4+ T cells is important in the induction of immunopathology and the suppression of nAb responses, CD4+ T cells from BL/6, IFNγ−/−, and TNFα−/− mice were adoptively transferred to CD27−/− recipients before infection with LCMV-WE. The transfer of CD4+ T cells from IFNγ−/− and TNFα−/− mice to CD27−/− recipients infected with LCMV-WE did not affect specific nAb responses (Fig. 4 C). Similarly, the adoptive transfer of CD4+ T cells from IFNγ−/− or TNFα−/− mice to CD27−/− recipients before LCMV-WE infection had little effect on immunopathology (Fig. 3, A and B).

Earlier studies with B cells constitutively expressing CD70 have shown that ligation of CD70 by CD27 and consequent reverse signaling through CD70 can lead to a reduction of antibody secretion (25, 26). Therefore, the enhanced nAb response against LCMV-WE in CD27−/− mice may be caused by the absence of inhibitory signals mediated by CD70 signaling. To address this possibility, we assessed the number of CD27-expressing CD4+ T cells in CD27−/− recipients after the adoptive transfer of CD4+ T cells of BL/6, IFNγ−/−, and TNFα−/− mice (Fig. 4 D). In this experimental setup, the CD27-expressing transferred CD4+ T cells are the only cells that provide CD70 ligation. CD4+ T cells from BL/6, TNFα−/−, or IFNγ−/− mice similarly engrafted in recipient mice, and, therefore, a comparable CD27–CD70 interaction was provided by the transferred cells. Despite this similar CD27–CD70 ligation in recipient mice, only the transfer of CD4+ T cells from BL/6 mice impaired antibody production, whereas the transfer of CD4+ T cells from IFNγ−/− or TNFα−/− mice did not. This largely excludes the possibility that reverse signaling through CD70 reduces the production of nAb. Therefore, we conclude that CD27 ligation on CD4+ T cells contributes to the secretion of IFNγ and TNFα, leading to immunopathology with delayed specific nAb responses.

**LCMV-induced immunosuppression of nAb responses to viral coinfections**

LCMV infection has been shown to induce an acquired immunodeficiency with reduced nAb responses and increased susceptibility to coinfection with VSV (21, 27). To elucidate whether CD27-dependent immunopathology also impairs antibody responses to unrelated antigens, we infected mice with VSV New Jersey (VSV-NJ) 8 d after LCMV-WE infection. BL/6 mice immunized with LCMV-WE and coinfected with VSV-NJ had a slight reduction in the nAb IgM response, whereas the switch to IgG was virtually absent (Fig. 5 A). In contrast, the nAb response to VSV-NJ was not impaired in LCMV-infected CD27−/− mice.

Similar results were obtained after challenging LCMV-infected CD27−/− and BL/6 mice with UV-inactivated VSV-NJ (Fig. S2, available at http://www.jem.org/cgi/content/full/jem.20060651/DC1). In addition, VSV-NJ only abortively replicates in immunocompetent mice and was eliminated similarly in LCMV-infected CD27−/− and BL/6 mice (Fig. S2). These controls exclude the possibility that differences in VSV replication in CD27−/− and BL/6 mice account for the observed differences in nAb responses. Although LCMV-infected BL/6 mice and CD27−/− mice possess similar numbers of B cells (Fig. 3 C), it may be possible that B cells with VSV-neutralizing specificity may have been eliminated by the CD27–CD70 interaction during LCMV infection. To analyze this, purified B cells from VSV-IgM transgenic mice crossed on a μMT background (T11(μMT; reference 28) were transferred to BL/6 and CD27−/− mice.
before infection with LCMV-WE (Fig. 5 B). A comparable number of B cells with VSV-neutralizing specificity 8 d later excluded the possibility that the observed reduction of VSV nAbs in LCMV-immune mice coinfected with VSV was caused by a reduced number of VSV-specific B cells in the presence of a functional CD27–CD70 interaction in BL/6 mice.

