TREE-WIDTH FOR FIRST ORDER FORMULAE

ISOLDE ADLER and MARK WEYER

Abstract. We introduce tree-width for first order formulae $\varphi$, $\text{fotw}(\varphi)$. We show that computing $\text{fotw}$ is fixed-parameter tractable with parameter $\text{fotw}$. Moreover, we show that on classes of formulae of bounded $\text{fotw}$, model checking is fixed parameter tractable, with parameter the length of the formula. This is done by translating a formula $\varphi$ with $\text{fotw}(\varphi) < k$ into a formula of the $k$-variable fragment $L^k$ of first order logic. For fixed $k$, the question whether a given first order formula is equivalent to an $L^k$ formula is undecidable. In contrast, the classes of first order formulae with bounded $\text{fotw}$ are fragments of first order logic for which the equivalence is decidable.

Our notion of tree-width generalises tree-width of conjunctive queries to arbitrary formulae of first order logic by taking into account the quantifier interaction in a formula. Moreover, it is more powerful than the notion of elimination-width of quantified constraint formulae, defined by Chen and Dalmau (CSL 2005): for quantified constraint formulae, both bounded elimination-width and bounded fotw allow for model checking in polynomial time. We prove that fotw of a quantified constraint formula $\varphi$ is bounded by the elimination-width of $\varphi$, and we exhibit a class of quantified constraint formulae with bounded fotw, that has unbounded elimination-width. A similar comparison holds for strict tree-width of non-recursive stratified datalog as defined by Flum, Frick, and Grohe (JACM 49, 2002).

Finally, we show that fotw has a characterization in terms of a cops and robbers game without monotonicity cost.

1. Introduction

Model checking is an important problem in complexity theory. It asks for a given formula $\varphi$ of some class $\mathcal{C}$ of formulae and a structure $\mathcal{A}$, whether $\mathcal{A}$ satisfies $\varphi$.

Key words and phrases: treewidth, model checking, conjunctive queries, quantified constraint formulae, first-order logic, elimination-width, cops and robbers game.
Let $\mathcal{L}$ denote first order logic. It is well-known, that $\text{MC}(\mathcal{L})$ is $\text{PSPACE}$-complete. Motivated by this, much research has been done on finding fragments of $\mathcal{L}$ having a tractable model checking problem. For instance, for fixed $k$, the problem $\text{MC}(\mathcal{L}^k)$ can be solved in polynomial time, where $\mathcal{L}^k$ denotes the fragment of first order formulae with at most $k$ variables (see e.g. [17]).

The class of conjunctive queries, $\text{CQ}$, is an important fragment of first order logic. Many queries that occur in practice are conjunctive queries, and model checking of conjunctive queries on relational databases (i.e. relational structures) is an important and well-studied problem in database theory [29] [8] [18] [10] [20] [23]. It is equivalent to conjunctive query containment, to the constraint satisfaction problem studied in artificial intelligence and to the homomorphism problem for structures [7] [15]. A conjunctive query is a first order formula starting with a quantifier prefix using only existential quantifiers, followed by a conjunction of relational atoms. While $\text{MC}(\text{CQ})$ is NP-hard in general, several researchers proved independently that conjunctive queries of bounded tree-width can be evaluated in polynomial time [8] [18]. One way to prove this is the following. Suppose $\varphi$ is a conjunctive query having tree-width $k$. Then we can compute a tree decomposition of width $k$ in linear time using Bodlaender’s algorithm [6]. From the decomposition we can actually read off the syntax of an equivalent formula $\varphi' \in \mathcal{L}^{k+1}$. Finally, we use the fact that $\text{MC}(\mathcal{L}^{k+1})$ is solvable in polynomial time. Essentially, bounded tree-width is even necessary for polynomial time solvability of $\text{MC}(\text{CQ})$ [24] [22].

In this paper, we introduce a notion of tree-width for first order formulae $\varphi$, $\text{fotw}(\varphi)$. Our notion generalises the notion of tree-width of conjunctive queries, and we show that the class $\mathcal{C}_k$ of all first order formulae $\varphi$ with $\text{fotw}(\varphi) \leq k$ satisfies the following properties.

1. $\mathcal{C}_k$ has a polynomial time membership test (Corollary 4.8).
2. $\mathcal{C}_k$ has the same expressive power as $\mathcal{L}^{k+1}$, the fragment of first order formulae with at most $k + 1$ variables (Theorem 5.5).
3. There is an algorithm that computes for given $\varphi \in \mathcal{C}_k$ an equivalent formula $\varphi' \equiv \varphi$ with $\varphi' \in \mathcal{L}^{k+1}$ (Theorem 5.5).
4. $\text{MC}(\mathcal{C}_k)$ is fixed parameter tractable with parameter the length of $\varphi$, i.e. for input $\varphi \in \mathcal{C}_k$ and $A$, the running time is $p(\|A\|)f(|\varphi|)$ for a polynomial $p$ and a computable function $f$ (Corollary 5.6).

Obviously, properties 1 and 3 imply property 4. While $\text{MC}(\mathcal{L}^k)$ is solvable in polynomial time, we do not obtain a polynomial algorithm for $\text{MC}(\mathcal{C}_k)$. Nevertheless, in typical applications one can expect the length of the formula to be small compared to the size of the structure (database). For a fixed formula the running time is polynomial, and moreover, the problem is fixed-parameter tractable (in FPT), meaning that changing $\varphi$ does not alter the exponent of the polynomial (see [13] [17]).

Note that for fixed $k > 0$ it is undecidable, whether a first order formula $\varphi$ is equivalent to an $\mathcal{L}^k$ formula. Hence it is not surprising that our notion of $k$-bounded first order tree-width does not capture semantic equivalence to $\mathcal{L}^k$ (we will give more details in Section 5).

Quantified constraint formulae generalise conjunctive queries by allowing arbitrary quantifiers in the quantifier prefix. In [9], Chen and Dalmau introduce elimination orderings for quantified constraint formulae. These elimination orderings must respect the quantifier prefix. In this way, Chen and Dalmau obtain a notion of elimination-width$^1$, which

---

$^1$Actually, the notion is called tree-width for quantified constraint formulae in [9]. But since the notion is defined via elimination orderings, we prefer the term elimination-width.
allows for model checking of quantified constraint formulae of bounded elimination-width in polynomial time, using a consistency algorithm. Hereby, they answer a question posed in [19] positively, whether bounded tree-width methods work for formulae more general than conjunctive queries. Introducing a notion of tree-width for arbitrary first order formulae, we even go further. We show that for quantified constraint formulae \( \varphi \), elimination-width of \( \varphi \) is at least as large as \( \text{fotw}(\varphi) \), and we exhibit a class of quantified constraint formulae with bounded first order tree-width and unbounded elimination-width. We show that quantified constraint formulae of bounded \( \text{fotw} \) allow for model checking in polynomial time. Hence \( \text{fotw} \) is more powerful than elimination-width.

In [16], Flum, Frick and Grohe introduce strict tree-width for non-recursive stratified datalog (NRS) programs. They show that model checking for NRS programs of bounded strict tree-width can be done in polynomial time. Since NRS programs have a canonical translation into first order formulae, our notion of tree-width can be transferred from first order formulae to NRS programs. We show that if an NRS program \( \Pi \) has strict tree-width at most \( k \), then the formula \( \varphi_\Pi \) obtained from \( \Pi \) has elimination-width at most \( k \) and hence it satisfies \( \text{fotw}(\varphi_\Pi) \leq k \). Again there are classes of NRS programs with unbounded strict tree-width, whose corresponding first order formulae have bounded first order tree-width. Hence our notion of first order tree-width yields larger subclasses of \( \mathcal{L} \), that still allow for tractable model checking.

Actually, we introduce first order tree-width as a special case of a more abstract notion which we term stratified tree-width. We expect that stratified tree-width will find further, quite different, applications.

The rest of this paper is organised as follows. Section 2 fixes some terminology. Section 3 introduces the notion of stratified tree-width, the special case of first order tree-width, and the notion of xenerp normal form of a formula \( \varphi \) – a kind of opposite of prenex normal form. We show that fotw is invariant under transformation into xenerp normal form. In Section 3.4 we relate fotw to the natural notion of tree-width stratified by the alternation depth of a formula. In Section 4 we show how to compute stratified tree decompositions and, in particular, how to compute first order tree-width. In Section 5 we prove that bounded first order tree-width is expressively equivalent to bounded variable fragments of first order logic and that model checking for formulae of bounded first order tree-width is fixed-parameter tractable. In Section 6 we relate our notion to existing notions and give a game characterisation of stratified tree-width. We conclude with some open problems in Section 7.

We wish to thank the anonymous referees for many useful suggestions.

2. Well-known definitions

A vocabulary \( \sigma = \{R_1,\ldots,R_n,c_1,\ldots,c_m\} \) is a finite set of relation symbols \( R_i \), \( 1 \leq i \leq n \), and constant symbols \( c_j \), \( 1 \leq j \leq m \). Every \( R_i \) has an associated arity, an integer \( \text{ar}(R_i) > 0 \). A \( \sigma \)-structure \( A \) is a tuple \( A = (A,R_1^A,\ldots,R_n^A,c_1^A,\ldots,c_m^A) \) where \( A \) is a finite set, the universe of \( A \), \( R_i^A \subseteq A^{\text{ar}(R_i)} \) for \( 1 \leq i \leq n \), and \( c_j^A \in A \) for \( 1 \leq j \leq m \).

Given a \( \sigma \)-structure \( A \) we distinguish between the cardinality \( |A| \) of the universe \( A \) of \( A \) and the size \( \|A\| \) of \( A \), given by \( \|A\| = |\sigma| + |A| + \sum_{i=1}^{n} |R_i^A| \cdot \text{ar}(R_i) \).

In [16], the authors also introduce a notion of tree-width for first order formulae. But their notion disregards the quantifier interaction, and they only use it for conjunctive queries with negation.
We use $L$ to denote relational first order logic with constants, and for simplicity, we refer to $L$ as first order logic. We assume that the reader is familiar with the basic notions of first order logic (see for instance [14]). For a formula $\varphi$ we let $\text{free}(\varphi)$ denote the set of free variables of $\varphi$. A formula $\varphi$ is a sentence, if $\text{free}(\varphi) = \emptyset$. We sometimes write $\varphi(x_1, \ldots, x_n)$ to indicate that $\text{free}(\varphi) \subseteq \{x_1, \ldots, x_n\}$.

For a structure $A$, a formula $\varphi(x_1, \ldots, x_n)$, and elements $a_1, \ldots, a_n \in A$ we write $A \models \varphi(a_1, \ldots, a_n)$ to denote that $A$ satisfies $\varphi$ if the variables $x_1, \ldots, x_n$ are interpreted by $a_1, \ldots, a_n$, respectively. We let

$$\varphi(A) := \{(a_1, \ldots, a_n) \mid A \models \varphi(a_1, \ldots, a_n)\}.$$ 

For sentences we have $\varphi(A) = \text{true}$, if $A$ satisfies $\varphi$, and $\text{false}$ otherwise. If the vocabularies of $\varphi$ and $A$ are different, we let $\varphi(A) = \emptyset$.

The Query Evaluation Problem for a class $C$ of formulae is the following problem:

| Eval($C$) |
| --- |
| **Input:** A structure $A$ and a formula $\varphi \in C$. |
| **Problem:** Compute $\varphi(A)$. |

Note that if $\varphi$ is a sentence, then $\text{Eval}(C)$ and $\text{MC}(C)$ coincide. We say that a formula $\varphi \in L$ is straight, if no variable in $\varphi$ is quantified over twice, if no free variable is also a quantified variable, and if each quantified variable actually occurs in some atom. All formulae are straight, unless stated otherwise. Moreover, we assume that all formulae are in negation normal form, i.e. the negation symbols only appear in front of atoms.

We denote a graph $G$ as a pair $G = (V(G), E(G))$, where the set $V(G)$ of vertices is finite, and every edge $e \in E(G)$ is a two-element subset of $V(G)$. A tree decomposition of a graph $G = (V, E)$ is a pair $(T, B)$, consisting of a rooted tree $T$ and a family $B = (B_t)_{t \in T}$ of subsets of $V$, the pieces of $T$, satisfying:

- **(TD1):** For each $v \in V$ there exists $t \in T$, such that $v \in B_t$. We say the node $t$ covers $v$.
- **(TD2):** For each edge $e \in E$ there exists $t \in T$, such that $e \subseteq B_t$. We say the node $t$ covers $e$.
- **(TD3):** For each $v \in V$ the set $\{t \in T \mid v \in B_t\}$ is connected in $T$.

The width of $(T, B)$ is defined as $w(T, B) := \max\{|B_t| \mid t \in T\} - 1$. The tree-width of $G$ is defined as

$$\text{tw}(G) := \min\{w(T, B) \mid (T, B) \text{ is a tree decomposition of } G\}.$$ 

**Fact 2.1.** Every graph $G$ of tree-width at most $k$ has at most $k \cdot |V(G)|$ edges. □

Fact 2.1 can be shown by induction on the number of vertices (see e.g. [17]). We will make frequent use of the following well-known fact about tree decompositions (see [11]):

**Fact 2.2.** Let $(T, B)$ be a tree decomposition of some graph $G$, and let $C \subseteq V(G)$. If for all $v, w \in C$, some piece of $(T, B)$ covers both $v$ and $w$, then there is some piece $B_t$ covering $C$ entirely, i.e. $C \subseteq B_t$.

In particular, every clique in $G$ is covered by some piece. □
3. First order tree-width

3.1. Stratified tree-width. We start with defining stratified tree-width. Then, first order tree-width is defined as a special case. Although it is our only application of stratified tree-width, stating results in greater generality allows us to focus on their essence. It is also quite possible, that further applications will arise in the future.

Any rooted tree $T$ induces a natural partial order $<_T$ on its nodes, where the smallest element is the root. For a tree decomposition $(T, B)$ of a graph $G$ and a vertex $v \in V(G)$, let $t_v \in T$ denote the $<_T$-minimal tree node that covers $v$. By (TD3), the node $t_v$ is well-defined. Now, let $d : V(G) \rightarrow \mathbb{N}$ be a function. We say that a tree decomposition $(T, B)$ of $G$ is $d$-stratified, if all $u, v \in V(G)$ with $t_u <_T t_v$ satisfy $d(u) \leq d(v)$. The tree-width of $(G, d)$ is defined as

$$\text{tw}(G, d) := \min \{w(T, B) \mid (T, B) \text{ is a } d\text{-stratified tree decomposition of } G\}.$$  

It will sometimes be convenient to work with an alternative characterization of stratified tree width: let $G = (V, E)$ be a graph and $d : V \rightarrow \mathbb{N}$. An elimination ordering of $(G, d)$ is a linear ordering $(v_1, \ldots, v_n)$ of $V$ which respects $d$, i.e. $i < j$ implies $d(v_i) \leq d(v_j)$. With an elimination ordering we associate a sequence of graphs as follows:

- $G_n := G$
- $V(G_{i-1}) := V(G_i) \setminus \{v_i\}$, and
- $E(G_{i-1}) := \{e \in E(G_i) \mid v_i \notin e\} \cup \{(u, w) \mid u \neq w, \{u, v_i\}, \{v_i, w\} \in E(G_i)\}$ for $1 < i \leq n$.

The width of the elimination ordering is $\max_{i \in [n]} \{\deg(v_i)\}$ in $G_i$. The elimination-width of $(G, d)$, $\text{ew}(G, d)$, is the minimum width of an elimination ordering of $(G, d)$. It is well-known that the tree-width of a graph $G$ equals the elimination-width of $G$ (see [5]), and this fact can be generalised to our setting.

Theorem 3.1. Let $G$ be a graph and $d : V(G) \rightarrow \mathbb{N}$. Then $\text{tw}(G, d) = \text{ew}(G, d)$.

Proof. Towards a proof of $\text{tw}(G, d) \geq \text{ew}(G, d)$, let $(T, B)$ be a $d$-stratified tree decomposition for $G$ of width $k$. We may assume that $(T, B)$ is small, i.e. all nodes $s, t \in V(T)$ with $s \neq t$ satisfy $B_s \not\subseteq B_t$. Recall that for a vertex $v \in V(G)$, $t_v$ denotes the $<_T$-minimal node of $T$ with $v \in B_t$. We now define an ordering $v_1, \ldots, v_n$ of $V(G)$ such that for all $1 \leq i, j \leq n$ we have

- $i < j$ implies $d(v_i) \leq d(v_j)$,
- there is a piece $B_i$ of $(T, B)$ containing $v_i$ and all the neighbours of $v_i$ in $G_i$.

In particular, $v_1, \ldots, v_n$ is an elimination ordering of $(G, d)$ of width at most $k$.

Claim 1. There exists a vertex $v \in V(G)$ with $d(v)$ maximum, such that $v$ appears in exactly one piece $B_\ell$ of $(T, B)$, and $\ell$ is a leaf.

