Ultrafast heat transport in nanoscale metal multilayers is of great interest in the context of optically induced demagnetization, remagnetization and switching. If the penetration depth of light exceeds the bilayer thickness, layer-specific information is unavailable from optical probes. Femtosecond diffraction experiments provide unique experimental access to heat transport over single digit nanometer distances. Here, we investigate the structural response and the energy flow in the ultrathin double-layer system: gold on ferromagnetic nickel. Even though the excitation pulse is incident from the Au side, we observe a very rapid heating of the Ni lattice, whereas the Au lattice initially remains cold. The subsequent heat transfer from Ni to the Au lattice is found to be two orders of magnitude slower than predicted by the conventional heat equation and much slower than electron–phonon coupling times in Au. We present a simplified model calculation highlighting the relevant thermophysical quantities.
Ultrafast heating and cooling of thin metal films has been studied extensively to elucidate the fundamentals of electron–phonon interactions and heat transport at the nanoscale. The energy flow in metal multilayers following optical excitation attracted particular attention in the context of heat-assisted magnetic recording and all-optical magnetic switching. The role of temperature in optically induced femtosecond demagnetization is intensely discussed, particularly with regard to multipulse switching scenarios. Two- or three-temperature models (TTMs) are often used to fit the experimental observations. The microscopic three-temperature model (M3TM), which uses Elliot–Yafet spin-flip scattering as the main mechanism for ultrafast demagnetization is often contrasted against superdiffusive spin transport. Such electron transport is closely related to ultrafast spin–Seebeck effects, which require a description with independent majority and minority spin temperatures. The heat flow involving electrons, phonons, and spins has been found to play a profound role in ultrafast magnetization dynamics. The description of the observed dynamics in TTM or the M3TM model challenges by ab initio theory which explicitly holds the nonequilibrium distribution responsible for the very fast photoinduced demagnetization.

The presence of multiple subsystems (lattice, electrons, and spins), e.g., in ferromagnetic metals, poses a formidable challenge for experimental studies of their coupling and thermal transport on ultrafast time scales when these subsystems are generally not in equilibrium with each other. Temperature dynamics in metal films are typically monitored using optical probe pulses via time-domain thermoreflectance (TDTR). This technique has been a workhorse of nanoscale thermal transport studies, but experiences significant limitations when applied to ultrathin multilayers with individual layer thicknesses falling below the optical skin depth, which are in the focus of ultrafast magnetism research. Optical probes are generally sensitive to electronic and lattice temperatures, although in some cases the lattice temperature, or the spin temperature, may be deduced. In order to understand the thermal energy flow, it is highly desirable to directly access the temperature of the lattice, which provides the largest contribution to the specific heat. Ultrafast X-ray diffraction is selectively sensitive to the crystal lattice, and material-specific Bragg angles enable measurements of multiple layers even when they are thinner than the optical skin depth and/or buried below opaque capping layers. The lattice constant variations of each layer can be measured with high accuracy, making it possible to determine the amount of deposited heat in metal bilayers that was debated recently. The great promise of ultrafast X-ray diffraction (UXRD) for nanoscale thermal transport measurements and ultrafast lattice dynamics has already been demonstrated in experiments with synchrotron-based sources. However, limited temporal resolution of these experiments (~100 ps) only allowed to study heat transport on a relatively slow (nanosecond) time scale and over distances >100 nm. Ultrafast nanoscale thermal transport research will greatly benefit from femtosecond X-ray sources. While free electron laser facilities are in very high demand, an alternative is offered by laser-based plasma sources of femtosecond X-rays, which lack the coherence and high flux of a free electron laser but are fully adequate for UXRD measurements. As an example, a recent experiment on 6 nm thick Au nanotriangles confirmed the $\tau_{\text{ph}} = 5$ ps electron–phonon excitation time generally accepted for high fluence excitation of Au. For similar fluences ultrafast electron diffraction reported $\tau_{\text{ph}} = 0.75$ to 1 ps for Ni thin films between room temperature and Curie temperature.