We also tested whether the adoptive transfer of BL/6 CD4+ T cells to CD27−/− recipients affected the nAb response in mice first infected with LCMV and coinfected 8 d later with VSV-NJ. In these mice, there was an impaired switch to VSV-NJ–specific IgG antibodies (Fig. 5 C). Mice receiving CD8+ T cells did not have an impaired antibody response (Fig. 5 C). Similar to the impaired nAb response to LCMV infection, the reduced nAb to coinfection with VSV-NJ was mediated by IFNγ and TNFα. The transfer of CD4+ T cells from IFNγ−/− and TNFα−/− mice to CD27−/− recipients infected with LCMV and coinfected with VSV did not reduce the production of specific nAb as much as CD4+ T cells from BL/6 mice (Fig. 5 D). Therefore, CD27 ligation on CD4+ T cells contributes to the secretion of IFNγ and TNFα, leading to virus-induced immunodeficiency with impaired antibody responses to related and unrelated viral antigens.

**Blocking CD27 signaling eliminates an otherwise persistent infection with LCMV-Docile**

Infection with the LCMV strain Docile establishes chronic infection in mice with the functional exhaustion of specific CTLs and no nAb response (29). This model of persistent infection was used to analyze the physiological role of CD27 and CD4+ T cell–dependent immunopathology and immunodeficiency. After the infection of BL/6 mice with LCMV-Docile, nAb titers were below the detection level, and the virus established persistent infection (Fig. 6, A and B). In contrast, CD27−/− mice mounted nAb within 20–30 d after infection, and high titers were reached 50 d after infection (Fig. 6 A). CD27−/− mice were also able to control and eliminate LCMV-Docile infection in the blood (Fig. 6 B) and organs within 60 d (Fig. 6 C). In contrast, high viral titers were found in BL/6 mice in all organs analyzed up to 100 d after infection (Fig. 6, B and C). Antibody-deficient Jj−/− and CD27−/−×Jj−/− mice did not control LCMV-Docile infection, indicating that nAbs were crucial for virus control (Fig. 6, A and B).

8, 20, and 40 d (not depicted) after the infection of CD27−/− and BL/6 mice with LCMV-Docile, only a few LCMV gp33-specific CTLs were detectable by tetramer staining (Fig. 6 E). CTL function, as analyzed by the lysis of peptide-pulsed target cells or by intracellular IFNγ staining, was also impaired in BL/6 and CD27−/− mice 8 and 40 d after infection (Fig. 6, D and E). These results indicate that specific CTLs were functionally exhausted or anergic. Surprisingly, after the elimination of LCMV-Docile, CD27−/− mice regained a functional CTL response to LCMV gp33 and np396 (not depicted), as documented in a 51Cr release cytotoxicity assay (Fig. 6 D) or by intracellular IFNγ staining (Fig. 6 E).
We next wanted to determine whether blocking CD27 signaling could be a therapeutic approach to prevent chronic viral infection. Because CD70 expression peaked 8 d after infection on CD8 \( ^+\) T cells and even later on B and CD4 \( ^+\) T cells (Fig. 1 C), we decided to test CD70 blockade several days after infection. BL/6 mice infected with LCMV-Docile were treated for 5 wk with a blocking monoclonal antibody to CD70 (FR70; reference 30) starting 4 d after infection. LCMV-Docile was detectable in all animals at day 4 after infection, with 1.3 \( \times \) \( 10^5 \) (\( \pm \) 0.02 \( \times \) \( 10^5 \)) pfu/ml in the blood. Similar to the results obtained in CD27 \(-/-\) mice, treatment with the blocking mAb to CD70 elicited a nAb response and resulted in reduced viral titers (Fig. 7, A and B).

Interestingly, immunohistochemistry and analysis of B cell subpopulations by flow cytometry revealed that the splenic architecture was largely restored in BL/6 mice 35 d after LCMV-Docile infection in spite of virus persistence (Fig. 8, A and B). Nevertheless, no nAbs were produced in BL/6 mice even up to 100 d after infection (Fig. 6 A). This may be explained by the fact that no functional IFN\( \gamma \)-producing LCMV-specific CD4 \( ^+\) T cells were detectable 35 d after infection with LCMV-Docile (unpublished data). Therefore, it was not surprising that treating LCMV-Docile–infected mice from day 35 to 60 after infection with mAb to CD70 neither induced protective nAb responses nor eliminated the virus (Fig. 8, D and E). In summary, these results suggest that the kinetics of CD70 expression and CD4 \( ^+\) T cell function determine the time frame in which blocking CD27 signaling efficiently eliminates chronic viral infections.