Proof. Choose any vertex $w$ with $d(w)$ maximum. If $w$ is contained in a piece $B_t$ of $(B, T)$ where $t$ is not a leaf (otherwise we are done), then choose a leaf $\ell \geq_T t$ of $T$. Let $s$ be the parent of $\ell$. Choose $v \in B_\ell \setminus B_s$ (such a $v$ exists since the decomposition is small). Since $(T, B)$ is $d$-stratified and $t_w <_T \ell = t_v$, we have $d(w) \leq d(v)$, and hence by maximality $d(w) = d(v)$, proving the claim.

Let $v_n := v$. Then we replace $G$ by $G_{n-1}$, we restrict $d$ and $(T, B)$ to $G_{n-1}$ and we proceed by induction.
Towards $\text{tw}(G,d) \leq \text{ew}(G,d)$, let $v_1, \ldots, v_n$ be an ordering of $V(G)$ of width at most $k$ and let $G_1, \ldots, G_n = G$ be the associated sequence of graphs. For $i = 1, \ldots, n$ we define tree decompositions for the $G_i$ that respect $d$ and have width at most $k$. For $i = 1$ we take the trivial decomposition. Given a tree decomposition of $G_{i-1}$, we choose a piece containing all the neighbours of $v_i$ in $G_i$ (such a piece exists, because the neighbours induce a clique in $G_{i-1}$), and we attach to it a new piece containing $v_i$ and all neighbours of $v_i$ in $G_i$. Let $(T, B)$ be the tree decomposition obtained for $G = G_n$. Obviously, $(T, B)$ has width at most $k$. Moreover, $(T, B)$ is $d$-stratified: let $v_i, v_j \in V(G)$. If $t_{v_i} <_T t_{v_j}$, then, by construction, we have $i < j$. Since $v_1, \ldots, v_n$ is an elimination ordering of $(G, d)$, this implies $d(v_i) \leq d(v_j)$. □

3.2. First order tree-width. For a formula $\varphi$, the formula graph is the undirected graph $G_\varphi$, with vertices $\text{var}(\varphi)$, and edges $\{x, y\}$ whenever $x$ and $y$ are free variables, or when $x$ and $y$ occur together in some atom of $\varphi$. (If $\varphi$ is not straight, then we obtain the formula graph of $\varphi$ by first making it straight.) Note that the formula graph depends on the syntax of the formula. Logically equivalent formulae may have different formula graphs.

We now introduce a partial order $\preceq_\varphi$ on the variables of a formula $\varphi$, from which we then obtain the essential alternation depth, $\text{ead}_\varphi(x)$, of a variable $x \in \text{var}(\varphi)$. Given a tree decomposition of $G_\varphi$ of width $k - 1$ that respects $\text{ead}_\varphi$, we show in Section 5 how to transform the formula $\varphi$ bottom up along the decomposition into an equivalent $\mathcal{L}^k$-formula. In this transformation, we want to ‘reuse’ as many variables as possible, so, intuitively, the ‘worst case’ is that $\varphi$ is in prenex normal form. Hence we want to ‘undo’ prenex normal form, pushing quantifiers as far as possible away from the root in the syntax tree. Of course, we have to make sure that we obtain an equivalent formula. Intuitively, $\preceq_\varphi$ gives us a partial order of quantifications that we have to respect while undoing prenex normal form.

For a bound variable $x$, let $Q_x \in \{\exists, \forall\}$ be the type of quantifier used to quantify $x$ in $\varphi$. Then the scope of $x$ is the unique subformula $\psi$ of $\varphi$ such that $Q_x x \psi$ is a subformula of $\varphi$. For bound variables $x, y$ of $\varphi$, we write $x \preceq_\varphi y$ to denote that $x = y$ or $y$ is quantified in the scope of $x$. For a set $X$ of variables, we use $\varphi_{[X]}$ to denote the minimal (with respect to subformulaship) subformula of $\varphi$ which contains all atoms using variables from $X$.

Definition 3.2. Let $\preceq$ be a binary relation on the variables of some formula $\varphi$. Then two variables $x$ and $y$ are entangled with respect to $\preceq$ and $\varphi$, if $x$ occurs in $\varphi_{[y\preceq]}$ and $y$ occurs in $\varphi_{[x\preceq]}$ (as usual, we use $x \preceq$ to denote $\{x' \mid x \preceq x'\}$).

Definition 3.3. Let $\varphi$ be a straight formula. Then $\preceq_\varphi$ is the minimal (with respect to $\preceq$) binary relation on $\text{var}(\varphi)$, such that the following hold.

1. $\preceq_\varphi$ is reflexive.
2. $\preceq_\varphi$ is transitive.
3. If $x \preceq_\varphi y$, $Q_x \neq Q_y$ and there is a sequence $x = z_0, \ldots, z_n = y$ of bound variables such that for all $0 \leq i < n$ we have that $z_i, z_{i+1}$ are entangled with respect to $\preceq_\varphi$ and $\varphi$ and that $x \preceq_\varphi z_i$ or $y \preceq_\varphi z_i$, then $x \preceq_\varphi y$ (Alternation).

In order to see that $\preceq_\varphi$ is well-defined, observe that Definition 3.3 is in fact an inductive definition: all three conditions can be restated as closure of $\preceq_\varphi$ under some operator on binary relations, and all three operators are monotone with respect to $\preceq$. The least obvious case is the one of the operator underlying Alternation. To establish monotonicity in this case, assume that $\preceq$ and $\preceq'$ are binary relations on $\text{var}(\varphi)$ and that $(\preceq) \subseteq (\preceq')$. We have to show that whenever two variables $x, y$ satisfy Alternation with respect to $\preceq$, then they also
do with respect to $\leq'$. For any variable $z$ we have $(z \leq) \subseteq (z \leq')$, so $\varphi_{(z \leq)}$ is a subformula of $\varphi_{(z \leq')}$. Thus, entanglement of some variables with respect to $\leq$ and $\varphi$ implies entanglement with respect to $\leq'$ and $\varphi$. Hence any witness for Alternation with respect to $\leq$ is also one with respect to $\leq'$.

At many places, we will use proof by induction on the inductive definition of $\preceq_\varphi$. Therefore, we explicate how the inductive principle works in this case.

**Lemma 3.4.** Let $\varphi$ be a formula and $P$ a property of pairs of variables from $\varphi$. If

1. $P(x, x)$ holds for all $x \in \text{var}(\varphi)$,
2. $x \preceq_\varphi y$, $y \preceq z$, $P(x, y)$ and $P(y, z)$ imply $P(x, z)$, and
3. if $x \preceq_\varphi y$, $Q_x \neq Q_y$, $Q_{(\leq)} \subseteq (\preceq_\varphi)$ such that $P(x', y')$ holds for all $x' \preceq y'$, and for some sequence $x = z_0, \ldots, z_n = y$ and all $0 \leq i < n$ we have $z_i \in (x \leq) \cup (y \leq)$ and entanglement of $z_i$ and $z_{i+1}$ with respect to $\leq$ and $\varphi$, then $P(x, y)$,

then $P(x, y)$ holds for all $x, y$ such that $x \preceq_\varphi y$.

**Remark 3.5.**

1. The relation $\preceq_\varphi$ is a subrelation of $\preceq_\varphi$: $(\preceq_\varphi) \subseteq (\preceq_\varphi)$,
2. the relation $\preceq_\varphi$ is a partial order, and
3. $x \preceq_\varphi y$ holds whenever $x$ and $y$ are entangled, $Q_x \neq Q_y$, and $x \preceq_\varphi y$.

**Proof.** 1 follows since $\preceq_\varphi$ satisfies all closure conditions.

2: $x \preceq_\varphi y$ is reflexive and transitive by definition, and it inherits anti-symmetry from $(\preceq_\varphi)$ by 1.

3: this follows by letting $n = 1$ in Alternation.

**Example 3.6.** Let $\varphi := \exists xy \exists z (Pxy \land \forall u (Ryu \lor Pzu))$. Then $x \preceq_\varphi y$ and $z \preceq_\varphi u$ by Remark 3.5, 3, $y \preceq_\varphi z$ by Alternation (witnessed by the sequence $y, u, z$), and $x \preceq_\varphi z$, $y \preceq_\varphi u$, and $x \preceq_\varphi u$ by Transitivity. In this example, all entanglements are due to the two variables in question occurring in the same atom.

We use $\varphi_x$ as a shorthand for $\varphi_{(x \preceq_\varphi)}$, and we say that $x$ and $y$ are entangled in $\varphi$, if they are entangled with respect to $\preceq_\varphi$ and $\varphi$. Note that this is the case if and only if $x$ occurs in $\varphi_y$ and $y$ occurs in $\varphi_x$. Observe further that $\varphi_x$ is a subformula of the scope of $x$. The idea behind entanglement is to capture interaction between variables.

**Example 3.7.** Let $\varphi := \forall x \forall x' \exists y (((Py \land Pz) \lor Pz') \land ((Py \land Pz') \lor Pz'))$. Then $\varphi_{[\{y\}]}$ already is the whole quantifier free part of $\varphi$, hence so is $\varphi_y$. Further, $\varphi_x$ contains $\varphi_{[\{x\}]} = (Py \land Pz) \lor Pz$. Thus $x$ occurs in $\varphi_y$ and $y$ occurs in $\varphi_x$, so $x$ and $y$ are entangled. It follows that $x \preceq_\varphi y$, so $\varphi_x$ contains $\varphi_y$. As this is the whole quantifier free part, we have $\varphi_x = \varphi_y$. In a similar way we obtain $\varphi_{x'} = \varphi_y$. Consequently, $x$ and $x'$ are entangled as well. Intuitively, $x$ and $x'$ interact through $y$.

**Example 3.8.** Let $\varphi := \forall x \exists y \exists z (Rzy \lor (Px \land Py))$. Then $y$ and $z$ are entangled, because they occur in the same atom. $x$, however, is not entangled with any other variable, because $\varphi_{[\{x\}]} = Px$ does not contain any variable besides $x$. The same holds for $\psi := \exists y (\forall z Rzy \lor (\forall x Px \land Py))$, which illustrates that $x$ does not interact at all. Thus, $(\preceq_\varphi) = \{(y, z), (x, x), (y, y), (z, z)\}$. 
Example 3.9. For \( n > 0 \) let

\[
\varphi_n := \exists x_1 \ldots \exists x_n \forall y \exists z \left( \bigwedge_{1 \leq i \leq n} Rx_i z \land Py \right)
\]

and

\[
\psi_n := \exists x_1 \ldots \exists x_n \forall y \exists z \left( \bigwedge_{1 \leq i \leq n} (Rx_i z \land Py) \right).
\]

In \( \varphi_n \), the only entanglements are between the \( x_i \) and \( z \). Consequently, \( \preceq_{\varphi_n} \) is the equality relation on \( \text{var}(\varphi_n) \). On the other hand, both \((\psi_n)_y\) and \((\psi_n)_z\) coincide with the quantifier free part of \( \psi_n \), so \( y \) and \( z \) are entangled in \( \psi_n \). It follows that \( y \preceq_{\psi_n} z \). Nevertheless, as \( y \) does not occur in \((\psi_n)_{x_i} = Rx_i z, y \) is not entangled with \( x_i \) in \( \psi_n \).

Definition 3.10. Let \( \varphi \) be a first order formula and \( x \in \text{var}(\varphi) \). The essential alternation depth of \( x \) in \( \varphi \), denoted by \( \text{ead}_\varphi(x) \), is the maximum over all \( \preceq_{\varphi} \)-paths \( P \) ending in \( x \) of the number of quantifier changes in \( P \), adding \( +1 \) in case the first variable on \( P \) is existentially quantified and \( +2 \) if it is universally quantified. If \( x \) is a free variable, we let \( \text{ead}_\varphi(x) = 0 \).

The \( +1 \) respectively \( +2 \) in the definition makes sure that \( \text{ead}_\varphi(x) \) is odd if and only if \( Q_x = \exists \).

Example 3.11. The formula from Example 3.6 satisfies \( \text{ead}_\varphi(x) = 1 \), \( \text{ead}_\varphi(y) = 2 \), \( \text{ead}_\varphi(z) = 3 \), and \( \text{ead}_\varphi(u) = 4 \).

The formula from Example 3.7 satisfies \( \text{ead}_\varphi(x) = \text{ead}_\varphi(x') = 2 \) and \( \text{ead}_\varphi(y) = 3 \).

The formulae from Example 3.8 satisfy \( \text{ead}_\varphi(x) = \text{ead}_\varphi(z) = 2 \), \( \text{ead}_\varphi(y) = 1 \), and \( \text{ead}_\psi = \text{ead}_\varphi \).

For the formulae from Example 3.9 we have \( \text{ead}_{\varphi_n}(x_1) = \text{ead}_{\psi_n}(x_1) = \text{ead}_{\varphi_n}(z) = 1 \), \( \text{ead}_{\varphi_n}(y) = \text{ead}_{\psi_n}(y) = 2 \), and \( \text{ead}_{\psi_n}(z) = 3 \).

Definition 3.12. If we replace \( \preceq_{\varphi} \) by \( \preceq_{\varphi} \) in Definition 3.10 we obtain the (usual) alternation depth of \( x \) in \( \varphi \), which we denote by \( \text{ad}_\varphi \).

Remark 3.13. Every formula \( \varphi \) satisfies \( \text{ead}_\varphi \leq \text{ad}_\varphi \).

Example 3.14. For the formulae from Examples 3.6 and 3.7 we have \( \text{ad}_\varphi = \text{ead}_\varphi \).

The formulae from Example 3.8 satisfy \( \text{ad}_\varphi(x) = 2 \), \( \text{ad}_\varphi(y) = 3 \), \( \text{ad}_\varphi(z) = 4 \), and \( \text{ad}_\psi = \text{ead}_\psi \).

For the formulae from Example 3.9 we have \( \text{ad}_{\varphi_n} = \text{ad}_{\psi_n} = \text{ead}_{\psi_n} \).

Definition 3.15 (First order tree-width). For a formula \( \varphi \) we define the first order tree-width of \( \varphi \) by \( \text{fotw}(\varphi) := \text{tw}(G_\varphi, \text{ead}_\varphi) \).

Accordingly, we say that \( (T, B) \) is a tree decomposition for \( \varphi \), if \( (T, B) \) is an \( \text{ead}_\varphi \)-stratified tree decomposition for \( G_\varphi \).

Note that for a formula \( \varphi \), the variables free(\( \varphi \)), as well as the variables of any atom or literal in \( \varphi \) induce cliques in \( G_\varphi \). In particular, since \( \text{ead}_\varphi(x) = 0 \) for any free variable \( x \), by Fact 2.2 it is no restriction to require that the free variables be covered in the root of a tree decomposition.

In general, the difference between \( \text{fotw}(\varphi) \) and \( \text{tw}(G_\varphi) \) can be unbounded:

Proposition 3.16. For every \( n > 0 \) there is a formula \( \varphi_n \) with \( \text{fotw}(\varphi_n) = n \) and \( \text{tw}(G_{\varphi_n}) = 1 \).
Proof. Let
\[ \varphi_n = \exists x_1 \ldots \exists x_n \forall y \bigwedge_{1 \leq i \leq n} E x_i y. \]
Then \( G_{\varphi_n} \) is the \( n \)-star with center \( y \), and we have ead\(_{\varphi_n}(x_i) = 1 \) for all \( 1 \leq i \leq n \), and ead\(_{\varphi_n}(y) = 2 \). It is easy to see that any ead\(_{\varphi_n}\)-stratified tree decomposition \((T,B)\) of \( G_{\varphi_n} \) has a piece \( \{x_1,x_2,\ldots,x_n,y\} \), namely \( B_{t_y} \). On the other hand, such a tree decomposition needs no other pieces. Hence \( \text{fow}(\varphi_n) = n \). Since \( G_{\varphi_n} \) is a tree we have \( \text{tw}(G_{\varphi_n}) = 1 \).

**Lemma 3.17.** Given a formula \( \varphi \), we can compute \( \preceq_\varphi \) and ead\(_{\varphi} \) in polynomial time.

**Proof.** In order to compute \( \preceq_\varphi \), consider the three closure operators implicit in its definition. As \( \preceq_\varphi \) is a binary relation on \( \text{var}(\varphi) \), a quadratic number of applications of the closure operators suffices to produce \( \preceq_\varphi \). Hence it remains to show that each closure operator is computable in polynomial time. This is immediate for Reflexivity and Transitivity. For Alternation, let \( (\preceq) \subseteq \text{var}(\varphi)^2 \) be the current approximation of \( \preceq_\varphi \). First, we compute the formulae \( \varphi[\preceq] \) for all variables \( z \), and from these the entanglement relation. Then, checking whether some pair \((x,y)\) needs to be added to \( R \) because of Alternation basically amounts to reachability in the entanglement graph restricted to \((x \preceq) \cup (y \preceq)\).

It is clear that ead\(_{\varphi} \) can be computed from \( \varphi \) and \( \preceq_\varphi \) in polynomial time.

### 3.3. Xenerp normal form.

Prenex normal form aims to make the scopes of quantifiers as large as possible. Working in the opposite direction, we obtain what we term xenerp normal form.

**Definition 3.18.** A subformula \( \chi \) of a formula \( \varphi \) is in **xenerp normal form with respect to \( \varphi \)**, if for all variables \( x \) quantified in \( \chi \) the following holds: \( \varphi_x \) is immediately preceeded by a quantifier sequence which contains \( Q_x x \).

