Abstract

This paper presents two Markov chain Monte Carlo (MCMC) algorithms for Bayesian inference of probabilistic context-free grammars (PCFGs) from terminal strings, providing an alternative to maximum-likelihood estimation using the Inside-Outside algorithm. We illustrate these methods by estimating a sparse grammar describing the morphology of the Bantu language Sesotho, demonstrating that with suitable priors Bayesian techniques can infer linguistic structure in situations where maximum likelihood methods such as the Inside-Outside algorithm only produce a trivial grammar.

1 Introduction

The standard methods for inferring the parameters of probabilistic models in computational linguistics are based on the principle of maximum-likelihood estimation; for example, the parameters of Probabilistic Context-Free Grammars (PCFGs) are typically estimated from strings of terminals using the Inside-Outside (IO) algorithm, an instance of the Expectation Maximization (EM) procedure (Lari and Young, 1990). However, much recent work in machine learning and statistics has turned away from maximum-likelihood estimation in favor of Bayesian methods, and there is increasing interest in Bayesian methods in computational linguistics as well (Finkel et al., 2006). This paper presents two Markov chain Monte Carlo (MCMC) algorithms for inferring PCFGs and their parses from strings alone. These can be viewed as Bayesian alternatives to the IO algorithm.

The goal of Bayesian inference is to compute a distribution over plausible parameter values. This “posterior” distribution is obtained by combining the likelihood with a “prior” distribution $P(\theta)$ over parameter values $\theta$. In the case of PCFG inference $\theta$ is the vector of rule probabilities, and the prior might assert a preference for a sparse grammar (see below). The posterior probability of each value of $\theta$ is given by Bayes’ rule:

$$P(\theta|D) \propto P(D|\theta)P(\theta).$$  (1)

In principle Equation 1 defines the posterior probability of any value of $\theta$, but computing this may not be tractable analytically or numerically. For this reason a variety of methods have been developed to support approximate Bayesian inference. One of the most popular methods is Markov chain Monte Carlo (MCMC), in which a Markov chain is used to sample from the posterior distribution.

This paper presents two new MCMC algorithms for inferring the posterior distribution over parses and rule probabilities given a corpus of strings. The first algorithm is a component-wise Gibbs sampler which is very similar in spirit to the EM algorithm, drawing parse trees conditioned on the current parameter values and then sampling the parameters conditioned on the current set of parse trees. The second algorithm is a component-wise Hastings sampler that “collapses” the probabilistic model, integrating over the rule probabilities of the PCFG, with the goal of speeding convergence. Both algo-
algorithms use an efficient dynamic programming technique to sample parse trees.

Given their usefulness in other disciplines, we believe that Bayesian methods like these are likely to be of general utility in computational linguistics as well. As a simple illustrative example, we use these methods to infer morphological parses for verbs from Sesotho, a southern Bantu language with agglutinating morphology. Our results illustrate that Bayesian inference using a prior that favors sparsity can produce linguistically reasonable analyses in situations in which EM does not.

The rest of this paper is structured as follows. The next section introduces the background for our paper, summarizing the key ideas behind PCFGs, Bayesian inference, and MCMC. Section 3 introduces our first MCMC algorithm, a Gibbs sampler for PCFGs. Section 4 describes an algorithm for sampling trees from the distribution over trees defined by a PCFG. Section 5 shows how to integrate out the rule weight parameters in a PCFG, allowing us to sample directly from the posterior distribution over parses for a corpus of strings. Finally, Section 6 illustrates these methods in learning Sesotho morphology.

2 Background

2.1 Probabilistic context-free grammars

Let \( G = (T, N, S, R) \) be a Context-Free Grammar in Chomsky normal form with no useless productions, where \( T \) is a finite set of terminal symbols, \( N \) is a finite set of nonterminal symbols (disjoint from \( T \)), \( S \in N \) is a distinguished nonterminal called the start symbol, and \( R \) is a finite set of productions of the form \( A \to BC \) or \( A \to w \), where \( A, B, C \in N \) and \( w \in T \). In what follows we use \( \beta \) as a variable ranging over \( \{N \times N\} \cup T \).