In this report, we demonstrate that the use of a femtosecond X-ray probe enables thermal transport measurements over a distance as small as ~5 nm in a Au/Ni bilayer with thickness $d_{\text{Au}} = 5.6$ nm and $d_{\text{Ni}} = 12.4$ nm grown on MgO. By monitoring the dynamics of the lattice constants of Au and Ni, we find that the Ni lattice fully expands within about 2 ps, while the Au lattice initially remains cold even if a significant fraction of the excitation light is absorbed by the electronic subsystem in Au. The Au lattice then heats up slowly, reaching the maximum temperature about 80 ps after the optical excitation. The observed thermal relaxation of the bilayer structure is two orders of magnitude slower than 1 ps predicted by the heat equation and also much slower than the usual electron–phonon equilibration time $\tau_{\text{ph}} = 1–5$ ps (see Table 1). We explain this surprising result in a model (see Fig. 1) based on the careful insight into the physics of transport with Poisson electron fluctuations. For our 5.6 nm thick Au film, the destructive interference of light reflected at the interfaces additionally contributes to the suppressed absorption at 800 nm.

The strains $\varepsilon_{\text{Au,NI}}$ determined via Bragg’s law from UXRD data (Fig. 2b, c) can be converted to lattice temperature changes $\Delta T_{\text{Au,NI}}$ and energy density changes $\rho^Q_{\text{Au,NI}}$ via

$$
\varepsilon_{\text{Au,NI}} = \alpha^\text{df}_{\text{Au,NI}} \Delta T_{\text{Au,NI}} \tag{1}
$$

where $\alpha^\text{df}_{\text{Au,NI}}$ is the thermal expansion coefficient of the Au/Ni bilayer. The thermal expansion coefficient $\alpha^\text{df}_{\text{Au,NI}}$ and thermal conductivity $\kappa_{\text{Au,NI}}$ are tabulated in Table 1. The strains in Au and Ni differ. While the Au lattice expands only slightly, the Ni lattice fully expands within about 2 ps.

| Parameter | Symbol | Value |
|-----------|--------|-------|
| Lattice specific heat | $C_P$ (10^3 Jm^-3 K^-1) | 2.5^4 | 3.8^5 |
| Sommerfeld constant | $\gamma$ (Jm^-3 K^-2) | 67.5^2 | 1074^2 |
| Electron–phonon coupling constant | $g$ (10^6 Wm^-3 K^-1) | 1-4^2 | 36-105^2 |
| e-ph coupling time isolated layers | $\tau_{\text{e-ph}}$ (ps) | 1.7-6.7 | 1-3 |
| Thermal conductivity, $\kappa$ (Wm^-1 K^-1) | | 318^5 | 93^5 |
| Thermal conductivity (lattice) | | 556^5 | 9.6^5 |
| Expansion coefficient with Poisson correction | $\alpha^\text{df}$ (10^-5 K^-1) | 3.16^5 | 2.8^5 |

Light source.
using effective out-of-plane expansion coefficients $\alpha_{\text{Au,Ni}}^\text{uf}$ and specific heats $C_{\text{Au,Ni}}$ which are generally temperature dependent. For our experimental conditions temperature-independent coefficients are good approximations. The effective expansion coefficients $\alpha_{\text{Au,Ni}}^\text{uf}$ take into account the crystalline orientation of the films and the fact that on ultrafast (uf) timescales the film can exclusively expand out-of-plane, since the uniform heating of a large pump-spot region leads to a one-dimensional situation, as in-plane forces on the atoms by the thermal stresses vanish. For details about $\alpha_{\text{Au,Ni}}^\text{uf}$ and a description how heat in electrons and phonons drive the transient stress via macroscopic Grüneisen coefficients see the Methods section.