A formula \( \varphi \) is in **xenerp normal form**, if it is in xenerp normal form with respect to itself.

**Example 3.19.** Recall the formulae \( \varphi \) and \( \psi \) from Example 3.8. We have already seen that ead\(_{\varphi} \) = ead\(_{\psi} \). Furthermore, \( \varphi \) and \( \psi \) are equivalent and \( \psi \) is in xenerp normal form, whereas \( \varphi \) is not in xenerp normal form.

The following lemma presents equivalent transformations of formulae, such that neither the formula graph, nor the essential alternation depth, nor the corresponding tree decompositions change.

**Lemma 3.20.** Let \( \varphi \) and \( \psi \) be formulae satisfying either 1, 2 or 3.

1. **There are formulae \( \chi_1,\ldots,\chi_n \), a positive Boolean combination \( \theta \) of \( n \) arguments, and a variable \( x \) which does not occur in \( \chi_2,\ldots,\chi_n \), such that \( \psi \) is obtained from \( \varphi \) by replacing a subformula \( \theta(Q_x x \chi_1,\chi_2,\ldots,\chi_n) \) by \( Q_x x \theta(\chi_1,\chi_2,\ldots,\chi_n) \).**

2. **There are a formula \( \chi \), and variables \( x,y \) with \( Q_x = Q_y \), such that \( \psi \) is obtained from \( \varphi \) by replacing a subformula \( Q_x x Q_y y \chi \) by \( Q_y y Q_x x \chi \).**

3. **There are a formula \( \chi \), and variables \( x,y \) with \( \varphi_x \) a proper subformula of \( \varphi_y \), such that \( \psi \) is obtained from \( \varphi \) by replacing a subformula \( Q_x x Q_y y \chi \) by \( Q_y y Q_x x \chi \), where \( Q_y y \chi \) is xenerp with respect to \( \varphi \).**
Then \( \varphi \equiv \psi \), ead_{\varphi} = ead_{\psi}, and \( G_{\varphi} = G_{\psi} \). Consequently, tree decompositions for \( \varphi \) coincide with tree decompositions for \( \psi \) and in particular \( \text{fotw}(\varphi) = \text{fotw}(\psi) \).

Implicitly, we assume in these cases that \( Q_x \) and \( Q_y \) are the same with respect to the formula \( \varphi \) and with respect to the formula \( \psi \).

**Proof.** In all three cases the formulae differ only in the position of quantifiers, so \( G_{\varphi} = G_{\psi} \) is immediate. Also, for all \( X \subseteq \text{var}(\varphi) = \text{var}(\psi) \), the formulae \( \varphi|_{X} \) and \( \psi|_{X} \) are essentially equal: the only potential difference between them is the same shift of quantifiers which led from \( \varphi \) to \( \psi \). In particular, the same variables occur in \( \varphi|_{X} \) as in \( \psi|_{X} \). Hence, all differences between \( \leq_{\varphi} \) and \( \leq_{\psi} \) (and thus between ead_{\varphi} and ead_{\psi}) must ultimately stem from differences between \( \leq_{\varphi} \) and \( \leq_{\psi} \).

For the first replacement, the equivalence \( \varphi \equiv \psi \) is well-known. For the other parts of the statement, the only change between \( \leq_{\varphi} \) and \( \leq_{\psi} \) is, that for all variables \( y \) quantified in \( \chi_{i} \) for some \( 2 \leq i \leq n \), we have \( x \not\leq_{\varphi} y \) but \( x \leq_{\psi} y \). We show that this change has no impact on \( \leq \). Clearly \( (\leq_{\varphi}) \subseteq (\leq_{\psi}) \) because of \( (\leq_{\varphi}) \subseteq (\leq_{\psi}) \). For the converse we use induction on derivations. More precisely, we show by induction on the inductive definition of \( \leq_{\psi} \) that for all \( x' \leq_{\varphi} y' \) we have \( x' \leq_{\psi} y' \). That is the inductive property \( P(x',y') \) as in Lemma 3.4 is \( x' \leq_{\varphi} y' \). The first two inductive rules are trivial, because we know that \( \leq_{\varphi} \) is reflexive and transitive. Hence we can concentrate on Alternation. So let \( x' \leq_{\psi} y', (\leq) \subseteq (\leq_{\psi}) \cap (\leq_{\varphi}) \), and \( x' = z_{0}, \ldots, z_{n} = y' \) be given such that \( Q_{x} \neq Q_{y} \), and for all \( 0 \leq i < n \) we have \( z_{i} \in (x' \leq) \cap (y' \leq) \) and entanglement of \( z_{i}, z_{i+1} \) with respect to \( \leq \) and \( \psi \). By our above observation on the similarity of \( \varphi|_{X} \) and \( \psi|_{X} \) for any set \( X \) of bound variables, it follows that \( z_{i} \) and \( z_{i+1} \) are also entangled with respect to \( \leq_{\psi} \) and \( \varphi \). Consequently, either \( x' \leq_{\varphi} y' \) holds (and we are done), or \( x' \not\leq_{\varphi} y' \). Then, together with \( x' \leq_{\psi} y' \) it follows that \( x' = x \) and \( y' \) is quantified in \( \chi_{j} \) for some \( 2 \leq j \leq n \). As \( x \leq_{\varphi} z_{i} \) or \( y' \leq_{\varphi} z_{i} \) for all \( 0 \leq i < n \), all \( z_{i} \) are quantified either in \( Q_{x} \) or in \( \chi_{j} \). As the former is true for \( z_{0} = x \) and the latter for \( z_{n} = y' \), there is some \( 0 \leq i < n \) such that \( z_{i} \) is quantified in \( Q_{x} \) and \( z_{i+1} \) in \( \chi_{j} \). Then \( \varphi|_{[z_{i},z_{i+1}]} \) is a subformula of \( \varphi_{z_{i}} \), which in turn is a subformula of the scope of \( z_{i} \) and thus of \( Q_{x} \). Similarly, the scope of \( z_{i+1} \) is a subformula of \( \chi_{j} \). As all occurrences of \( z_{i+1} \) are in its scope and \( \chi_{j} \) is disjoint from \( Q_{x} \), this contradicts the fact that \( z_{i+1} \) occurs in \( \psi_{[z_{i},z_{i+1}]} \).

In the second replacement, the equivalence \( \varphi \equiv \psi \) also is well-known. So let us show \( (\leq_{\varphi}) = (\leq_{\psi}) \). As the replacement is symmetric, it suffices to show \( (\leq_{\varphi}) \subseteq (\leq_{\psi}) \), which we do by induction. Again, the cases of Reflexivity and Transitivity are clear. For Alternation, let \( \leq \) and \( x' = z_{0}, \ldots, z_{n} = y' \) be given as above. Again, we obtain that Alternation also yields \( x' \leq_{\varphi} y' \) unless \( x' \not\leq_{\varphi} y' \). But then \( x' = x \) and \( y' = y \) contradicting \( Q_{x} = Q_{y} \).

In the third replacement, if \( Q_{x} = Q_{y} \) then this case is subsumed by the second replacement so we may assume \( Q_{x} \neq Q_{y} \). Let us start by showing \( \varphi \equiv \psi \). We will even show \( Q_{x} Q_{y} \) \( \equiv Q_{y} Q_{x} \) \( \chi \). As \( Q_{y} \) \( \chi \) is in xeneral norma] form we have, for variables \( v, w \) quantified in \( Q_{y} \chi \), that \( \varphi_{w} \) is a subformula of \( \varphi_{v} \) whenever \( v \leq_{\varphi} w \). In this case \( w \) occurs in \( \varphi_{v} \) (as the formula is straight, \( w \) does occur somewhere, and it can only occur in \( \varphi_{w} \) which is a subformula of \( \varphi_{v} \)). So for entanglement of \( v \) and \( w \) it suffices to show that \( v \) occurs in \( \varphi_{w} \). Let \( V := \{ v \in \text{var}(\varphi) \mid y \leq_{\varphi} v \} \) and \( \varphi_{x} \) is a subformula of \( \varphi_{v} \). Observe, that \( V \) is linearly ordered by \( \leq_{\varphi} \).

**Claim 1.** There is a subformula \( \theta \) of \( \chi \) which is a superformula of \( \varphi_{x} \) such that no variable from \( V \) occurs free in \( \theta \).
Proof. For contradiction, assume the opposite. Then we inductively define a sequence \(v_0, v_1, \ldots\) of variables. Take \(v_0\) to be \(x\). For all \(i \geq 1\) we will have \(v_i \in V\). For defining \(v_{i+1}\) from \(v_i\), let \(\theta_i\) be \(\varphi_{v_i}\), together with the sequence of quantifications of variables from \(V\) which immediately precedes \(\varphi_{v_i}\). Hence \(\theta_i\) is a subformula of \(Q_y\psi\chi\). If \(\theta_i = Q_y\psi\chi\), then we terminate the sequence. Otherwise, by our assumption, some variable from \(V\) occurs free in \(\theta_i\). Then let \(v_{i+1}\) be such a variable. As \(Q_y\psi\chi\) is xenerp, \(\theta_i\) is a proper subformula of \(\varphi_{v_{i+1}}\). This implies that \(v_i\) occurs in \(\varphi_{v_{i+1}}\) and the converse holds by choice of \(v_{i+1}\), because \(\theta_i\) essentially coincides with \(\varphi_{v_i}\). Hence \(v_i\) and \(v_{i+1}\) are entangled whenever both are defined. If furthermore \(i \neq 0\), then we also have \(v_{i+1} \leq \varphi v_i\) and \(v_{i+1} \neq v_i\), because \(Q_y\psi\chi\) is xenerp and \(\varphi_{v_i}\) is a proper subformula of \(\varphi_{v_{i+1}}\). Hence, as \(V\) is finite, the sequence \(v_0, \ldots\) must terminate, say with \(v_n\). As \(\varphi_x\) is a proper subformula of \(\varphi_y\), we have \(\theta_0 \neq Q_y\psi\chi\), so \(n > 0\). Now let \(0 \leq m \leq n\) be minimal such that \(Q_{v_m} = Q_y\). The case that there are no such \(m\) will be handled later. As \(Q_{v_0} = Q_x \neq Q_y\), we have \(m > 0\) so \(\varphi_x\) is a proper subformula of \(\varphi_{v_m}\). We obtain \(v_m \preceq \varphi v_i\) for all \(1 \leq i \leq m\) using a backwards induction as follows. The base case is Reflexivity. For the inductive step we have a chain \(v_m, \ldots, v_i\) of entanglements and by the inductive hypothesis we have \(v_m \preceq \varphi v_j\) for all intermediate \(j > i\). Further \(v_m \leq v_i\) and \(Q_{v_m} = Q_y \neq Q_{v_i}\), so we obtain \(v_m \preceq \varphi v_i\) using Alternation. Then, in total we have a chain \(x = v_0, v_1, \ldots, v_m\) of entanglements such that \(x \preceq \varphi v_0\) by Reflexivity, \(v_m \preceq \varphi v_i\) for all \(1 \leq i < m\) and \(Q_x \neq Q_y = Q_{v_m}\), so Alternation implies \(x \preceq \varphi v_m\). But then \((v_m \preceq \varphi) \subseteq (x \preceq \varphi)\), contradicting that \(\varphi_x\) is a proper subformula of \(\varphi_{v_m}\). Now for the case that \(Q_{v_i} = Q_x\) for all \(i\) such that \(v_i\) is defined. Then \(\theta_n = Q_y\psi\chi\), so \(\varphi_{v_n} = \varphi_y\) and thus \(v_n\) and \(y\) are entangled. This time we have a chain \(y, v_n, \ldots, v_1, x\) of entanglements with the same properties as the sequence \(v_m, \ldots, v_1, x\) above: it is descending with respect to \(\preceq \varphi\) except for the last step, the first variable has the same quantifier as \(y\) and all other variables have the same quantifier as \(x\). Thus similar to the above we obtain \(x \preceq \varphi y\), this time in contradiction to \(\varphi_x\) being a proper subformula of \(\varphi_y\). This proves the claim. ■

So let \(\theta\) be a subformula of \(\chi\) and a superformula of \(\varphi_x\) such that no variable from \(V\) occurs free in \(\theta\). Hence all free variables of \(\theta\) except \(x\) are also free variables of \(Q_xQ_y\chi\).

Without loss of generality we may assume that \(Q_x = \exists\) and \(Q_y = \forall\). It is well-known that \(\exists\forall\forall\chi\) implies \(\forall\exists\forall\chi\). For the converse, let \(I\) be an interpretation for \(\exists\forall\forall\chi\) such that \(I \models \forall\exists\forall\chi\). We need to show that \(I \models \exists\forall\forall\chi\). For a value \(a\) from the universe of the interpretation \(I\), we have that \(I^a_\exists\) is an interpretation for \(\forall\forall\chi\). As all free variables of \(\theta\) are also free in \(\forall\forall\chi\), we have that \(I^a_\exists\) also is an interpretation for \(\theta\). Now let \(a_0\) be some value such that \(I^a_\exists \models \theta\). If no such \(a_0\) exists, let instead \(a_0\) be arbitrary. Now for all \(a\) we have that \(I^a_\exists \models \theta\) implies \(I^a_\forall \models \chi\). Now let \(b\) be an arbitrary value. As \(I \models \forall\exists\forall\chi\), we have that \(I_\exists \models \forall\exists\forall\chi\), hence \(I_\exists \models \chi\) for some value \(a'\). Let us examine the impact that replacing \(I_\exists\) by \(I_\exists \models \forall b\) has on the formula \(\chi\). Recall that \(\varphi_x\) is a subformula of \(\theta\), so in particular \(x\) does not occur free in \(\chi\) except in \(\theta\). Hence the only possible change comes from \(\theta\). If \(I_\exists \models \theta\), then also \(I_\exists \models \theta\) and nothing changes, that is \(I_\exists \models \chi\). The same argument holds if \(I_\exists \models \theta\) and \(I_\exists \models \theta\). Otherwise \(I_\exists \models \theta\) and \(I_\exists \models \theta\). In this case recall, that all formulae are in negation normal form, so \(\chi\) is positive in \(\theta\). Thus \(I_\exists \models \chi\) again implies \(I_\exists \models \chi\). So \(I^a_\exists \models \chi\) for all values \(b\), which implies \(I^a_\exists \models \forall\forall\chi\) and then \(I \models \exists\forall\forall\chi\).

Next, let us compare \(\preceq \varphi\) with \(\preceq \psi\). The only difference between \(\preceq \varphi\) and \(\preceq \psi\) is, that \(x \preceq \varphi y\) \(\not\preceq \varphi x\) while \(x \preceq \psi y\) \(\preceq \psi x\). To show \((\preceq \varphi) = (\preceq \psi)\), we show inclusion in both directions by induction. Let us start with \((\preceq \psi) \subseteq (\preceq \psi)\). As in the proofs for the other replacements, the only interesting case is where \(x' \preceq \varphi y'\) but \(x' \not\preceq \psi y'\). This implies \(x' = x\)
and $y' = y$. Then $x \preceq \varphi y$ in contradiction to $\varphi x$ being a proper subformula of $\varphi y$. For the other inclusion we need to recall a little more from the above cases: we obtain a sequence of entanglements (which are such both in $\psi$ and in $\varphi$) $x' = z_0, \ldots, z_n = y'$ such that for all $0 \leq i < n$ we have $x' \preceq \varphi z_i$ and $x' \preceq \varphi z_i$ or $y' \preceq \varphi z_i$ and $y' \preceq \varphi z_i$. Also we have $x' \preceq \psi y'$ and we are done unless $x' \not\preceq \varphi y'$, hence $x' = y$ and $y' = x$. But then we have $x \preceq \psi y$ and a chain $x = v_n, \ldots, v_0 = y$ of entanglements. As further $x \preceq \psi v_n$ by Reflexivity, we obtain $x \preceq \varphi y$ which again gives a contradiction. This concludes the proof of Lemma 3.20. 

Observe, that the first class of replacements in the previous lemma are exactly what is used in turning a formula into prenex normal form. For xenerp normal form, we need the first and third class.

**Corollary 3.21.** Let $\varphi$ be a formula and let $\psi$ be a prenex normal form (obtained in the usual way) of $\varphi$. Then $\text{fotw}(\varphi) = \text{fotw}(\psi)$. 

**Lemma 3.22.** From a formula $\varphi$ we can compute in polynomial time a formula $\psi$ in xenerp normal form, such that $\varphi = \psi$, $G_\varphi = G_\psi$, $ead_\varphi = ead_\psi$, and consequently, tree decompositions for $\varphi$ coincide with those for $\psi$.

**Proof.** We work by applying replacements from Lemma 3.20 in one direction or the other. More precisely, we apply replacements of the first kind backwards whenever possible. Whenever no such replacement is applicable, then each quantifier sequence ends with some quantifier $Q_x x$ such that the scope of $x$ is an atom, a negated atom, or a conjunction or disjunction of two subformulae, both of which contain $x$. In all three cases, $\varphi x$ contains the scope of $x$. As the reversed inclusion always holds, we have that $Q_x x$ immediately precedes $\varphi x$.