A Probabilistic Context-Free Grammar \((G, \theta)\) is a pair consisting of a context-free grammar \( G \) and a real-valued vector \( \theta \) of length \(|R|\) indexed by productions, where \( \theta_{A \to \beta} \) is the production probability associated with the production \( A \to \beta \in R \). We require that \( \theta_{A \to \beta} \geq 0 \) and that for all nonterminals \( A \in N \), \( \sum_{\beta \in R} \theta_{A \to \beta} = 1 \).

A PCFG \((G, \theta)\) defines a probability distribution over trees \( t \) as follows:

\[
P_G(t|\theta) = \prod_{r \in R} \theta_{r}^{f_{r}(t)}
\]

where \( t \) is generated by \( G \) and \( f_{r}(t) \) is the number of times the production \( r = A \to \beta \in R \) is used in the derivation of \( t \). If \( G \) does not generate \( t \) let \( P_G(t|\theta) = 0 \). The yield \( y(t) \) of a parse tree \( t \) is the sequence of terminals labeling its leaves. The probability of a string \( w \in T^+ \) of terminals is the sum of the probability of all trees with yield \( w \), i.e.:

\[
P_G(w|\theta) = \sum_{t: y(t) = w} P_G(t|\theta).
\]

2.2 Bayesian inference for PCFGs

Given a corpus of strings \( w = (w_1, \ldots, w_n) \), where each \( w_i \) is a string of terminals generated by a known CFG \( G \), we would like to be able to infer the production probabilities \( \theta \) that best describe that corpus. Taking \( w \) to be our data, we can apply Bayes’ rule (Equation 1) to obtain:

\[
P(\theta|w) \propto P_G(w|\theta)P(\theta), \quad \text{where}
\]

\[
P_G(w|\theta) = \sum_{i=1}^{n} P_G(w_i|\theta).
\]

Using \( t \) to denote a sequence of parse trees for \( w \), we can compute the joint posterior distribution over \( t \) and \( \theta \), and then marginalize over \( t \), with \( P(\theta|w) = \sum_{t} P(t, \theta|w) \). The joint posterior distribution on \( t \) and \( \theta \) is given by:

\[
P(t, \theta|w) \propto P(w|t)P(t|\theta)P(\theta)
\]

\[
= \left( \prod_{i=1}^{n} P(w_i|t_i)P(t_i|\theta) \right) P(\theta)
\]

with \( P(w_i|t_i) = 1 \) if \( y(t_i) = w_i \), and 0 otherwise.

2.3 Dirichlet priors

The first step towards computing the posterior distribution is to define a prior on \( \theta \). We take \( P(\theta) \) to be a product of Dirichlet distributions, with one distribution for each non-terminal \( A \in N \). The prior is parameterized by a positive real valued vector \( \alpha \) indexed by productions \( R \), so each production probability \( \theta_{A \to \beta} \) has a corresponding Dirichlet parameter \( \alpha_{A \to \beta} \). Let \( R_A \) be the set of productions in \( R \).
with left-hand side $A$, and let $\theta_A$ and $\alpha_A$ refer to
the component subvectors of $\theta$ and $\alpha$ respectively
indexed by productions in $R_A$. The Dirichlet prior
$P_D(\theta|\alpha)$ is:

$$
P_D(\theta|\alpha) = \prod_{A \in N} P_D(\theta_A|\alpha_A), \quad \text{where}
$$

$$
P_D(\theta_A|\alpha_A) = \frac{1}{C(\alpha_A)} \prod_{r \in R_A} \theta_r^{\alpha_r - 1} \quad \text{and}
$$

$$
C(\alpha_A) = \sum_{r \in R_A} \Gamma(\alpha_r)
$$

where $\Gamma$ is the generalized factorial function and
$C(\alpha)$ is a normalization constant that does not de-
pend on $\theta_A$.

Dirichlet priors are useful because they are con-
jugate to the distribution over trees defined by a
PCFG. This means that the posterior distribution
on $\theta$ given a set of parse trees, $P(\theta|t, \alpha)$, is also a
Dirichlet distribution. Applying Bayes’ rule,

$$
P_G(\theta|t, \alpha) \propto P_G(t|\theta) P_D(\theta|\alpha)
$$

$$
\propto \left( \prod_{r \in R} \theta_r^{f_r(t)} \right) \left( \prod_{r \in R} \theta_r^{\alpha_r - 1} \right)
$$

$$
= \prod_{r \in R} \theta_r^{f_r(t) + \alpha_r - 1}
$$

which is a Dirichlet distribution with parameters
$f(t) + \alpha$, where $f(t)$ is the vector of production
counts in $t$ indexed by $r \in R$. We can thus write:

$$
P_G(\theta|t, \alpha) = P_D(\theta|f(t) + \alpha)
$$

which makes it clear that the production counts com-
bine directly with the parameters of the prior.