We now discuss the information that can be directly inferred from the measured transient strains (Fig. 3) in the laser-excited metallic bilayer without any advanced modeling. For convenience, we added two right vertical axes to Fig. 3a, b showing the layer-specific temperature and energy density according to Eqs. (1) and (2). Initially Ni expands, while the Au layer gets compressed by the expansion of the Ni film. Around 3 ps Au shows a pronounced expansion, while the compression wave turns into an expansion wave upon reflection at the surface. Less pronounced signatures of the strain wave are observed in Ni as well. A surprisingly long time of about 80 ps is required to reach the maximum expansion of Au by transport of heat from the adjacent Ni until $T_{\text{Au}} \approx T_{\text{Ni}}$. For times $t > 100$ ps, cooling by heat transfer to the substrate dominates the signal. In Fig. 3c we show the heat energy $\Delta Q_{\text{MgO}}$ flowing through a unit area A into the Ni.
substrate, which we can directly calculate from the measured energy densities via
\[
\Delta Q_{\text{MgO}}(t)/A = -d_{\text{Au}}\Delta \rho_{\text{Au}}^Q(t) - d_{\text{Ni}}\Delta \rho_{\text{Ni}}^Q(t).
\]
(3)

\[
\Delta \rho_{\text{Ni,Au}}^Q(t) = \rho_{\text{Ni}}^Q(t) - \rho_{\text{Ni,Au}}^Q(0)
\]
are the changes of the energy densities \(\rho_{\text{Ni}}^Q\) and \(\rho_{\text{Au}}^Q\) with respect to the initially deposited energy densities. Even when the temperatures are equilibrated at \(t > 100\) ps, \(\rho_{\text{Ni}}^Q\) and \(\rho_{\text{Au}}^Q\) differ strongly because of the different specific heat of Au and Ni. Figure 3c confirms that within the first 20 ps the heat energy \(\Delta Q_{\text{Au}} = d_{\text{Au}}\Delta \rho_{\text{Au}}^Q(t)\) flowing from Ni into Au is similar to the amount \(\Delta Q_{\text{MgO}}\) transported into the substrate. At about 150 ps half of the energy deposited in the film has been transported into the substrate. However, leaking a fraction of the thermal energy to the insulating substrate does not explain why the ultrathin Au layer is not much more rapidly heated via electronic heat transport typical of metals.

**Modeling.** Inspired by the recent studies using TDTR, we set up a modified two-temperature model graphically represented in Fig. 1b to rationalize the slow Au heating observed in Fig. 3a. We first justify this simplified modeling. The high electron conductivity—potentially including ballistic and superdiffusive electrons—rapidly equilibrates the electron systems of Ni and Au. The fact that the Au layer is equally compressed in the first 2 ps irrespective of the excitation wavelengths is an experimental proof of the rapid equilibration of electron temperatures. Otherwise the high electron pressure in Au after 400 nm excitation (cf. Fig. 1c) would counterbalance the compression caused by the Ni expansion. As Ni has a much larger Sommerfeld constant (Table 1) the electronic specific heat \(C_e = \gamma T\) is dominated by Ni and the ratio of energy densities \(\Delta \rho_{\text{Ni}}^Q/\Delta \rho_{\text{Au}}^Q \approx 10\) is large at 1 ps. A significant electronic interface resistance that would prevent a rapid equilibration of electron temperatures in Au and Ni is clearly incompatible with our measurements at 400 nm. If the electrons did not equilibrate much faster than 1 ps and effectively remove the heat deposited in the electron system of Au, we would not observe the same strong compression of the Au lattice, since electronic pressure would instantaneously force the Au to expand. In the diffuse-mismatch model, the electronic interface conductance of metals increases linearly with the temperature and can be calculated from the Sommerfeld constant and the Fermi velocity. Immediately after excitation, the electron temperature reaches several thousand Kelvin, which leads to a rapid equilibration of electron temperatures in Au and Ni.

The only fitting parameters of our model are the initial temperatures of the two thin films, neglecting heat transport to the substrate is

\[
T^f = T^i \frac{d_{\text{Ni}}C_{\text{Ni}}}{d_{\text{Au}}C_{\text{Au}} + d_{\text{Ni}}C_{\text{Ni}}}
\]
(7)

This very simple model (dashed lines of Fig. 4a) for the transient quasi-equilibrium temperatures agrees very well with the data. In particular, the exponential decay of \(T^f\) and the exponential decay of \(T^i\) converge around 80 ps. Deviations at longer times originate mainly from heat transport into the MgO substrate, which is not included in the model (dashed lines).