**DISCUSSION**

The induction of nAbs represents a central protective mechanism of the immune system and is the basis of most currently available vaccines. Unfortunately, attempts to improve protective antibody responses against persisting viruses such as HIV in humans or LCMV in mice have repeatedly failed (12, 32). Different mechanisms may contribute to the inefficient generation of nAbs. For LCMV, one study (12) showed that...
the kinetics of nAb responses are crucially dependent on intrinsic factors of the surface antigen and that LCMV glycoprotein expressed on the immunogenic VSV backbone did not induce LCMV-specific nAb. In addition, B cells with a receptor of neutralizing specificity against LCMV may exist at very low frequencies and may only be generated by substantial somatic hypermutation. More potent LCMV-specific nAb responses in mice genetically engineered to express LCMV-neutralizing B cell receptors argue in favor of such mechanisms (10). In this study, we define an additional and novel mechanism by which a virus avoids the efficient production of nAb to establish persistent infection. The virus-induced expression of CD70, which was mainly on B and T cells, resulted in CD27-dependent destruction of the splenic architecture and suppression of nAb responses.

Intact secondary lymphatic organ structure is important in the generation of antibody responses (23). The marginal zone and marginal zone B cells seem to be important in the initiation of antibody responses against blood-borne pathogens (33, 34). We found that the splenic marginal zone and germinal centers were virtually absent and that numbers of marginal zone B cells were reduced in BL/6 mice during acute LCMV infection. Immunopathology in the spleen was provoked by IFNγ and TNFα secreted by CD4+ T cells. Moreover, CD27 ligation on LCMV-specific CD4+ T cells increased the secretion of IFNγ and TNFα, suggesting that CD27-dependent immunopathology is induced by the increased secretion of these inflammatory cytokines. This conclusion is supported by the observation that B cell numbers in CD70 transgenic mice progressively increase in primary and secondary lymphoid organs as a result of the CD27-induced production of IFNγ by T cells (24). Likewise, cytokines that bind to receptors for TNF and IFN type I or type II are involved in the destruction of the splenic architecture after repetitive CpG treatment (35). TNFα as well as IFNγ have cytotoxic action when secreted in the vicinity of target cells (36). In addition, IFNγ may render cells more sensitive to TNFα-induced apoptosis (37). Similarly, a TNFα-dependent destruction of splenic architecture has been observed after Leishmania infection (38). Recent data have suggested that after Leishmania infection, the TNFα-mediated loss of stromal cells leads to the reduced production of CCL19 and CCL21, which are both important for maintenance of the marginal zone (39).

Interestingly, it has been demonstrated that B cells are crucial for the maintenance of the splenic marginal zone and that the depletion of B cells in a Cre/lox P system resulted in destruction of the integrity of the marginal zone (40). In our study, LCMV infection resulted in a selective depletion of marginal zone B cells and T1B cells without reducing the number of other B cell subsets or total B cells. Therefore, the destruction of the splenic architecture and marginal zone after LCMV infection is not caused by reduced total B cell numbers. However, the destruction of the splenic architecture may be initiated indirectly by the elimination of B cell subsets, macrophages, or stromal cells, which provide chemokines, integrin ligands, and receptors that are important for the splenic architecture (39, 41, 42).

LCMV infection has been shown to induce an acquired immunosuppression with temporally impaired antibody responses to viral coinfections (21, 27). Preservation of the splenic architecture after LCMV infection in CD27−/− mice also enhanced the nAb response to coinfection with VSV. This indicates that CD27-dependent destruction of the splenic architecture causes a general immunodeficiency, resulting in impaired nAb responses against both LCMV and unrelated viral coinfections. In addition, as a result of polyclonal B cell activation, 90% of the antibodies produced after LCMV infection are not specific for the virus (20). This hypergammaglobulinemia is also observed after HIV and HCV infections (18, 43). Because polyclonal B cell activation is dependent on B cell–T cell interactions (20), the preservation of the splenic architecture in CD27−/− mice facilitated this interaction and augmented hypergammaglobulinemia.