If the formula $\varphi'$ at hand is xenerp, we are done. Otherwise let $x$ be $\leq \varphi'$-maximal such that the quantifier sequence containing $Q_x x$ does not precede $\varphi x$. By the above, this sequence does not end with $Q_x x$, so the scope of $x$ has the form $Q_y y x$. By maximality of $x$, $Q_y y x$ is xenerp with respect to $\varphi'$. In particular, the quantifier sequence containing $Q_x x$ is followed by $\varphi y$. By the choice of $x$ we conclude that $\varphi x \neq \varphi y$, so $\varphi x$ is a proper subformula of $\varphi y$. Hence a replacement of the third kind is applicable (in the forward direction).

It remains to show, that repeatedly applying these replacements terminates. As a first semi-invariant, consider the sum, taken over all variables $x$, of the distance that $Q_x x$ has from the root in the syntax tree of the formula. (Backwards) replacements of the first kind increase this semi-invariant while replacements of the third kind do not change it at all. On the other hand, replacements of the third kind decrease the number of variable pairs $(x, y)$, such that $x \leq \varphi' y$ and $\varphi x$ is a proper subformula of $\varphi y$. As both semi-invariants are polynomially bounded in $|\varphi|$, and each replacement (including the test for applicability) requires only polynomial time (recall Lemma 3.17), the procedure runs in polynomial time. 

**3.4. Comparing $ead$ with $ad$.** Let $\varphi$ be a first order formula. As $\preceq \varphi$ is coarser than $\preceq \varphi$, it is immediate that $ead_\varphi \preceq ad_\varphi$. However, this does not directly imply that $\text{fotw}(\varphi) \leq \text{tw}(G_\varphi, ad_\varphi)$ also holds. Variables which are incomparable by $\preceq \varphi$ (and thus by $\preceq \varphi$) are given an order by $ead_\varphi$ and by $ad_\varphi$, but not necessarily the same one. Consequently, not every $ad_\varphi$-stratified tree decomposition is also $ead_\varphi$-stratified. Nevertheless $\text{fotw}(\varphi) \leq \text{tw}(G_\varphi, ad_\varphi)$ does hold, and it is the purpose of this subsection to show this fact.

At the core of our proof there is a double induction which we cast into two auxiliary lemmata. An entanglement chain (in some formula $\varphi$) is, of course, a sequence $v_0, \ldots, v_n$
of variables such that for all $0 \leq i < n$ the variables $v_i$ and $v_{i+1}$ are entangled in $\varphi$. The entanglement chain is hanging, if $v_0, v_n \preceq \varphi v_i$ for all $0 < i < n$. It is crossing, if $Q_{v_0} \neq Q_{v_n}$. It is nice, if $\min_{\preceq_\varphi}(v_0, v_n) \preceq_\varphi v_i$ for all $0 \leq i \leq n$. (We will only talk about nice chains in contexts where the existence of $\min_{\preceq_\varphi}(v_0, v_n)$ is guaranteed a priori. As a side note it is not hard to see that this minimum exists for all hanging chains.)

**Lemma 3.23.** Let $\varphi$ be a formula such that $\preceq_\varphi$ is a total order (for example $\varphi$ is in prenex normal form). Let $x = v_{-m}, \ldots, v_{-1}, y = v_0, v_1, \ldots, v_n = z$ be an entanglement chain without repetitions such that the following hold:

1. $Q_x \neq Q_y = Q_z$.
2. $x \preceq_\varphi v_i$ for all $-m \leq i < n$.
3. The subchain $y = v_0, v_1, \ldots, v_n = z$ is hanging.
4. $x \preceq_\varphi v_i$ for all $-m \leq i \leq 0$, i.e. the subchain $x = v_{-m}, \ldots, v_{-1}, v_0 = y$ is nice.
5. For all $0 \leq k < \ell \leq n$, if the subchain $v_k, \ldots, v_\ell$ is hanging and crossing, then it is also nice.

Then the chain is nice.

**Proof.** Otherwise assume a counterexample with $n$ minimal. Obviously, $n > 0$. If $n = 1$, then we can use the chain to derive either $x \preceq_\varphi z$ or $z \preceq_\varphi x$ by Alternation. In the first case we are done, in the second case we use Transitivity with $x$ to derive $z \preceq_\varphi v_1$ for all $-m \leq i \leq 0$.

Hence in the following we may assume $n > 1$. Let $0 < k < n$ be such, that $v_k \preceq_\varphi v_i$ for all $0 < i < n$, that is the subchains $v_0, \ldots, v_k$ and $v_k, \ldots, v_n$ are hanging. If $Q_{v_k} = Q_z$, then the last premise gives $y \preceq_\varphi v_i$ for all $0 \leq i \leq k$ and $z \preceq_\varphi v_i$ for all $k \leq i \leq n$. The former, together with $x \preceq_\varphi v_0 = y$, gives $x \preceq_\varphi v_i$ for all $0 \leq i \leq k$. Hence, for all $-m \leq i \leq n$ we have $x \preceq_\varphi v_i$ or $z \preceq_\varphi v_i$. Thus the chain again witnesses $x \preceq_\varphi z$ or $z \preceq_\varphi x$, so transitivity also gives $x \preceq_\varphi v_i$ for all $k \leq i \leq n$ or $z \preceq_\varphi v_i$ for all $-m \leq i \leq k$.

So we are left with the case $Q_{v_k} = Q_y = Q_z$. Then the subchain $x = v_{-m}, \ldots, v_k$ satisfies all conditions of this lemma. Minimality of $n$ implies that $x \preceq_\varphi v_i$ for all $-m \leq i \leq k$. Now we set $m' = m + k$, $n' = n - k$, and $v'_i = v_{i+k}$ for all $-m' \leq i \leq n'$. The thus shifted entanglement chain again satisfies all conditions, so minimality of the counterexample implies that the shifted chain is nice. Then so is the original chain. 

**Lemma 3.24.** Let $\varphi$ be a formula such that $\preceq_\varphi$ is a total order. Then every hanging and crossing entanglement chain is nice.

**Proof.** Otherwise assume a counterexample $v_0, \ldots, v_n$ with minimal $n$. The fact that the chain is crossing prohibits $n = 0$. If $n = 1$, the claim follows from Alternation. Hence we assume $n > 1$. Let $0 < k < n$ be such, that $v_k \preceq_\varphi v_i$ for all $0 < i < n$. We have $Q_{v_k} = Q_x$ or $Q_{v_k} = Q_y$, without loss of generality the latter. Then by minimality of the counterexample the shifted entanglement chain with $v_k$ in the middle satisfies all conditions of Lemma 3.23. Hence the claim follows from that lemma.

**Theorem 3.25.** For all $\varphi \in \mathcal{L}$ we have $\text{fotw}(\varphi) \leq \text{tw}(G_\varphi, \text{ad}_\varphi)$.

**Proof.** Without loss of generality, we may assume that $\varphi$ is in prenex normal form: otherwise let $\varphi'$ be a prenex normal form of $\varphi$ such that $\text{ad}_\varphi = \text{ad}_\varphi'$. Such a $\varphi'$ can be obtained by moving quantifiers to the left in $\varphi$ (which is the normal procedure for making a formula prenex) while always choosing a variable with minimal $\text{ad}_\varphi$. Among the prenex normal forms of $\varphi$, this $\varphi'$ is a sensible prenex normal form anyway, in that it does not introduce
unecessary alternation. Observe that $G_\varphi = G_\varphi'$. Now by Lemma 3.20 we have $\text{fotw}(\varphi) = \text{fotw}(\varphi')$ while the choice of $\varphi'$ implies $\text{tw}(G_\varphi, \text{ad}_\varphi) = \text{tw}(G_\varphi', \text{ad}_\varphi')$.

By virtue of Theorem 3.1 it suffices to prove $\text{ew}(G_\varphi, \text{ead}_\varphi) \leq \text{ew}(G_\varphi, \text{ad}_\varphi)$. We show that for all formulae $\varphi$ in prenex normal form, all $k$, and all elimination orderings of $(G_\varphi, \text{ad}_\varphi)$ of width $k$, there is an elimination ordering of $(G_\varphi, \text{ead}_\varphi)$ of width $k$. Let $\varphi = Q_x,x_1 \ldots Q_{x_n}x_n \theta$ where $\theta$ is quantifier free.

For any ordering $y_1, \ldots, y_n$ of $\{x_1, \ldots, x_n\}$, a $\varphi$-fault is a pair $1 \leq i < i' \leq n$ such that $\text{ead}_\varphi(y_i) > \text{ead}_\varphi(y_{i'})$. Let us assume that $\varphi$ and $y_1, \ldots, y_n$ form a counterexample with $\varphi$-faults and $\psi$-faults of equal width, in contradiction to Lemma 3.24. In particular, $\psi$-faults coincide. By construction, $\text{ead}_\varphi$ and $\text{ad}_\varphi$ are due to Reflexivity. As $\psi$ is quantifier free, hence $\psi$-faults and $\varphi$-faults coincide.

For any ordering $y_1, \ldots, y_n$ of $\{x_1, \ldots, x_n\}$, a $\varphi$-fault is a pair $1 \leq i < i' \leq n$ such that $\text{ead}_\varphi(y_i) > \text{ead}_\varphi(y_{i'})$. Let us assume that $\varphi$ and $y_1, \ldots, y_n$ form a counterexample with $\varphi$-faults and $\psi$-faults of equal width, in contradiction to Lemma 3.24. In particular, $\psi$-faults coincide. By construction, $\text{ead}_\varphi$ and $\text{ad}_\varphi$ are due to Reflexivity. As $\psi$ is quantifier free, hence $\psi$-faults and $\varphi$-faults coincide.
Alternation is applicable eventually yields some $u'$ such that $w \preceq \psi u' \preceq \psi u \preceq \psi y_i$ and $Q_w \neq Q_{u'} \neq Q_u \neq Q_{y_i}$. Then $\text{ead}_\psi(w) + 1 = \text{ead}_\psi(y_i) \geq \text{ead}_\psi(w) + 3$, a contradiction. Hence $w \preceq \psi y_i$ is due to Alternation, so there is some corresponding entanglement chain. Prepending it to the one we have yields a chain $w = v_{-m}, \ldots, v_{-1}, v_0 = y_i, v_1, \ldots, v_n = y_{i+1}$. Furthermore this chain satisfies the first three conditions of Lemma 3.23 (with respect to $\psi$). By virtue of Lemma 3.24, the other two conditions are implied. Hence Lemma 3.23 yields $w \preceq \psi y_{i+1}$, so $\text{ead}_\psi(y_{i+1}) \geq \text{ead}_\psi(w) + 1 = \text{ead}_\psi(y_i)$, contradicting $\text{ead}_\psi(y_{i+1}) < \text{ead}_\psi(y_i)$. 

The following example shows that the difference in the opposite direction can be unbounded.

**Example 3.26.** For $n > 0$, recall the formula $\varphi_n$ from Example 3.9. We have seen that $\text{ead}_{\varphi_n}(x_i) = \text{ad}_{\varphi_n}(x_i) = 1 = \text{ead}_{\varphi_n}(z)$ for $i \leq n$, and $\text{ead}_{\varphi_n}(y) = \text{ad}_{\varphi_n}(y) = 2$, whereas $\text{ad}_{\varphi_n}(z) = 3$. Figure 1 shows the formula graph of $\varphi_n$ together with an $\text{ead}_{\varphi_n}$-stratified tree decomposition of width 1 of $\varphi_n$. We actually have $\text{tw}(G_{\varphi_n}, \text{ad}_{\varphi_n}) = 1$. On the other hand, it is easy to see that every $\text{ad}_{\varphi_n}$-stratified tree decomposition of $\varphi_n$ has a piece $\var{\varphi_n}$ or $\var{\varphi_n} \setminus \{y\}$, and hence $\text{tw}(G_{\varphi_n}, \text{ad}_{\varphi_n}) = n$.

4. Computing stratified tree decompositions

In this section, we show that computing stratified tree decompositions of optimal width is fixed-parameter tractable, where the parameter is the stratified tree-width. In fact, the running time is essentially linear for bounded stratified tree-width. In the next section, we will use the algorithm developed here as a first step for formula evaluation.

**Definition 4.1.** Let $G = (V, E)$ be a graph and $d : V \to \mathbb{N}$. We say that $(G, d)$ is normalized, if for $n := |V|$ we have $V = \{1, \ldots, n\}$ and $d(v) \leq n$ for all $v \in V$.

We obtain a linear time algorithm only for normalized inputs. In the following, let $(G, d)$ with $G = (V, E)$ be normalized. We set $d_{\max} := \max_{v \in V} d(v)$ and for any integer $i$ we let $X_i := \{v \in V \mid d(v) = i\}$. Let $N_G(C)$ denote the set of neighbours of $C$ in $V \setminus C$.

**Definition 4.2.** For $0 \leq i \leq d_{\max}$, let $G^{(i)}$ be the graph with vertex set $V$, such that two vertices $x, y$ form an edge in $G^{(i)}$, if in $G$ there is a path from $x$ to $y$ with all internal vertices in $\bigcup_{j > \max(i, d(x), d(y))} X_j$. 
In particular, every edge of $G$ is present in all $G^{(i)}$ by virtue of a path without any internal vertices. For $G^{(d_{\text{max}})}$, we can use only such paths, so $G^{(d_{\text{max}})} = G$. Observe the similarity of the graphs $G^{(i)}$ to the graphs $G_j$ in the definition of elimination orderings: in both cases the connectivity through some vertices is redirected to hold immediately between those vertices thus connected. The main differences are granularity (the number of graphs is $d_{\text{max}} + 1$, respectively $|V| + 1$) and the fact that in the definition of $G^{(i)}$, no vertices are deleted. Indeed, we have $G^{(i)}[\bigcup_{j \leq i} X_j] = G[\bigcup_{j \leq i} X_j]$. This also explains our interest in the $G^{(i)}$. We are (implicitly) looking for elimination orderings for $G$ which respect $d$. Such elimination orderings keep the $X_i$ intact, so the $G^{(i)}$ will (up to vertex deletion) occur as the $G_j$ at the boundaries between the different $X_i$.

**Definition 4.3.** The component tree of $(G, d)$ is a rooted tree with nodes $t$ labelled by two subsets of $V$, denoted by $C_t$ and $D_t$. For the root $r$, we let $C_r := V$. For a node $t$ at level $i$ (where the root has level 0), we let $D_t := C_t \cap \bigcup_{j \leq i} X_j$. For each (nonempty) connected component $C$ of $G[C_t \setminus D_t]$, node $t$ has a child $t_C$ and we let $C_{t_C} := C \cup N_G(C)$. Further, we let $D^1_t := D_t \cap X_i$ and $D^2_t := D_t \setminus D^1_t$.

**Lemma 4.4.** Let $G$ be a graph and $d: V(G) \rightarrow \mathbb{N}$. Let $t, u$ be nodes of the component tree of $(G, d)$, where $u$ is a child of $t$. Then

1) $D_t \cap D_u = D_{tu} \cap C_u$.
2) Let $(T, B)$ be a $d$-stratified tree decomposition of $G$. Then some piece of $(T, B)$ covers $D_t \cap D_u$.

**Proof.** Let $i$ be the depth of $t$ in the component tree and let $C$ be the connected component of $G[C_t \setminus D_t]$ such that $C_u = C \cup N_G(C)$.

1) It suffices to prove $D_t \cap D_u \supseteq D_{tu} \cap C_u$. If $x \in D_t \cap C_u$, then $x \in D_t \subseteq \bigcup_{0 \leq j \leq i} X_j$ and hence $x \in C_u \cap \bigcup_{0 \leq j \leq i+1} X_j = D_u$.

2) By Fact 2.2, it suffices to show that any pair of distinct vertices $x, y \in D_t \cap D_u$ occurs together in some piece of $(T, B)$. As $x, y \in D_t$, we have $x, y \notin C$, so $x, y \in N_G(C)$. Since $C$ is a connected component, there is a path $P$ from $x$ to $y$ with all internal vertices in $C$. Hence $d(z) > d(x)$ and $d(z) > d(y)$ for all internal vertices $z$ of $P$.

Let $x = x_0, x_1, \ldots, x_n = y$ be the path $P$. If $n = 1$, then $G$ already contains the edge $\{x, y\}$, which hence is covered by $(T, B)$. Otherwise, the set of tree nodes covering vertices from $P \setminus \{x, y\}$ induces a nonempty connected subtree $T'$ in $T$. Let $s$ be the $\leq_T$-minimal node of $T'$ and let $1 < i < n$ be such that $s = x_i$. As $\{x, x_1\}$ is an edge of $G$, the vertex $x$ is covered by some node $t'$ of $T'$. By definition of $s$ and $t_x$, we have $s \leq_T t'$ and $t_x \leq_T t'$. Hence, both $t_x$ and $s$ lie on the unique path from the root of $T$ to $t'$ and thus they are comparable by $\leq_T$. As $t_{x_i} = s <_T t_x$ would contradict $d$-stratifiedness, $t_x \leq_T s \leq_T t'$ follows. Using (TD3), we conclude that $s$ covers $x$. Analogously, $s$ covers $y$, so $x$ and $y$ occur together in $B_s$.