The only fitting parameters of our model are the initial temperature \(T^i\) and the electron–phonon coupling constant of Au. With our simple model we get the best fit using \(g_{\text{Au}} = 6.5 \times 10^{16} \text{ W m}^{-3} \text{ K}^{-1}\), which is somewhat larger than the range from 1 to 4 \times 10^{16} \text{ W m}^{-3} \text{ K}^{-1}\) reported in the literature. If we disregard electronic heat conduction in Au, the literature value for \(\kappa^p_{\text{Au}}\) in Table 1 would lead to an equilibration of Au and Ni temperature exclusively via phonons three times faster than we observe.

The phonon heat transport is probably much less efficient than this prediction because of additional interface resistances for phonon heat transport and because the mean free path of phonons is on the order of the layer thickness. However, we do not attempt to quantify \(\kappa^p_{\text{Au}}\) and \(g_{\text{Au}}\) here. We only note qualitatively that to conform to the expected values of electron–phonon coupling in Au, the phonon heat conduction must become important in nanoscale multilayers, even though...
normal the heat conduction in metals is dominated by electrons ($k \gg k_F$ see Table 1). Phonon heat transport is not included in our calculations, because in fact the heat diffusion equation is not valid at such small length scales below the phonon mean free path. Similarly, a complex theoretical modeling would be required to simulate the heat transport to the substrate, e.g., by heat transfer from Ni electrons to MgO phonons at the interface. Figure 3c provides a benchmark of the experimentally determined phonon heat transport into the substrate.

Discussion

In summary, the modified TTM model (Eqs. (4) and (5)) captures the essence of heat transport between ultrathin metal films: the electrons in Au and Ni are rapidly equilibrated. This is evidenced by the fact that 400 and 800 nm excitation both initially only heat Ni, regardless of the energy absorbed in Au. For 400 nm excitation we showed an intricate process of shutting heat energy back and forth between the layers: the electrons first rapidly transport energy from Au into Ni ($e-e$ equilibration $<1$ ps) before they transport some of the heat back from the Ni phonons to the Au phonons. Finally, the heat flows back through Ni toward the substrate. Heat transport by phonons can account for a fraction of the Au heating. The energy transported from the Ni phonons via Ni and Au electrons into the Au lattice is throttled by the weak electron–phonon coupling in Au. We believe that our results will have an important impact on ultrafast studies of the spin–Seebeck effect, superdiffusive electron transport as well as optical demagnetization and remagnetization. Precise measurements of the total heat in the system after few picoseconds will help to determine the actually required laser fluence in ultrafast demagnetization studies, which currently diverge by an order of magnitude in the literature. The lattice is not only discussed as the sink of angular momentum in the ultrafast demagnetization: with its dominant heat capacity the lattice constitutes the heat bath which controls the speed of reordering of the spin systems at high fluence. Our detailed account of heat flow in Ni after photo-excitation must influence the interpretation of MOKE data, which were fitted in previous studies by using a value for the specific heat of the Ni phonon system which is a factor of two below the Dulong–Petit value.

We have demonstrated the power of UXRD in probing nanoscale heat transport in an ultrathin metallic bilayer system which is relevant to current magnetic recording developments such as heat-assisted magnetic recording. To understand the all-optical, and helicity-dependent switching in ferrimagnets and two different timescales observed in the demagnetization of transition metals or rare earths, precise calibration of the lattice temperature is crucial. We are convinced that the direct access to the lattice, the layer-specific information for layers thinner than the optical skin depth, the conceptual simplicity of the arguments and the experimental geometry make the paper particularly useful for comparisons to previous and future work on optical manipulation of spins.