This study provides evidence that blocking the CD27–CD70 interaction may be an attractive strategy to prevent chronic infection after virus inoculation. This finding was surprising because, as outlined in the Introduction, different mechanisms, including structural aspects of LCMV glycoprotein, contribute to the delayed and inefficient generation of nAbs. The time frame in which blocking CD27 signaling reduces immunopathology and improves antibody responses may be dependent on characteristics of the viral infection, such as replication kinetics and infectious dose. For LCMV infection, we showed that CD70 is expressed at high levels up to 20 d after infection. At later time points, CD70 was no longer detectable, and the splenic architecture was restored. Therefore, in this infectious model, αCD70 mAb treatment had to be started during acute infection and was inefficient when started 35 d after infection. Nevertheless, αCD70 mAb treatment was efficient when started several days after infection at a time point when LCMV replicated to high titers and was clearly detectable in blood samples.

Further studies will be necessary to evaluate whether our findings can be generalized to other types of viral infections that are characterized by a late and inefficient induction of nAbs, such as HIV and HCV (6, 7). In analogy to LCMV, structural factors of the surface glycoproteins limit the efficient induction of nAb against HIV (4, 44). Furthermore, the frequency of B cells with neutralizing B cell receptors to HIV is low, probably as a result of cross-reactivity to self-antigens, leading to the depletion of specific B cells from the repertoire (45). Interestingly, CD70 is overexpressed on B cells and T cells in active HIV infection, suggesting a possible role for this costimulatory molecule in the induction of immunopathology and suppression (17, 18). In fact, immunopathology of the splenic architecture with the reduction of marginal zone B cells has been shown in HIV infection (46).

In summary, blocking CD27 interaction is a novel strategy for therapeutically influencing persistent virus infections by reducing immunopathology and acquired immunosuppression and, thereby, enhancing nAb production. Our findings
Materials and Methods

Mice. BL/6 mice were obtained from Harlan, and CD27^−/− (47) mice were obtained from the Netherlands Cancer Institute. SMARTA (48), P14 (49), T11µMT (28), and J6^−/− (50) mice were obtained from the Institute for Laboratory Animals (Zurich, Switzerland), and TNFα^−/− (51) mice were obtained from C. Muller (Division of Immunopathology, University of Berne, Bern, Switzerland). JFNY^−/− (B6.129S7-Ifngms1Tc) was purchased from the Jackson Immunoresearch Laboratories. All animal experiments were performed with 6-8-wk-old age- and sex-matched mice at the central animal facility of the University of Berne (Bern, Switzerland) and were approved by the Experimental Animal Committee of the Canton of Berne.

Viruses and peptides. LCMV-WE and -Docile isolates were obtained from R.M. Zinkernagel (Institute of Experimental Immunology, University of Zurich, Zurich, Switzerland) and were propagated in L929 fibroblasts and Madin–Darby canine kidney cells, respectively. Mice were infected i.v. with 10^6 pfu of LCMV-WE or 2 × 10^6 pfu LCMV-Docile in all experiments. VSV-IND and VSV-NJ isolates were obtained from R.M. Zinkernagel and were grown in BHK21 cells. Mice were infected i.v. with 2 × 10^6 pfu VSV-IND or -NJ in all experiments. For UV inactivation, VSV-NJ was irradiated (G15W; Osram Sylvania) for 30 s at a distance of 5 cm in a thin layer of liquid in a 35-mm petri dish. UV inactivation was tested in a focus-forming assay. The LCMV glycoprotein peptide amino acids gp33 (KAVYNFATM), p13 (GLNGPDIYKGVYQFVS), and p13 (GLNGPDIYKGVYQFVS) were purchased from the Jackson Immunoresearch Laboratories.

Detection of virus and nAb titers. The detection of LCMV virus titers and nAbs has been described previously (21, 52). Neutralizing total (IgM and IgG) and IgG antibodies to VSV as well as virus titers were measured as described previously (23).

Cr release assay. S1Cr release assays directly ex vivo or after restimulation in vitro were performed as described previously (23).

Administration of αCD70. Mice were treated i.p. with 300 μg αCD70 (FR70; reference 30) twice a week from day 4 until day 35 or from day 35 until day 60. Rat IgG (Sigma-Aldrich) was used as a control.