While the component tree is useful for mentally addressing the task of computing a stratified tree decomposition, we cannot afford to actually compute it: its size is superlinear and we want to achieve a linear running time. The algorithm instead works with a modified variant. First, we can do without the $C$-sets, so the algorithm only computes the tree itself and the $D$-sets. This projection is necessary to obtain a linear size, as is the following second modification: in case for some node $t$ at level $i > 0$ we have $D_t \cap X_i = \emptyset$, then we omit the node $t$, making its only child instead a child of the parent of $t$. We term $t$ a *dropped node*. 
Whenever we talk about the level of a node in the modified component tree, we always refer to the level the node had prior to dropping any nodes. As a third modification, for each node $t$, say at level $i$, we store $G^{(i-1)}[D_t]$ alongside $D_t$. For technical reasons which will become clear in the proof of Lemma 4.5, we allow the encodings of these $G^{(i-1)}[D_t]$ to have multiedges. To keep the notation simple, let us fix the convention that $|E|$ for some edge set $E$ with multiedges denotes the sum of multiplicities of edges from $E$.

**Lemma 4.5.** We can compute a modified component tree of a normalized $(G, d)$ in time $O(|V| \cdot \text{tw}(G, d)^2)$.

*Proof. Let $k := \text{tw}(G, d)$. The modified component tree is computed in a bottom-up fashion. For this observe, that the various $C$ used in the definition of the component tree at level $i$ are the connected components of $G[\bigcup_{j \geq i} X_j]$. Hence each $C_t$ for $t$ at level $i$ is $C \cup N_G(C)$ for such a $C$. In order to determine the corresponding $D_t$, we do not need the full graph: it is irrelevant which edges between vertices of $\bigcup_{j \geq i} X_j$ are present; it suffices to know what connectivity these induce on $\bigcup_{j \leq i} X_j$. This information is present in $G^{(i)}$. More precisely, we can transform the defining equality $D_t = (C \cup N_G(C)) \cap \bigcup_{j \leq i} X_j$, where $C$ is some connected component of $G[\bigcup_{j \geq i} X_j]$, into the equality $D_t = D \cup (N_{G[0]}(D) \cap \bigcup_{j < i} X_j)$, where $D$ is the corresponding connected component of $G^{(i)}[X_i]$.

Recall that, as $(G, d)$ is normalized, the vertices of $G$ are $1, \ldots, n$, and $d_{\text{max}} \leq n$, where $n = |V|$. More precisely, we assume that $G$ is given as an array of adjacency lists and that $d$ is given as an array of $d$’s values, where both arrays are indexed with vertices. Using bucket sort, we compute the sets $X_0, \ldots, X_{d_{\text{max}}}$ in time $O(n + d_{\text{max}})$, which is $O(n)$ thanks to $d_{\text{max}} \leq n$.

For the bottom-up run, the algorithm uses a loop $i = d_{\text{max}}, \ldots, 1$. As an invariant, at the beginning of run $i$ it has the following data:

- The graph $G^{(i)}$ (possibly with multiedges).
- An array of lists of subtrees of the modified component tree. Overall, the lists contain all subtrees rooted at level $i + 1$. For all $0 \leq j \leq d_{\text{max}}$, the list at entry $j$ contains the subtrees which, after dropping nodes, end up at level $j$.

For $j > 0$, we also store an element from $D_t \cap X_{j-1}$ alongside each subtree, where $t$ is the root of the subtree.

The graph is initialized to $G^{(d_{\text{max}})} = G$. This can be done in zero time, because $G$ is not needed any more. The array is initialized with empty lists, using time $O(d_{\text{max}})$ and thus $O(n)$. For a single run of the loop, we first do a depth-first search through $G^{(i)}[X_i]$. More precisely, the search is in $G^{(i)}$, it uses all elements from $X_i$ as entry points, and it terminates recursion in elements from other $X_j$. In this way, the connected components $D$ of $G^{(i)}[X_i]$ are found, and we also directly obtain the corresponding $D \cup (N_{G[0]}(D) \cap \bigcup_{j < i} X_j)$, that is some new $D_t$. During the search, we do some more things, which only increase the running time by a constant factor: for each such $D_t$, we generate the tree node $t$ and we label each vertex of $D_t$ with $t$. The label persists only until the next $i$. Also, for each such $t$, while constructing $D_t$, we also compute the sets $D^1_t$ and $D^2_t$, and we start constructing $G^{(i-1)}[D_t]$ by building a graph with vertex set $D_t$ and all edges from $G^{(i)}[D_t]$ incident to (at least one vertex of)
Furthermore, we determine the maximal \( j \), such that \( D^2_i \cap X_j \neq \emptyset \) and we remember some \( x \in D^2_i \cap X_j \). The running time of the search is \( O(|X_i| + |\{e \in E(G^{(i)}) | e \cap X_i \neq \emptyset \}|) \).

The second part, the number (respecting multiplicities) of edges of \( G^{(i)} \) incident with \( X_i \), is bounded by the number of edges of \( G^{(0)} \) incident with \( X_i \). Summing over all \( i \), the total running time of all searches is then \( O(n + |E(G^{(0)})|) \).

Next, we update \( G^{(i)} \) to \( G^{(i-1)} \) by introducing, for each new \( t \), edges between each two vertices from \( D^2_i \). We also do this in the graph stored at node \( t \), which thus becomes \( G^{(i-1)} \) as needed. We do not check whether the edges were already present (because we do not have enough time to do so), hence multiedges may be introduced. The running time is \( O(|D_t| + \ell) \), where \( \ell \) is the number of edges introduced. Summing over all iterations, the first part \( |D_t| \) is bounded in the same way as the running time of the depth-first searches. The second part \( \ell \) is bounded by \( \binom{t}{2} \), where \( k := tw(G, d) + 1 \) as \( D_t \cap \bigcup X_j = D_t \cap D_u \) for the parent \( u \) of \( t \), we can conclude \( |D^2_i| = |D_t \cap \bigcup X_j| \leq k \) from Lemma 4.4. 2. Hence in total, the second part induces a running time of \( O(m \cdot k^2) \), where \( m \) is the size of the tree. As this is the only place, where we add edges to \( G^{(i)} \), we can also bound \( |E(G^{(0)})| \) by \( |E(G)| + m \cdot k^2 \).

We already have all the nodes for level \( i \). We only need to connect them to the nodes of level \( i + 1 \) (in case \( i < d_{\text{max}} \)). For this, for each tree in the list at the array entry \( i + 1 \), say with root \( u \), we look at its element from \( D_u \cap X_i \), say \( y \), then look at the label of \( y \) generated above (as \( y \in X_i \), we did consider \( y \) in the depth-first search), say \( t \), and make \( u \) a child of \( t \). As this is done at most once for each tree node, the total running time of doing this throughout the loop is linear in the size of the tree. Last, for all new \( t \), we recall \( j \) and \( x \) determined above, and we add the tree rooted at \( t \) together with \( x \) to the list at array entry \( j + 1 \).

This concludes the description of the loop. After it has finished, we generate the root node \( r \), set \( D_r := X_0 \) and make all trees in the list at array entry 0 children of \( r \). The total running time of computing the modified component tree is thus \( O(n + |E(G)| + m \cdot k^2) \), where, again, \( m \) is the number of nodes of the modified component tree. For the second term we have \( |E(G)| \leq n \cdot tw(G) \leq n \cdot k \) by Fact 2.1. Now, let us estimate \( m \). Each non-root node \( t \) of the modified component tree is a non-root node of the original component tree, say at level \( i > 0 \), satisfying \( D_t \cap X_i \neq \emptyset \). Hence, there is an element \( x_t \in D_t \cap X_i \). Let \( u \) be the parent of \( t \) in the original component tree. Then \( x_t \) belongs to the connected component \( C \) of \( C_u \setminus D_u \), such that \( C_t = C \cup N_G(C) \). For different \( t \) at level \( i \), the \( x_t \) come from different connected components, so there can be at most \(|X_i| \) such \( t \). In total, \( m \leq n \), so the running time is \( O(n \cdot k^2) \).

Remark 4.6. As a corollary to the previous proof, let us observe that \( G^{(0)} \) is obtained from \( G \) by turning all \( D^2_i \) into cliques.

Theorem 4.7. There is an algorithm that, given a normalized \((G, d)\), computes a \( d \)-stratified tree decomposition of \( G \) of minimum width in time \( O(|V(G)| \cdot 2^{\text{poly}(tw(G, d))}) \).

Proof. Observe that, if \( u \) is a child of \( t \) in the component tree, then \( D_t \cap D_u = D_u^2 \). Then Lemma 4.4 2 and Remark 4.6 imply that \( d \)-stratified tree decompositions of \( G \) coincide with those of \( G^{(0)} \). Hence it suffices to compute a \( d \)-stratified tree decomposition for \( G^{(0)} \) of minimum width. This is achieved in four phases. First, a modified component tree is computed as in Lemma 4.3.
In the second phase, for each node $t$ of the component tree, an optimal tree decomposition of $G^{(0)}[D_t]$ is computed. Observe, that, if $i$ is the level of $t$, then $G^{(0)}[D_t]$ coincides with $G^{(i−1)}[D_t]$, which we have stored at node $t$. Hence, for a single $t$, using Bodlaender’s algorithm [6] (which works well even in the presence of multiedges), the tree decomposition can be obtained in time $\|G^{(i−1)}[D_t]\| \cdot 2^{\text{poly}(k)}$. Observe, that the sum of all $\|G^{(i−1)}[D_t]\|$ is bounded by the encoding size of the modified component tree, which is bounded by the time it took to compute it. Hence, overall this phase takes time $n \cdot 2^{\text{poly}(k)}$.

In the third phase, for each node $t$ of the component tree and each parent or child $u$ of $t$, we determine a node $x_{t,u}$ of the tree decomposition of $G^{(0)}[D_t]$, whose piece fully contains $D_t \cap D_u$. Observe, that $D_t \cap D_u$ coincides with $D_t^2$ or with $D_u^2$, depending on whether $u$ is a parent or a child of $t$. Hence, $D_t \cap D_u$ is a clique in $G^{(0)}$, and then also in $G^{(0)}[D_t]$, so there must be some $x_{t,u}$ as above. We find $x_{t,u}$ by first reading $D_t^2$ respectively $D_u^2$ from the modified component tree, and then checking each element from each piece of the tree decomposition against this set $D_t \cap D_u$, until some adequate $x_{t,u}$ is found. Even without sophisticated search structures, $O(\ell \cdot |D_t \cap D_u| \leq \ell \cdot k)$ time suffices, where $\ell$ is the size of the tree decomposition. Overall, this phase takes time $O(n \cdot k^3)$.

In the fourth phase, we use a bottom-up recursion to construct, for all nodes $t$, an optimal tree decompositions of $G^{(0)}[C_t]$. It will happen to extend the above tree decomposition of $G^{(0)}[D_t]$. The recursion works as follows: we cycle through the children of $t$. By virtue of bottom-up-ness, for each such child $u$, we already know an optimal tree decomposition of $G^{(0)}[C_u]$. As it contains the known decomposition of $G^{(0)}[D_u]$, it also contains the node $x_{u,t}$. Hence we connect it to the known decomposition of $G^{(0)}[D_t]$ by adding an edge between $x_{u,t}$ and $x_{t,u}$. The result still is a tree decomposition, because the intersection $D_t \cap D_u$ separates $D_t$ from $C_u$ (Lemma 4.4 1). It is an optimal tree decomposition, because its width is the maximum of the widths of the participating tree decompositions, which were optimal for their respective subgraphs. In the end, the recursion yields an optimal tree decomposition $(T, B)$ of $G^{(0)}[C_t] = G^{(0)}$. It takes time $O(m)$.

Last, pick some node $s$ from the tree decomposition of $G^{(0)}[D_t]$. As $B_s \subseteq D_r \subseteq X_0$, choosing $s$ as the root of $(T, B)$ makes it $d$-stratified. This concludes the proof of Theorem 4.7. □

As each $(G, d)$ can be normalized in time $O(n \log n)$, a similar statement holds for arbitrary $(G, d)$, albeit not with linear running time. Theorem 4.7 implies that we can efficiently decide whether a formula $\varphi$ satisfies $\text{fotw}(\varphi) \leq k$:

**Corollary 4.8.** There is an algorithm that, given a formula $\varphi \in \mathcal{L}$, computes a tree decomposition of $\varphi$ of minimum width in time $\text{poly}(\|\varphi\| + \text{var}(\varphi)) \cdot 2^{\text{poly}(\text{fotw}(\varphi))}$.

**Proof.** Given $\varphi$, it is first turned into a straight formula. Then, $G_\varphi$ and $\text{ead}_\varphi$ are computed and normalized in polynomial time. The last step is a call to the algorithm from Theorem 4.7. □

5. Query Evaluation on Bounded First Order Tree-Width

This section contains the second main result: evaluating formulae of bounded tree-width is fixed parameter tractable with parameter the length of the formula. Moreover, we show that evaluating quantified constraint formulae of bounded first order tree-width can be done in polynomial time. This is stronger than Chen and Dalmau’s result [29] for quantified
constraint formulae of bounded elimination-width: as we will see in Section 6, bounded elimination-width (i.e. bounded tree-width in [9]) implies bounded first order tree-width, but there are classes of quantified constraint formulae with unbounded elimination-width, that have bounded first order tree-width.

**Definition 5.1.** Let \( k \geq 0 \) be an integer. The fragment \( \mathcal{L}^k \) of \( \mathcal{L} \) consists of those (not necessarily straight) formulae \( \varphi \) such that \( |\text{var}(\varphi)| \leq k \). In contrast, let \( \tilde{\mathcal{L}}^k \) be the fragment of formulae \( \varphi \) of \( \mathcal{L} \) such that all subformulae of \( \varphi \) have at most \( k \) free variables.

**Remark 5.2.** Obviously, \( \mathcal{L}^k \subseteq \tilde{\mathcal{L}}^k \). On the other hand, formulae from \( \tilde{\mathcal{L}}^k \) can be turned into equivalent formulae from \( \mathcal{L}^k \) by renaming bound variables. The algorithm runs in polynomial time, and in linear time for fixed \( k \).

By Remark 5.2, we can use \( \mathcal{L}^k \) and \( \tilde{\mathcal{L}}^k \) interchangeably. It will be more convenient to work with the latter.

**Remark 5.3.** For all \( k \), the question whether a given formula is equivalent to an \( \mathcal{L}^k \) formula is undecidable. The statement is folklore, but we provide a proof for completeness’ sake.

**Proof.** We reduce from satisfiability of \( \mathcal{L} \). By introducing a new unary predicate \( U \) and relativizing all quantifiers to \( U \), satisfiability reduces to the question, whether a given formula from \( \mathcal{L} \) is satisfiable by an infinite structure. By the theorem of Löwenheim and Skolem, this in turn is equivalent to satisfiability by a countable infinite structure. Now let \( \varphi \) be some fixed formula such that \( \varphi \) does not have finite models, and such that \( \varphi \) is not equivalent to any \( \mathcal{L}^k \)-formula. Then a given formula \( \psi \) is unsatisfiable by infinite structures, if and only if \( \varphi \land \psi' \) is equivalent to an \( \mathcal{L}^k \) formula, where \( \psi' \) is obtained from \( \psi \) by renaming all symbols (constant symbols, relation symbols, and free variables) to be disjoint from all symbols of \( \varphi \). For the ‘only if’ part, unsatisfiability by infinite structures of \( \psi \) implies the same for \( \psi' \). Then, \( \varphi \land \psi' \) is unsatisfiable and hence equivalent to \( P_c \land \neg P_c \) from \( \mathcal{L}^0 \). For the ‘if’ part, assume that \( \psi \) is satisfiable and that \( \varphi \land \psi' \) is equivalent to \( \chi \in \mathcal{L}^k \). We obtain \( \chi' \) from \( \chi \) by renaming all symbols which do not occur in \( \varphi \) to be disjoint from all symbols of \( \psi' \). By choice of \( \chi \) we have \( \chi \models \varphi \) and then \( \chi' \models \varphi \). The converse would contradict that \( \varphi \) is not equivalent to any \( \mathcal{L}^k \)-formula, so there is some interpretation \( \mathcal{I}_0 \) such that \( \mathcal{I}_0 \models \varphi \land \neg \chi' \). As \( \varphi \) does not have any finite models, the domain of \( \mathcal{I}_0 \) is infinite, and by Löwenheim-Skolem we can assume without loss of generality that it is countable. On the other hand, satisfiability of \( \psi \) implies that of \( \psi' \), say by an interpretation \( \mathcal{I}_2 \) with countable infinite domain. By virtue of all the renaming done above, \( \mathcal{I}_1 \) and \( \mathcal{I}_2 \) do not have any symbols in common. Furthermore, their domains are of the same cardinality. Hence there is an interpretation \( \mathcal{I} \) which extends both (up to isomorphisms), that is we have \( \mathcal{I} \models \varphi \land \psi' \) but \( \mathcal{I} \not\models \chi \), a contradiction to the assumed equivalence.

As a consequence, there is no computable width parameter such that width-\( k \) captures all formulae logically equivalent to a formula of \( \mathcal{L}^k \). For any width parameter, only formulae which are ‘syntactically close’ to a formula of \( \mathcal{L}^k \) are captured, for varying values of ‘syntactically close’.