Methods

Sample growth and UXRD. Ni/Au stacks with different Ni and Au thicknesses were grown by molecular beam epitaxy onto a MgO(001) substrate at 100°C. The MgO(001) substrates were degassed at 350°C for 10 min. The pressure during growth never exceeded 6 × 10⁻¹⁰ mbar. We measured the layer thicknesses $d_{\text{Au}} = 5.6$ nm and $d_{\text{Ni}} = 12.4$ nm of the investigated sample by X-ray reflectivity. The 24 laser planes of Ni yield a symmetric (111) Bragg reflection (Fig. 2a) at $\theta = 19.29^\circ$ well separated from the asymmetric (200) Ni peak at 25.92° originating from 70 lattice planes. The lattice strains are $\Delta \rho_{\text{Ni}} = -\rho(0\theta)\Delta\alpha(0\theta)$ perpendicular to the sample surface are directly retrieved from the time-resolved Bragg-peak positions $\tau(T)$ (Fig. 2b, c) [45,46]. These UXRD data were recorded at our laser-driven plasma X-ray source at the University of Potsdam, that emits 200 fs X-ray pulses with a photon energy of 8 keV. The sample was excited by p-polarized 400 and 800 nm laser pulses of about 100 fs duration with a pulse energy of 0.3 mJ and a diameter of 1.5 mm (FWHM). Since the angle between the pump pulse and the Bragg-reflecting X-ray probe pulse is fixed in the setup, we take into account the modified angle of incidence of the optical pulse of 44° (51°) with respect to the surface normal for the Ni (Au) reflection to calculate the incident fluence of 9.8 mJ/cm² and an absorbed fluence of 3.2 (9.9) mJ/cm² for our bilayer system using a matrix formalism, which also yields the absorption profiles at 400 and 800 nm excitation shown in Fig. 1c [52]. The above values are for 800 nm excitation, and the 400 nm data in Fig. 3 are scaled up for better comparison of the two different excitation conditions.

Correction of the thermal expansion coefficient. The effective expansion coefficient $\alpha_{\text{eff,Ni}}$ valid for heating a thin epitaxial layer is based on the lattice constants and strains predicted from equilibrium thermal expansion coefficients, corrected according to the Poisson effect [53]. In cubic materials with (100) surface orientation the correction of the thermal expansion coefficients at high temperature is based on the lattice constants

$C_{11} = 23$ for Ni and would be 2.6 for Au. For thin Ni (111) cubic crystal surface, the above equation is still valid if the elastic constants are calculated in the rotated coordinate system, in which the x-axis is [111]. We find that the newly obtained $C_{11}$ and $C_{12}$ coincidently yield the same correction factor of 2.2 for Au (111) as for Ni (100).

Strain waves prove ultrafast electron-equilibration. The pronounced compression and expansion of the Au layer (see Fig. 4a) clearly originates from the laser-induced stress generated in Ni. In order to show that our modified TTM predicting negligible energy density in Au immediately after the excitation can quantitatively explain the signal oscillations, we have used the transient temperatures $T_{\text{loc}}(t)$ from our TTM as input parameters for a full thermo-elastic simulation tool, which are represented as solid lines in Fig. 4a [59]. For convenience, Fig. 4b shows the spatio-temporal strain map from which the solid lines in Fig. 4a are calculated by spatial averaging over the layer for each time delay. Multiple reflections of strain waves at the interfaces are strongly damped by transmission to the substrate.

Macroscopic Grüneisen coefficients. Several recent ultrafast X-ray diffraction and electron diffraction experiments on thin metal films have highlighted two contributions of electrons and phonons to the transient stress $\sigma$, which drives the observed strain waves. A very useful concept uses the macroscopic Grüneisen coefficient $\Gamma^e$ and $\Gamma^p$, which relate the energy densities $\rho_e$ and $\rho_p$ to the stress $\sigma = \Gamma \rho_p$. While in Au the electronic Grüneisen constant $\Gamma^e_a = 1.5$ is about half of its phonon counterpart $\Gamma^p_a = 3.0$, in Ni $\Gamma^e_a = 2.6$ is only slightly different from $\Gamma^p_a = 1.7$ [51]. For our analysis the distinction of the origin of pressure in Ni is not very relevant, since the redistribution of energy from electrons to phonons only increases the...
stress by 15%. In Au the electron pressure is negligible in our bilayer system, since the data that support the findings of this study are available from the corresponding authors on reasonable request.