Immunohistochemistry. Freshly removed organs were immersed in Hank’s balanced salt solution and snap frozen in liquid nitrogen. Tissue sections of 5-μm thickness were cut in a cryostat and treated as described previously (23). Tissue sections were stained with rat monoclonal antibodies against the following antigens: IgM (clone R6-60.2), CD21/35 (clone 7G6), follicular dendritic cells (clone FDC-M1; all from BD Biosciences), and metallophilic marginal zone macrophages (MOMA-1; BMA Biomedicals AG). Lectin staining of follicular center cells was performed with biotinylated peanut agglutinin (PNA; Vector Laboratories) followed by preformed alkaline phosphatase–labeled avidin–biotin complexes (DakoCytomation).

Flow cytometry. All antibodies were obtained from ebioscience except MHC class I (H-2D^d) tetramers complexed with gp33 or np396, which were purchased from ProImmune, and αVα2, αCD21/35, and αCD8, which were obtained from BD Biosciences. For intracellular staining, lymphocytes (10^5/well) were stimulated for 5 h with gp33 or np396 peptide (10^−6 M/well) in the presence of recombinant 25 U/ml IL-2 and 5 μg/ml brefeldin A (Sigma-Aldrich). Cells were stained for surface molecules, fixed with 4% paraformaldehyde, and cell membranes were permeabilized with Perm buffer (PBS, 2% FCS, 5 mM EDTA, 0.1% saponin, and 0.2% NaN_3) and stained with αIFNγ-FITC. Relative fluorescence intensities were measured using a flow cytometer (FACScan or BD LSRII; Becton Dickinson) and analyzed using FlowJo software (Tree Star). Sorting of live cells was performed using a flow cytometry system (FACSVantage; Becton Dickinson).

Cytokine measurement. 10^5 SMARTA or SMARTA × CD27^−/− spleenocytes were injected i.v. into BL/6 recipients that were immunized on the following day with LCMV-WE. 8 d after infection, CD4^+Va2^+ T cells were sorted by flow cytometry, and 3 × 10^6 CD4^+Va2^+ T cells were cultured with 5 × 10^5 gp13-pulsed and irradiated (1,500 rad) naive BL/6 spleenocytes in a 96-well plate in a total of 200 μl IMDM supplemented with 10% FCS for 16 h. 120 μl of the supernatant was harvested and analyzed for cytokines using a mouse Fluorokine MAP Multiplex Assay (R&D Systems). An identical experimental setup was used to analyze cytokine secretion by P14 and P14 × CD27^−/− spleenocytes except that harvesting was performed after 6 h of cultivation.

Adaptive transfer of CD4^+ and CD8^+ cells. CD4^+ and CD8^+ T cells were purified by MACS (Miltenyi Biotec) using αCD4 or αCD8 magnetic beads. 10^5 CD4^+ or CD8^+ T cells were injected i.v. into CD27^−/− mice that were infected on the same day with LCMV-WE.

Adaptive transfer of CD19^+ B cells of T11µMT mice. CD19^+ B cells were purified by MACS (Miltenyi Biotec) using αCD19 magnetic beads. 5 × 10^6 CD19^+ B cells were injected i.v. into CD27^−/− and BL/6 mice, which were then infected with LCMV-WE.

Serum protein electrophoresis. Total serum immunoglobulin was detected by capillary zone electrophoresis using an electrophoresis system (Paragon CZ2 2000; Beckman Coulter), and total serum protein was measured on an analyzer (model 917; Hitachi) according to the Biuret method.

Statistical analysis. Statistical comparison between groups was performed with a two-tailed unpaired Student’s t test using Prism 4 software (GraphPad Software). Data was considered statistically significant when the p-value was <0.05.

Online supplemental material. Fig. S1 shows the control of LCMV-WE in the absence of CD27 signaling in the lung, kidney, and liver. Fig. S2 presents the nAb response to nonreplicating VSV-UV and replication of VSV-NJ in LCMV-WE–infected mice. Online supplemental material is available at http://www.jem.org/cgi/content/full/jem.20060651/DC1.

We would like to thank J. Borst (Division of Immunology, Netherlands Cancer Institute, Amsterdam, Netherlands) for providing CD27^−/− mice and R.M. Zinkernagel for critically reading the manuscript.

This work was supported by the Swiss National Foundation grant 3200006020, Oncosuisse grant 01312-02-2003, and the Cancer League of the Canton of Bern, Switzerland.

The authors have no conflicting financial interests.