The following example shows that first order tree-width indeed does not capture equivalence to \( \mathcal{L}^2 \).

**Example 5.4.** Let \( n > 2 \). \( \varphi_n = \psi_n \lor \chi \), where \( \chi \in \mathcal{L}^2 \) and \( \text{fotw}(\psi_n) = n \), but \( \psi_n \) is unsatisfiable. Then \( \varphi_n \equiv \chi \in \mathcal{L}^2 \), but \( \text{fotw}(\varphi_n) = n \).
First order sentences of tree-width at most \( k - 1 \) have the same expressive power as \( \tilde{L}^k \) (and by Remark 5.2 hence as \( L^k \)). More generally we have the following.

**Theorem 5.5.** Let \( k \geq 0 \).

1. For any formula \( \varphi \) with \( \text{fotw}(\varphi) \leq k - 1 \) there is a formula \( \psi \in \tilde{L}^k \) with \( \varphi \equiv \psi \) which is computable from \( \varphi \).

2. Any formula \( \psi \in \tilde{L}^k \) satisfies \( \text{fotw}(\psi) \leq k - 1 \).

**Proof.** 2. By Theorem 3.25 it suffices to show that \( \text{tw}(G_\psi, \text{ad}_\psi) \leq k - 1 \). Without loss of generality, \( \psi \) is already straight. Let \( T \) be the syntax tree of \( \psi \). For a node \( t \), say \( t \) corresponds to the subformula \( \chi \) of \( \psi \), let \( B_t \) consist of the free variables of \( \chi \). As \( \psi \in \tilde{L}^k \), the width of \((T, B)\) is at most \( k - 1 \). (TD2) holds for \((T, B)\), because edges arise from atoms and atoms are among the subformulae \( \chi \) considered in the definition of \((T, B)\). Then (TD1) follows, because \( \psi \) is straight. (TD3) holds, because for all variables \( x \), the set \( \{ t \in T \mid x \in B_t \} \) union of all paths from (nodes corresponding to) atoms in which \( x \) occurs to (the node corresponding to) the scope of \( x \). It is easy to see that \((T, B)\) is \( \text{ad}_\varphi \)-stratified.

1. Given \( \varphi \), we use the algorithm of Corollary 4.8 to compute an \( \text{ead}_\varphi \)-stratified tree decomposition \((T, B)\) of width \( \text{fotw}(\varphi) \leq k - 1 \) for \( G_\varphi \).

Intuitively, we will iteratively replace subformulae of \( \varphi \) by equivalent \( \tilde{L}^k \)-formulae, until we obtain an \( \tilde{L}^k \) formula \( \psi \) equivalent to \( \varphi \). The replacement is done along a tree decomposition \((T, B)\) of \( \varphi \) of width at most \( k - 1 \). For our purposes it is more convenient only to work in leaves of the decomposition, so in every iteration we restrict the decomposition to the part of the formula that still has to be transformed into an \( \tilde{L}^k \) formula. In doing so, we treat the subformulae \( \varphi' \) of \( \varphi \) already in \( \tilde{L}^k \) as new atoms, defined on the variables \( \text{free}(\varphi') \). For this we make sure that these new atoms are covered in some piece of the remaining part of the tree decomposition.

More precisely, we describe an iterative algorithm. In every iteration, we are given a formula \( \varphi' \) in xenerp normal form, a tree decomposition \((T', B')\) of \( \varphi' \) of width at most \( k - 1 \), and a second order substitution \( S \), substituting relation symbols of \( \varphi' \) by \( \tilde{L}^k \) formulae with the appropriate number of free variables, such that we have \( \varphi'S \equiv \varphi \). We will need to extend the syntax of formulae: we allow any monotone Boolean function as a single Boolean connective. Of course, this extended syntax still allows for negation normal form, and we still assume that all formulae are in this normal form. This syntax extension carries over to the definition of \( \varphi'[X] \) and hence of \( \text{ead}_\varphi \).

We start by letting \( \varphi' \) be some xenerp normal form of \( \varphi \), \( (T', B') = (T, B) \), and \( S = \emptyset \). Now in every step we do the following.

1. If \( \varphi' \) is quantifier free, then \( \text{var}(\varphi') = \text{free}(\varphi) \). As \( |\text{free}(\varphi)| \leq \text{fotw}(\varphi) + 1 \leq k \) (recall, that \( \text{free}(\varphi) \) forms a clique in \( G_\varphi \)), we have \( \varphi' \in \tilde{L}^k \), so the algorithm stops with output \( \varphi'S \). More precisely, \( \varphi'S \) may still use our additional Boolean connectives, but it is trivial to eliminate these without leaving \( \tilde{L}^k \) (but in general making the formula non-straight).

2. Otherwise, if \((T', B')\) has a leaf \( \ell \) with parent \( t \) satisfying \( B_\ell \subseteq B_t \), then we remove \( \ell \) and \( B_\ell \) from \((T', B')\), keeping \( \varphi' \) and \( S \).

3. If neither 1 nor 2 apply, then we choose a variable \( x \in \text{var}(\varphi') \) as in the following claim.

**Claim 1.** There exists a bound variable \( x \in \text{var}(\varphi') \) with \( \text{ead}_{\varphi'}(x) \) maximum, such that \( x \) appears in exactly one piece \( B'_\ell \) of \((T', B')\), and \( \ell \) is a leaf.
Proof. This claim is a variant of Claim \[\text{I} \text{I}\] in the proof of Theorem \[\text{I} \text{I} \text{I}\], and in can be shown in the same way. Instead of smallness of the decomposition, we use the fact that Case 2 does not apply. Thus we obtain a variable \( x \) with \( \text{ead}_{\varphi'}(x) \) maximum and a leaf \( \ell \) such that \( x \) appears only in \( B_\ell \). As Case 1 does not apply, there are bound variables. As \( \text{ead}_{\varphi'}(x) \) is maximum, \( x \) is a bound variable.

Without loss of generality, suppose that \( Q_x = \exists \). Let \( \psi \) be the scope of \( x \) in \( \varphi' \) and let \( V \) be the set of variables quantified in \( \psi \). We partition \( V \) into the subsets \( V_1 \) and \( V_2 \), where \( V_1 \) contains the variables with which \( x \) is entangled in \( \varphi' \). As \( \varphi' \) is xenerp, \( \psi \) is \( \varphi_x' \) preceded by some quantifications of variables from \( V_1 \). By maximality of \( \text{ead}_{\varphi'}(x) \), we have \( Q_y = \exists \) for all \( y \in V_1 \).

Claim 2. No variable \( y \in V_1 \) is quantified in the scope of some variable \( z \in V_2 \).

Proof. Otherwise, \( x \) occurs in \( \varphi'_y \) (because \( x \) and \( y \) are entangled), \( \varphi'_y \) is a subformula of \( \varphi'_z \) (because \( \varphi' \) is xenerp and \( z \leq \varphi' y \)), and \( z \) occurs in \( \varphi'_z \) which is a subformula of \( \varphi'_x \). Hence \( x \) and \( z \) are entangled, contradicting \( z \in V_2 \). Thus the claim holds.

Claim 3. \( x \) is \( \leq_{\varphi'} \)-maximal.

Proof. Otherwise there is some \( y \neq x \) such that \( x \leq_{\varphi'} y \). In the inductive definition of \( \leq_{\varphi'} \), the pair \((x, y)\) is not introduced by Reflexivity. If it is introduced by Transitivity, say with intermediate variable \( z \), we can replace \( y \) by \( z \), so we can eventually assume that \( x \leq_{\varphi'} y \) is due to Alternation. In particular \( Q_x \neq Q_y \). Thus \( \text{ead}_{\varphi'}(y) > \text{ead}_{\varphi'}(x) \), contradicting \( \text{ead}_{\varphi'} \)-maximality of \( x \).

In the same way we can show that there are no \( \leq_{\varphi'} \)-relationships among \( V_1 \).

Let \( \psi' \) be obtained from \( \psi \) by removing all quantifications for variables from \( V_1 \). Letting \( \exists V_1 \) denote the sequence of all these quantifications in arbitrary order, \( \exists V_1 \psi' \) is obtained from \( \psi \) by a sequence of replacements as in Lemma \[\text{I} \text{I} \text{I} \text{I}\] parts 1 and 2. In particular, \( \exists x \psi \) is equivalent to \( \exists x \exists V_1 \psi' \).

As all variables quantified in \( \psi' \) are from \( V_2 \) and their scopes in \( \psi' \) are the same as in \( \psi \), we have that \( x \) does not occur in any quantified subformula of \( \psi' \). Hence \( \psi' \) is a positive Boolean combination of atoms, of negated atoms, and of subformulae in which \( x \) does not occur. By choosing the subformulae in which \( x \) does not occur maximal, \( \psi' \) is a positive Boolean combination of atoms using \( x \), of negated atoms using \( x \), and of maximal subformulae of \( \psi \) in which \( x \) does not occur. We transform this Boolean combination into disjunctive normal form \( \bigvee_{i \in I} \bigwedge_{j \in J_i} L_j \) with literals \( L_j \). Here each \( L_j \) is an atom using \( x \), a negated atom using \( x \), or a maximal subformula of \( \psi' \) in which \( x \) does not occur. Then

\[
\exists x \psi \equiv \exists x \exists V_1 \psi' \equiv \exists x \exists V_1 \bigvee_{i \in I} \bigwedge_{j \in J_i} L_j \equiv \exists V_1 \bigvee_{i \in I} \exists x \bigwedge_{j \in J_i} L_j.
\]

For \( i \in I \) let \( J_i^+ \subseteq J_i \) be the subset of indices \( j \) such that \( x \) does not occur in \( L_j \) and let \( J_i^- = J_i \setminus J_i^+ \). For convenience we let \( J^+ := \bigcup_{i \in I} J_i^+ \) and \( J^- := \bigcup_{i \in I} J_i^- \). Now

\[
\exists x \psi \equiv \exists V_1 \bigvee_{i \in I} \exists x \bigwedge_{j \in J_i} L_j \equiv \exists V_1 \bigvee_{i \in I} \bigwedge_{j \in J_i} L_j \bigwedge \exists x \bigwedge_{j \in J_i^+} L_j.
\]

Let \( j \in J^+ \). As \( (T', B') \) is a tree decomposition of \( \varphi' \), (the atom underlying) \( L_j \) is covered by some piece of \( (T', B') \). Since \( x \) is a variable of \( L_j \) and \( x \) occurs in \( B'_{l'} \) only, \( L_j \) is covered in \( B_{l'} \). Hence for \( i \in I \) and \( \psi_i^x := \exists x \bigwedge_{j \in J_i^+} L_j \) we have \( \var(\psi_i^x) \subseteq B'_{l'} \). Let \( x\tilde{y} \) be an enumeration
of $B'_i$, and for all $i \in I$ let $A^x_i$ be a new relation symbol of arity $|B'_i| - 1 \leq k - 1$. Replace $\exists x \psi$ in $\varphi'$ by $\exists V_1 \psi''$, where

$$\psi'' := \bigvee_{i \in I} \bigwedge_{j \in J^i} (L_j \land A^x_i \bar{y})$$

and let $\varphi''$ be the formula thus obtained from $\varphi'$. Let $S_x$ be the substitution which replaces every $A^x_i \bar{y}$ by $\psi^x_i$, respectively. Clearly, $\varphi' \equiv \varphi'' S_x$, so by setting $S' := S_x S$ we have $\varphi \equiv \varphi' S \equiv \varphi'' S'$. More precisely, in the definition of $\psi''$, we use a single positive Boolean connective (as allowed by the above syntax extension) for the entire disjunctive normal form. This Boolean connective has only one input for each $L_j$ used. In particular, we retain a single quantifier per variable quantified in $\psi$, that is we retain straightness.

We obtain a tree decomposition $(T'', B'')$ for $\varphi''$ by letting $T'' := T'$ and removing $x$ from $B'_i$. This tree decomposition still covers all (edges of $G_{\varphi''}$ created by) atoms of $\varphi''$ which also occur in $\varphi'$, because these do not use $x$. The new atoms $A^x_i \bar{y}$ are covered by $B''_i = B'_i \setminus \{x\}$. This shows (TD2). (TD1) and (TD3) are inherited from $(T', B')$.

In the rest of the proof we show that $(T'', B'')$ is ead$_{\varphi''}$-stratified.

**Claim 4.** Let $y$ be a bound variable and $Z$ a set of bound variables such that $x \neq y$ and $x \notin Z$. Then $y$ occurs in $\varphi''_Z$ if and only if $y$ occurs in $\varphi'_Z$ or $\varphi''_Z$ is a subform of $\varphi'_Z$ but not of any $L_j$ with $j \in J^-$ and $y$ occurs in $\varphi'_Z$.

**Proof.** Observe that $\varphi'_Z$ is generated already by at most two occurrences of variables from $Z$. If one of these occurrences is outside of $\psi$, then $\varphi'_Z$ is disjoint from $\psi$ and $\varphi'_Z$, or $\psi$ and $\varphi'_Z$ are proper subformulæ of $\varphi'_Z$. In either case we have to show that the same variables $y \neq x$ occur in $\varphi'_Z$ as in $\varphi''_Z$. This follows, because in the first case $\varphi'_Z = \varphi''_Z$ whereas in the second case $\varphi''_Z$ is obtained from $\varphi'_Z$ by replacing the subformula $\exists x \psi$ with $\exists V_1 \psi''$. It remains to consider the case where all (generating) occurrences of variables from $Z$ in $\varphi'$ are in $\psi$. Let $j_1, j_2$ be such that the generating occurrences are in $L_{j_1}$ and $L_{j_2}$. If $j_1 = j_2 \in J^-$, then $\varphi''_Z$ is a subform of $L_{j_1}$. Furthermore $\varphi''_Z = \varphi'_Z$, so the same variables $y$ occur in $\varphi''_Z$ as in $\varphi'_Z$ (including the special case of occurrence in the subformula $\varphi'_Z$ of $\varphi'_Z$). This follows because $\varphi''_Z = \psi''$ and $\psi''$ uses the same variables as $\varphi'_Z$. This shows the claim.

For arbitrary variables $y, z$ different from $x$, the two following claims show that $y \preceq_{\varphi'} z$ if and only if $y \preceq_{\varphi''} z$.

**Claim 5.** Let $y, z$ be variables different from $x$. Then $y \preceq_{\varphi'} z$ implies $y \preceq_{\varphi''} z$.

**Proof.** First, consider the following modification of $\preceq_{\varphi'}$. Relax, in the definition of entanglement with respect to $\preceq$ and $\varphi'$, the conditions of the form ‘$v$ occurs in $\varphi'_W$’ by ‘$v$ occurs in $\varphi'_W$’ or in $\varphi''_{W \setminus \{x\}}$, with the convention that no variable occurs in $\varphi'_W$. Let $\preceq$ denote the modified relation. It is clear that $y \preceq_{\varphi'} z$ implies $y \preceq z$. By induction on the definition of $\preceq$ it is easy to see that $x$ also is $\preceq$-maximal.

In order to transform derivations for $\preceq$ into derivations for $\preceq_{\varphi''}$, we start by normalizing them. First, we may assume that no entanglement chain used in any application of Alternation repeats elements. Also, we may assume that Reflexivity and Transitivity are
Claim 6. Let $y, z$ be variables different from $x$. Then $y \preceq_{\varphi''} z$ implies $y \preceq_{\varphi'} z$. 

always applied as early as possible. In particular, at each application of Alternation, the current approximation for $\preceq$ is reflexive and transitive. The third normalization concerns applications of Alternation, say with chain $v_0, \ldots, v_n$ and with $\preceq$ as the current approximation of $\preceq$. Such an application is normalized, if for entanglement, instead of the sets $v_i \preceq$, already the sets $(v_i \preceq) \setminus \{x\}$ suffice (unless $v_i = x$, in which case $(v_i \preceq) = \{x\}$ due to maximality of $x$). Now we claim that this normalization is always possible. We prove the claim by induction on derivations for $\preceq$ which are already in the first two normal forms. Only the Alternation step is nontrivial, so consider an application of Alternation with chain $v_0, \ldots, v_n$ and approximation $\preceq$ for $\preceq$. By the inductive hypothesis, all pairs from $\preceq$ can be derived in a normalized way. If our application of Alternation is not already normalized, then there is some $0 \leq i \leq n$ such that $x \neq v_i \preceq x$. After unfolding Transitivity, we obtain some $w$ such that $v_i \preceq w$ and such that $w \preceq x$ holds due to Alternation (possibly $w = v_i$).

Let $(\preceq') \subseteq (\preceq)$ be the approximation of $\preceq$ pertaining to this application of Alternation. Then there is another chain of entanglements ending with $u, x$, such that $w \preceq' u$ or $x \preceq' u$. Due to the normalizations from the inductive hypothesis, $x$ already occurs in $\varphi''(\{w\}) \setminus \{x\}$ or in $\varphi''(\{u\}) \setminus \{x\}$. As $x$ does not occur in $\varphi''$ at all, the former must be the case. As $w \preceq' u$ would contradict $\preceq$-maximality of $x$, we have $w \preceq' u$. Transitivity gives $v_i \preceq u$. Now consider one of the up to two neighbours of $v_i$ in the entanglement chain, without loss of generality we pick $v_{i+1}$. We distinguish the cases $v_{i+1} = x$ and $v_{i+1} \neq x$. In the first case, we already know that $x$ occurs in $\varphi''(\{u\}) \setminus \{x\}$. From $v_i \preceq u$ and transitivity we conclude $(u \preceq') \setminus \{x\} \subseteq (v_i \preceq) \setminus \{x\}$, so $x$ occurs in $\varphi''(\{v_i\}) \setminus \{x\}$ as needed. Now for the case that $v_{i+1} \neq x$. As $v_{i+1}$ occurs in $\varphi''(\{v_i\})$ or in $\varphi''(\{v_i\})$; it is easy to see that $v_{i+1}$ also occurs in $\varphi''(\{v_i\}) \cup \{u\}$. But as $v_i \preceq u$, this is $\varphi''(\{v_i\})$. In a last normalization step, we also eliminate $x$ from occurrences in entanglement chains in derivations. Hence assume that $v, x, w$ is part of such a chain, again with $\preceq$ as approximation of $\preceq$. As $x$ is $\preceq$-maximal, we have $(x \preceq) = \{x\}$, hence $v$ occurs in $\varphi''(\{x\})$. As $x$ occurs in $\varphi''(\{w\}) \setminus \{x\}$ (recall the previous normalization), we conclude that $\varphi''$ is a subformula of $\varphi''(\{w\}) \setminus \{x\}$. Thus $v$ occurs in $\varphi''(\{w\}) \setminus \{x\}$. Now assume some counterexample $y, z$ to the claim. Then $y \preceq z$. Let $y, z$ be derivation-minimal with respect to normalized derivations for $\preceq$. Then $y \neq z$ because $\varphi''$ is reflexive. Next assume that $y \preceq z$ is due to transitivity, say with intermediate variable $v$. If $v = x$ then $x \preceq z \neq x$ contradicting $\preceq$-maximality of $x$. Thus $v \neq x$, so $y \preceq_{\varphi''} v \preceq_{\varphi''} z$ by minimality of the counterexample. $y \preceq_{\varphi''} z$ follows. Finally for Alternation, let us assume some chain $y = v_0, \ldots, v_n = z$ of entanglements in the sense of $\preceq$, such that $y \preceq v_i$ or $z \preceq v_i$ for all $0 \leq i < n$. As always, denote the approximation of $\preceq$ by $\preceq$. By normalizing of derivations, no $v_i$ equals $x$ and $x$ is not needed for entanglement. From derivation-minimality we conclude $y \preceq_{\varphi''} v_i$ or $z \preceq_{\varphi''} v_i$, and that $(v_i \preceq) \setminus \{x\} \subseteq (v_i \preceq) \setminus \{x\}$ for all $0 \leq i \leq n$. By Claim 4 the occurrence of $v_{i+1}$ in $\varphi''(\{v_i\}) \setminus \{x\}$ or $\varphi''(\{v_i\}) \setminus \{x\}$ implies occurrence of $v_{i+1}$ in $\varphi''(\{v_i\})$. Similarly, $v_i$ occurs in $\varphi''(\{v_i\})$. Thus, the entanglement chain is also such a one in $\varphi''$. Also $y \preceq_{\varphi''} z$ implies $y \preceq_{\varphi''} z$ so we conclude $y \preceq_{\varphi''} z$. 

Now for the converse.
Theorem 5.5

Eventually the first case must trigger and the algorithm stops. This concludes the proof of tree intact and eliminates one variable. As both the tree and the set of variables are finite, the tree decomposition while it leaves the set of variables intact. The third case leaves the treed stratification of \( \phi \). Hence Claim 2. Hence \( z \) and \( u \) thus due to Alternation. Accordingly, let us assume the latter and recall that \( z \) is an original element of the chain, so which case we are done because \( \{u, v\} \). As \( u = t_0, \ldots, t_k \) are entangled, they are comparable by \( \leq \). Furthermore, \( v \) is an original element of the chain, so \( y < v \) or \( z < v \). Without loss of generality let us assume the latter and recall that \( z \neq v \). After unfolding, in the derivation of \( y < v \), some applications of Transitivity, we obtain some \( u \) such that \( z = u, v \) and \( u \neq v \) is due to Alternation. Accordingly, let \( u = t_0, \ldots, t_k \) be a witnessing entanglement chain. If \( v \leq x \), then we can extend this chain by \( x \) to obtain (together with the fact \( u \leq x \)) a witnessing chain for \( u \leq x \), which implies \( z \leq x \) using Transitivity. It remains to consider the case \( v \leq x \). But as \( u, x \) are entangled, they are comparable by \( \leq \), so \( x \leq v \) and thus \( v \in V_1 \) implying \( Q_v = Q_x \) and then \( Q_u \neq Q_x \). As \( u \leq x \) we have \( u \leq v \), so \( x \) and \( u \) are comparable by \( \leq \). \( x \leq u \) would imply \( u \in V_2 \) (since \( Q_u \neq Q_x \)), contradicting Claim 2. Hence \( u \leq x \) so the chain \( t_0, \ldots, t_k \) can be extended by \( x \) to show \( u \leq x \) and then \( z \leq x \).

Hence \( \leq \) and \( \leq \) coincide outside of \( x \). As \( x \) is \( \leq \) maximal, this implies that \( x \) and \( x \) coincide outside of \( x \). Hence \( x \) and \( x \) coincide outside of \( x \). Finally, we turn \( \phi \) into xenerp normal form. It is easy to see that the algorithm terminates: the second case decreases the size of the tree decomposition while it leaves the set of variables intact. The third case leaves the tree intact and eliminates one variable. As both the tree and the set of variables are finite, eventually the first case must trigger and the algorithm stops. This concludes the proof of Theorem 5.5.
It is well-known that first order query evaluation for $L^k$ can be done in time $n^{k+O(1)}$, see [28].

**Corollary 5.6.** Evaluating queries of bounded first order tree-width is fixed parameter tractable with parameter the length of the formula.

More precisely, given a finite structure $A$ and a formula $\varphi \in \mathcal{L}$, there is an algorithm that computes $\varphi(A)$ in time $\|A\|^{\text{fotw}(\varphi)+O(1)} f(|\varphi|)$ for some computable function $f$.

Here the function $f$ is basically the running time we need for translating the formula $\varphi$ with $\text{fotw}(\varphi) \leq k-1$ into an $L^k$ formula. It is $q$-times exponential, where $q$ is the alternation depth of $\varphi$. The exponentiations arise from converting some subformulas into disjunctive or conjunctive normal form. In special cases where this step is not needed, the running time is much lower.

**Corollary 5.7.** Evaluating formulae without disjunctions and of bounded first order tree-width can be done in polynomial time.

**Proof.** Let $\varphi$ be a formula without disjunctions such that $\text{fotw}(\varphi) < k$. Let us recall the algorithm underlying the proof of Theorem 5.5 1. The argument for termination (at the very end of the proof) actually shows that the main loop is iterated only a quadratic number of times. Case 1 of the main loop is only executed once, and it is polynomial in the data then present. Case 2 basically requires a search through the current tree, which is a subtree of the original one. It remains to show that Case 3 runs in polynomial time and to bound the way it increases the size of the data. In fact, all individual steps of Case 3 run in polynomial time even for general $\varphi$, with the exception of turning $\psi'$ into disjunctive normal form. But as our $\varphi$ does not contain any disjunctions, the same holds for $\varphi'$ and $\psi'$, so $\psi'$ already is in disjunctive normal form and there is nothing to do. Formally, the index set $I$ only contains one element and (up to reordering) we have $\psi' = \psi_\land \psi_\lor$, where $\psi_\land := \bigwedge_{j \in J^-} L_j$ and $\psi_\lor := \bigwedge_{j \in J^+} L_j$.

Let us now bound the data increase. The data consist of the tree decomposition (which only becomes smaller), the formula $\varphi'$, and the substitution $S$. It is easier to consider, instead of $\varphi'$ and $S$, the formula $\varphi'S$. The size difference between the two stems only from a collection of pairs $(x,i)$, where $x$ is a variable and $i$ is an index from the respective $I$. As each such $I$ is a singleton, there are at most $|\text{var}(\varphi)|$ such pairs. With respect to $\varphi'S$, all that happens in Case 3 is shifting quantifiers and then replacing $\exists x\forall V_1(\psi_\land \land \exists x\psi_\lor)$ by $\forall V_1(\psi_\land \land \exists x\psi_\lor)$. The size does not change.

Hence the algorithm from Theorem 5.5 1 runs in polynomial time. So does turning the formula from $\tilde{L}^k$ into one from $L^k$. We conclude with the time $n^{k+O(1)}$ for evaluating the latter.

Of course, the same applies to formulae without conjunctions. One example of formulae without disjunctions are quantified constraint formulae, which we define and discuss in detail in Section 6.

The fixed parameter tractability from Corollary 5.6 does not remain when we make the first order tree-width part of the parameter. This is even true for model checking instead of evaluation. Instead, the problem becomes AW[$*]$-hard: fotw is bounded by the length of the formula, and the model checking problem for first order logic, parameterized by the formula length, is AW[$*$]-complete [12].
6. Relation to similar notions

In this section we show that fotw and tree-width coincide on conjunctive queries, while fotw is more powerful than both elimination-width of quantified constraint formulae and strict tree-width of non-recursive stratified datalog programs. Finally, we extend the cops and robber game characterizing tree-width to stratified tree-width and we prove that requiring monotonicity does not limit the cops.

A (Boolean) conjunctive query is a sentence \( \varphi = \exists x_1 \ldots \exists x_n \psi \), where \( \psi \) is a conjunction of relational atoms such that \( \text{var}(\psi) = \{x_1, \ldots, x_n\} \). The tree-width of a conjunctive query \( \varphi \), \( \text{tw}(\varphi) \), is defined as the tree-width of \( G_\varphi \) (see [25]). Any conjunctive query \( \varphi \) satisfies \( \text{ead}_\varphi = 1 \). Hence the notion of fotw generalizes the notion of tree width of conjunctive queries.

**Remark 6.1.** Any conjunctive query \( \varphi \) satisfies \( \text{fotw}(\varphi) = \text{tw}(\varphi) \). \( \square \)

6.1. Quantified constraint formulae. A quantified constraint formula [9] is a sentence

\[ \varphi = Q_1 x_1 Q_2 x_2 \ldots Q_n x_n \psi, \]

where \( Q_i \in \{\forall, \exists\} \) for \( i = 1 \ldots n \) and \( \psi \) is a conjunction of relational atoms. In [9], Chen and Dalmau introduce the notion of tree-width of a quantified constraint formula and they show that model checking for quantified constraint formulae of bounded tree-width can be done in polynomial time using the \( k \)-consistency algorithm. Since their notion of tree-width is defined via an elimination ordering rather than via a decomposition, we call it elimination-width instead of tree-width. We show that fotw is less than or equal to Chen and Dalmau's elimination-width, and we give an example of a class of quantified constraint formulae having bounded fotw and unbounded elimination-width. By Corollary 5.7, model checking of quantified constraint formulae of bounded fotw can also be done in polynomial time.

Recall that by Theorem 3.1, any graph \( G \) and \( d : V(G) \to \mathbb{N} \) satisfies \( \text{tw}(G,d) = \text{ew}(G,d) \). Let \( \varphi \) be a quantified constraint formula with formula graph \( G_\varphi \). Let \( \text{ad}_\varphi \) be the mapping that assigns to a variable \( v \in \text{var}(\varphi) \) the number of quantifier changes occurring before \( v \) in the quantifier prefix of \( \varphi \), adding +1 (note that here we always add +1, regardless of the first quantifier of \( \varphi \)). Then Chen and Dalmau’s notion of elimination-width can be equivalently reformulated in our setting as \( \text{ew}(G_\varphi, \text{ad}_\varphi) \).

**Lemma 6.2.** Let \( \varphi \) be a first order formula. Then \( \text{fotw}(\varphi) \leq \text{ew}(G_\varphi, \text{ad}_\varphi') \).

**Proof.** By Theorem 3.1, we may use \( \text{tw} \) and \( \text{ew} \) interchangeably. Then, by Theorem 3.25, it suffices to show \( \text{tw}(G_\varphi, \text{ad}_\varphi) = \text{tw}(G_\varphi, \text{ad}_\varphi') \). First, assume that \( \varphi \) starts with a quantifier. If this quantifier is existential, then \( \text{ad}_\varphi = \text{ad}_\varphi' \). If it is universal, then \( \text{ad}_\varphi(x) = \text{ad}_\varphi'(x) = 0 \) for all free variables \( x \), and \( \text{ad}_\varphi(x) - 1 = \text{ad}_\varphi'(x) > 0 \) for all bound variables \( x \). In both cases, an elimination ordering respects \( \text{ad}_\varphi \) if, and only if, it respects \( \text{ad}_\varphi' \). Hence \( \text{ew}(G_\varphi, \text{ad}_\varphi) = \text{ew}(G_\varphi, \text{ad}_\varphi') \) and thus \( \text{tw}(G_\varphi, \text{ad}_\varphi) = \text{tw}(G_\varphi, \text{ad}_\varphi') \).

The same holds trivially, when \( \varphi \) is quantifier free.

Now for the general case: \( \varphi \) is a positive boolean combination of formulae \( \varphi_1, \ldots, \varphi_n \) which are quantifier free or start with quantifiers. Let \( F \) be the set of free variables of \( \varphi \). We already know that \( \text{tw}(G_{\varphi_i}, \text{ad}_{\varphi_i}) = \text{tw}(G_{\varphi_i}, \text{ad}_{\varphi_i}') \) for all \( 1 \leq i \leq n \). As the various \( \varphi_i \)
have pairwise distinct bound variables, \( G\phi - F \) is the disjoint union of the \( G\phi_i - F \). Then it is easy to see that
\[
\text{tw}(G\phi, \text{ad}\phi) = \max(|F| - 1, \max_{1 \leq i \leq n} \text{tw}(G\phi_i, \text{ad}\phi_i))
\]
and
\[
\text{tw}(G\phi, \text{ad}'\phi) = \max(|F| - 1, \max_{1 \leq i \leq n} \text{tw}(G\phi_i, \text{ad}'\phi_i)),
\]
from which it follows that \( \text{tw}(G\phi, \text{ad}\phi) = \text{tw}(G\phi, \text{ad}'\phi) \).

Remark 6.3. There exists a class of quantified constraint formulae having first order tree-width 1, where Chen and Dalmau’s elimination-width is unbounded: let the class consist of the \( \phi_n \) as in Example 3.26. Then \( \text{ad}\phi_n = \text{ad}'\phi_n \), and hence \( \text{tw}(G\phi_n, \text{ad}'\phi_n) = \text{ew}(G\phi_n, \text{ad}'\phi_n) = n \), while \( \text{fotw}(\phi_n) = 1 \).

6.2. Non-recursive stratified datalog. In [16], Flum, Frick and Grohe define strict tree-width of non-recursive stratified datalog (NRSO) programs and they show that the evaluation problem for NRSO programs can be solved in polynomial time on programs of bounded strict tree-width [16, Corollary 5.26]. NRSO programs have the same expressive power as \( \mathcal{L} \) and there are simple translations in both directions. This allows us to compare their notion with fotw. We show that if the NRSO program has tree-width at most \( k \), then the corresponding first order formula has fotw at most \( k \), and we exhibit a class of formulae with bounded fotw, whose corresponding NRSO programs have unbounded tree-width.

We assume that the reader is familiar with datalog and we only fix our notation, and we refer the reader to [16] otherwise. A datalog rule \( \rho \) with negation is an expression \( Qx_1 \ldots x_l \leftarrow \bigwedge_{i=1}^n \lambda_i \), where \( Q \) is a relation symbol and \( x_1, \ldots, x_n \in \text{var}\left(\bigwedge_{i=1}^n \lambda_i\right) \) are pairwise distinct variables, and the \( \lambda_i \) are literals \( (i = 1, \ldots, n) \). \( Qx_1 \ldots x_l \) is called the head of \( \rho \), and \( \bigwedge_{i=1}^n \lambda_i \) is called the body of \( \rho \). To define the semantics, let \( A \) be a structure whose vocabulary contains all the relation symbols occurring in the body of \( \rho \). Let \( y \) be a tuple that consists of all variables of \( \text{var}\left(\bigwedge_{i=1}^n \lambda_i\right) \setminus \{x_1, \ldots, x_l\} \), and let \( \varphi(\rho) = \exists y \bigwedge_{1 \leq i \leq n} \lambda_i \).

We let \( \rho(A) := \varphi(\rho)(A) \). A non-recursive stratified datalog (NRSO) program is a sequence \( \Pi = (\Pi_1, \ldots, \Pi_n) \) of non-recursive datalog programs \( \Pi_i \) (called the strata of \( \Pi \)) as defined in [16]. We denote the intentional vocabulary of \( \Pi \) by \( \text{int}(\Pi) \) and the extensional vocabulary of \( \Pi \) by \( \text{ext}(\Pi) \).

The strict tree-width of a datalog rule \( \rho \) is defined as \( \text{stw}(\rho) := \text{tw}(G\phi_\rho) \), and for an NRSO program \( \Pi = (\Pi_1, \ldots, \Pi_n) \) the strict tree-width of \( \Pi \) is defined as \( \text{stw}(\Pi) := \max\{\text{stw}(\rho) \mid \rho \in \bigcup_{i=1}^n \Pi_i\} \).

The following is proved in [16], Corollary 5.26 (2).

Theorem 6.4 (Flum, Frick, Grohe). For fixed integer \( k > 0 \), the evaluation problem for NRSO programs of strict tree-width at most \( k \) can be solved in polynomial time.

---

3In [16], the term strict tree-width refers to the fact that tree decompositions are required to cover all variables in the head of a datalog rule together in some piece.
It is well known that a query is definable in first order logic if and only if it is NRSδ definable. Actually, an NRSδ program $\Pi_Q$ (i.e. an NRSδ program with goal predicate $Q$) defines an equivalent first order formula $\varphi_{\Pi_Q}$ in a natural way, and vice versa. For proving our theorem, we make one direction explicit, associating a first order formula to an NRSδ program as follows.

Let $\Pi = (\Pi^1, \ldots, \Pi^n)$ be an NRSδ program and let $Q \in \text{int}(\Pi^i)$ for some $i \leq n$. Suppose for all $Q' \in \text{int}(\Pi)$ occurring in $(\Pi^1, \ldots, \Pi^{i-1})$, the formula $\varphi_{\Pi_Q'}$ is already defined. Let

$$\bar{\varphi}_{\Pi_Q} := \bigvee_{\rho \in \Pi^i, \text{Q occurs in the head of } \rho} \varphi_{\rho}^i,$$

and let

$$\varphi_{\Pi_Q} := \bigvee_{\rho \in \Pi^i, \text{Q occurs in the head of } \rho} \varphi_{\rho}^{\ast i},$$

where $\varphi_{\rho}^i$ is obtained from $\varphi_{\rho}$ by recursively replacing relation symbols $Q' \in \text{int}(\Pi)$ occurring in $\varphi_{\rho}$ by the corresponding formula $\bar{\varphi}_{\Pi_Q'}$ (i.e. $\varphi_{\Pi_Q}$ is an ext(\Pi)-formula). Let $A$ be an ext(\Pi)-structure. It is easy to see that we have $\Pi_Q(A) = \varphi_{\Pi_Q}(A)$.

Recall that $\text{ad}_{\varphi}$ is the mapping that assigns to a variable $v \in \text{var}(\varphi)$ the alternation depth of $v$ in $\varphi$.

**Theorem 6.5.** Any NRSδ program $\Pi$ with $Q \in \text{int}(\Pi)$ satisfies

$$\text{fotw}(\varphi_{\Pi_Q}) \leq \text{tw}(G_{\varphi_{\Pi_Q}}, \text{ad}_{\varphi_{\Pi_Q}}^{\ast}) \leq \text{stw}(\Pi).$$

**Proof.** The first inequality follows from Theorem 3.1 and Lemma 6.2.

Towards the second inequality, let $\Pi = (\Pi^1, \ldots, \Pi^n)$ and let $k := \text{stw}(\Pi) = \max\{|\text{stw}(\varphi_{\rho})| \mid \rho \in \bigcup_{i=1}^n \Pi_i\}$. We prove by induction on the number $n$ of strata of $\Pi$ that all $Q \in \text{int}(\Pi)$ satisfy $\text{tw}(G_{\varphi_{\Pi_Q}}, \text{ad}_{\varphi_{\Pi_Q}}^{\ast}) \leq k$. Let $Q\bar{x}$ be the head corresponding to $Q$ and let $i$ be such that $Q \in \text{int}(\Pi^i)$. Then $\varphi_{\Pi_Q}$ has exactly the free variables $\bar{x}$ and we have

$$\varphi_{\Pi_Q} = \bigvee_{\rho \in \Pi^i, \text{Q occurs in the head of } \rho} \varphi_{\rho}^{\ast i}.$$ 

Suppose all $Q' \in \text{int}(\Pi)$ occurring in $(\Pi^1, \ldots, \Pi^{i-1})$ satisfy $\text{tw}(\text{ad}_{\varphi_{\Pi_Q'}}^{\ast}, G_{\varphi_{\Pi_Q'}}) \leq k$.

We may assume that $\varphi_{\Pi_Q}$ and $\varphi_{\Pi_Q}$ are straight.

First we construct a tree decomposition for $\varphi_{\Pi_Q}$ as follows. For every $\rho \in \Pi^i$ with head $Q\bar{x}$, we take a tree decomposition of width at most $k$ of $G_{\varphi_{\rho}}$. Each of these decompositions has a piece containing the variables $\bar{x}$. We glue them together at one new root covering the variables $\bar{x}$. Then we orient the edges of the decomposition tree away from the root, and we obtain a tree decomposition $(T, B)$ for $\varphi_{\Pi_Q}$ of width at most $k$. By the inductive hypothesis, for every $Q' \in \text{int}(\Pi)$ such that $Q'\bar{y}$ occurs in $\varphi_{\Pi_Q}$, we have an $\text{ad}_{\varphi_{\Pi_Q'}}^{\ast}$-stratified tree decomposition $(T_{Q'}, B_{Q'})$ of $\varphi_{\Pi_Q'}(\bar{y})$. By definition, the variables in $\bar{y}$ are contained in the piece at the root $r$ of $T_{Q'}$. Moreover, $\bar{y}$ is covered in some piece of $(T, B)$. We choose such a piece $B_t$ and we attach $(T_{Q'}, B_{Q'})$ to this piece such that $r$ becomes a new successor of $t$. Having done this for all atoms $Q'\bar{y}$ (with $Q \neq Q'$), that occur in $\varphi_{\Pi_Q}$, we obtain a tree decomposition $(T, B)$ for $G_{\varphi_{\Pi_Q}}$ of width at most $k$. We may assume that $\varphi_{\Pi_Q}$ is in negation normal form. (If not, we transform $\varphi_{\Pi_Q}$ into negation normal form. Note that this does not change the formula graph.) Then, by construction, $(T, B)$ is $\text{ad}_{\varphi_{\Pi_Q}}^{\ast}$-stratified. \qed
The following remark shows that the difference can be unbounded in the opposite direction. Moreover, it shows that the difference between Chen and Dalmau’s elimination-width and tree-width of NRSD programs can be unbounded.

**Remark 6.6.** There is a class $C$ of NRSD programs with unbounded strict tree-width, such that $\text{fotw}(\varphi_{\Pi}) = \text{tw}(G_{\varphi_{\Pi}}, \text{ad}_{\varphi_{\Pi}}') = 0$ for all $\Pi \in C$.

**Proof.** For an integer $n > 0$ let $\psi_n := \exists x_1 \ldots \exists x_{n-1} \forall x_n (\bigwedge_{i=1}^n P x_i)$. Take $C$ to consist of the natural NRSD programs which are equivalent to the formulae $\psi_n$, for $n > 0$.

6.3. **Cops, Robbers and stratified tree-width.** We now introduce the cops and robbers game as defined in [27]. Let $G$ be a graph and let $k \geq 0$ be an integer. The cops and robbers game on $G$ (with game parameter $k$) is played by two players, the *cop player* and the *robber player*, on the graph $G$. The cop player controls $k$ cops and the robber player controls the robber. Both the cops and the robber move on the vertices of $G$. Some of the cops move to at most $k$ vertices and the robber stands on a vertex $r$ not occupied by the cops. In each move, some of the cops fly in helicopters to at most $k$ new vertices. During the flight, the robber sees which position the cops are approaching and before they land she quickly tries to escape by running arbitrarily fast along paths of $G$. Some of the cops fly in helicopters to escape the positions and the robber stands on a vertex $r$ not occupied by the cops. In each move, some of the cops fly in helicopters to at most $k$ new vertices. During the flight, the robber sees which position the cops are approaching and before they land she quickly tries to escape by running arbitrarily fast along paths of $G$ to a vertex $r'$, not being allowed to run through a standing cop. Hence, if $X \subseteq V(G)$ is the cops’ first position, the robber stands on $r \in V(G) \setminus X$, and after the flight, the cops occupy the set $Y \subseteq V(G)$, then the robber can run to any vertex $r'$ within the connected component of $G \setminus (X \cap Y)$ containing $r$. The cops win if they land a cop via helicopter on the vertex occupied by the robber. The robber wins if she can always elude capture. *Winning strategies* are defined in the usual way. The *cop-width* of $G$, $\text{cw}(G)$, is the minimum number of cops having a winning strategy on $G$.

A winning strategy for the cops is *monotone*, if for all plays played according to the strategy, if $X_1, X_2, \ldots$ is the sequence of cop positions, then the connected components $R_i$ of $G \setminus X_i$ containing the robber form a decreasing (with respect to $\subseteq$) sequence. The $R_i$ are called the *robber spaces*. The *monotone cop-width* of $G$, $\text{mon-cw}(G)$, is the minimum number of cops having a monotone winning strategy on $G$.

**Theorem 6.7** (Seymour, Thomas [27]). Any graph $G$ satisfies $\text{tw}(G) + 1 = \text{cw}(G) = \text{mon-cw}(G)$.  

Now let $G$ be a graph and let $d$ be a function $d: V(G) \rightarrow \mathbb{N}$. The *$d$-stratified* cops and robbers game on $G$ is played as the cops and robbers game on $G$, but in every move the cops have to satisfy the following additional condition. Intuitively, they can only clear vertices $v$ with $d(v) = i$ after they have cleared all vertices $w$ with $d(w) < i$. More precisely: for every move $(X, R)$, where $X \subseteq V(G)$ is the cop position and $R$ is the robber space, the cops have to make sure that $\max\{d(x) \mid x \in X\} \leq \min\{d(r) \mid r \in R\}$. Then $\text{cw}(G, d)$ and $\text{mon-cw}(G, d)$ are defined analogously, and for a formula $\varphi$ we let $\text{cw}(\varphi) := \text{cw}(G_{\varphi}, \text{ead}_{\varphi})$ and $\text{mon-cw}(\varphi) := \text{mon-cw}(G_{\varphi}, \text{ead}_{\varphi})$.

Although proving the following theorem is not very hard, it seems interesting to know that $\text{cw}(G, d)$ and $\text{mon-cw}(G, d)$ coincide. In many generalisations of the cops and robbers game to other settings, the analogous statements become false [1] [3] [26], and it might be helpful to explore the borderline.
Theorem 6.8. Let $G$ be a graph and $d : V(G) \to \mathbb{N}$. The following statements are equivalent:

1. $\text{tw}(G, d) \leq k - 1$,
2. $\text{mon-cw}(G, d) \leq k$, and
3. $\text{cw}(G, d) \leq k$.

In particular, any first order formula $\varphi$ satisfies $\text{fotw}(\varphi) + 1 = \text{mon-cw}(\varphi) = \text{cw}(\varphi)$.

Proof. $1 \Rightarrow 2$: suppose $\text{tw}(G, d) \leq k - 1$. Let $(T, B)$ be a $d$-stratified tree decomposition of width at most $k - 1$ for $G$. From $(T, B)$, the $k$ cops can read off a monotone winning strategy in the usual way, first moving to $B_r$ and then following the robber down the tree decomposition into the unique direction where the robber space is covered (see e.g. [3]). Since $(T, B)$ is $d$-stratified, the winning strategy is also $d$-stratified.

$2 \Rightarrow 3$: any monotone winning strategy is a winning strategy.

$3 \Rightarrow 1$: suppose $k$ cops have a winning strategy for the $d$-stratified game on $G$.

Claim 1. Let $t, u$ be nodes of $(G, d)$’s component tree, where $u$ is a child of $t$. Let $x, y \in D_t \cap D_u$. If, while playing against the $k$ cops, the robber can move to $x$ and no cop will land on $y$, then the robber can also move to $y$.

Let $i$ be the depth of $t$ in $(G, d)$’s component tree and let $C$ be the connected component of $G[C_t \setminus D_t]$ with $C_u = C \cup N(C)$. As $x, y \in D_t$ we have $x, y \notin C$, and hence $x, y \in N_G(C)$ and there is a path from $x$ to $y$ with all internal vertices in $C$. Hence $d(z) > i \geq d(x)$ and $d(z) > i \geq d(y)$ for all internal vertices of the path. Therefore, as long as the cops play on vertices with $d \geq i$, the path is free and the robber can use it. But the cops can never move to a vertex with $d > i$ before they have cleared $D_t \cap D_u$ completely, so the path from $x$ to $y$ is free whenever the robber can move to $x$.

Recall, from Section 4, that the graph $G^{(0)}$ is obtained from $G$ by adding all edges between any pair of distinct vertices $x, y \in D_t \cap D_u$ for all directed edges $(t, u)$ of the component tree. By the claim, any $d$-stratified winning strategy for $k$ cops on $G$ is also a $d$-stratified winning strategy on $G^{(0)}$. Forgetting $d$, obviously, $k$ cops have a winning strategy on $G^{(0)}$ and hence in particular on $G^{(0)}[D_t]$ for all nodes $t$ of $(G, d)$’s component tree. Thus $\text{cw}(G^{(0)}[D_t]) \leq k$ and by Theorem 6.7 this implies $\text{tw}(G^{(0)}[D_t]) \leq k - 1$. From the tree decompositions of the $G^{(0)}[D_t]$ of width $\leq k$ we can now construct tree decompositions for the $G^{(0)}[C_t]$ of width $\leq k - 1$ in a bottom-up manner as in the proof of Theorem 4.7. For the root $r$ of $(G, d)$’s component tree, we have $G^{(0)} = G^{(0)}[C_r]$ and it is easy to see that the tree decomposition for $G^{(0)}[C_r]$ of width $\leq k$ obtained in this way is $d$-stratified.

7. Conclusion

We introduced a notion of tree-width for first order formulae $\varphi$, $\text{fotw}(\varphi)$, generalising tree-width of conjunctive queries and elimination-width of quantified constraint formulae [9]. Our notion can also be seen as an adjustment of the notion of tree-width of first order formulae as defined in [10] (which only works for conjunctive queries with negation).

We proved that computing fotw is fixed-parameter tractable with parameter fotw (Theorem 4.7). Moreover, we showed that evaluating formulae of $k$-bounded first order tree-width is fixed-parameter tractable, with parameter the length of the formula (Theorem 5.5). This is done by first computing a tree decomposition of width at most $k$ for the
formula, and then translating the formula equivalently into a formula of the $k$-variable fragment $\mathcal{L}^k$ of first order logic. It is well-known that evaluating $\mathcal{L}^k$ formulae can be done in polynomial time. When translating the formula $\varphi$ into an equivalent $\mathcal{L}^k$ formula, we get a non-elementary explosion in the running time.

**Conjecture 7.1.** When translating a formula $\varphi$ satisfying $\text{fotw}(\varphi) \leq k$ into an equivalent $\mathcal{L}^k$ formula, a non-elementary explosion cannot be avoided.

Moreover, it is still unknown whether the explosion can be avoided in parameterized algorithms for evaluating queries of bounded first order tree-width.

We show that first order tree-width can be characterised by other notions such as elimination-width (Theorem 3.1), and the minimum number of cops necessary to catch the robber in the stratified cops and robbers game, as well as the minimum number of cops necessary in the monotone version of the game (Theorem 6.8). Hence our notion is very natural and robust.

Moreover, we showed that fotw is more powerful than the notion of elimination-width of quantified constraint formulae as defined in [9]: for quantified constraint formulae, both bounded elimination-width and bounded fotw allow for model checking in polynomial time. We proved that if $\varphi$ is a quantified constraint formula, then fotw$(\varphi)$ is bounded by the elimination-width of $\varphi$, and there are classes of quantified constraint formulae with bounded fotw and unbounded elimination-width.

Finally, we showed that fotw is more powerful than tree-width of non-recursive stratified datalog (NRSD) programs [16]. NRSD programs have the same expressive power as first order logic, in the sense that NRSD programs correspond to first order formulae and vice versa. We showed that first-order tree-width of (formula versions of) NRSD programs is bounded by the strict tree-width of the programs and that there are classes of first order formulae with bounded fotw, whose corresponding NRSD programs have unbounded strict tree-width.

For conjunctive query evaluation, methods more powerful than bounded tree-width are known. Conjunctive queries of bounded hypertree-width [20], bounded fractional hypertree-width [23] and bounded (hyper)closure tree-width [4] yield even larger tractable classes of instances. For example, conjunctive queries of bounded hypertree-width correspond to the $k$-guarded fragment of first order logic [21], and similar correspondences can be found for the other invariants. Why not generalise these notions to first order formulae? By generalising these notions to first order formulae $\varphi$ in the obvious way, a decomposition of bounded width would not give us an instruction how to translate $\varphi$ into the corresponding guarded fragment of first order logic (transforming subformulae of $\varphi$ into conjunctive normal form as in the proof of Theorem 5.5, 1 does not necessarily yield guarded subformulae).

Nevertheless, generalising these notions to quantified constraint formulae should indeed yield classes with an efficient query evaluation, that are strictly larger than classes of quantified constraint formulae of bounded first order tree-width. It would be interesting to find the largest fragment of first order formulae for which such a generalization is possible.