2.4 Markov chain Monte Carlo

Having defined a prior on $\theta$, the posterior distribu-
tion over $t$ and $\theta$ is fully determined by a corpus
$w$. Unfortunately, computing the posterior prob-
bility of even a single choice of $t$ and $\theta$ is intractable,
as evaluating the normalizing constant for this dis-
tribution requires summing over all possible parses
for the entire corpus and all sets of production prob-
babilities. Nonetheless, it is possible to define al-
gerithms that sample from this distribution using
Markov chain Monte Carlo (MCMC).

MCMC algorithms construct a Markov chain
whose states $s \in S$ are the objects we wish to sam-
ple. The state space $S$ is typically astronomically
large — in our case, the state space includes all pos-
sible parses of the entire training corpus $w$ — and
the transition probabilities $P(s'|s)$ are specified via a
scheme guaranteed to converge to the desired distribu-
tion $\pi(s)$ (in our case, the posterior distribution).
We “run” the Markov chain (i.e., starting in initial
state $s_0$, sample a state $s_1$ from $P(s'|s_0)$, then
sample state $s_2$ from $P(s'|s_1)$, and so on), with the probability that the Markov chain is in a particular state,
$P(s_i)$, converging to $\pi(s_i)$ as $i \to \infty$.

After the chain has run long enough for it to ap-
proach its stationary distribution, the expectation
$E_\pi[f]$ of any function $f(s)$ of the state $s$ will be
approximated by the average of that function over
the set of sample states produced by the algorithm.
For example, in our case, given samples $(t_i, \theta_i)$ for
$i = 1, \ldots, \ell$ produced by an MCMC algorithm, we
can estimate $\theta$ as

$$
E_\pi[\theta] \approx \frac{1}{\ell} \sum_{i=1}^{\ell} \theta_i
$$

The remainder of this paper presents two MCMC
algorithms for PCFGs. Both algorithms proceed by
setting the initial state of the Markov chain to a guess
for $(t, \theta)$ and then sampling successive states using
a particular transition matrix. The key difference be-
tween the two algorithms is the form of the transition
matrix they assume.

3 A Gibbs sampler for $P(t, \theta|w, \alpha)$

The Gibbs sampler (Geman and Geman, 1984) is
one of the simplest MCMC methods, in which tran-
sitions between states of the Markov chain result
from sampling each component of the state conditioned
on the current value of all other variables. In
our case, this means alternating between sampling
from two distributions:

$$
P(t|\theta, w, \alpha) = \prod_{i=1}^{n} P(t_i|w_i, \theta), \quad \text{and}
$$

$$
P(\theta|t, w, \alpha) = P_D(\theta|f(t) + \alpha)
$$

$$
= \prod_{A \in N} P_D(\theta_A|f_A(t) + \alpha_A).
$$

Thus every two steps we generate a new sample of
$t$ and $\theta$. This alternation between parsing and up-
dating $\theta$ is reminiscent of the EM algorithm, with
the Expectation step replaced by sampling $t$ and the
Maximization step replaced by sampling $\theta$.

The dependencies among variables in a PCFG are
depicted graphically in Figure 1, which makes clear
that the Gibbs sampler is highly parallelizable (just
like the EM algorithm). Specifically, the parses $t_i$
are independent given $\theta$ and so can be sampled in
parallel from the following distribution as described
in the next section.

$$P_G(t_i|w_i, \theta) = \frac{P_G(t_i|\theta)}{P_G(w_i|\theta)}$$

We make use of the fact that the posterior is a
product of independent Dirichlet distributions in or-
der to sample $\theta$ from $P_D(\theta|t, \alpha)$. The produc-
tion probabilities $\theta_A$ for each nonterminal $A \in N$
are sampled from a Dirichlet distribution with parameters
$\alpha_A = f_A(t) + \alpha_A$. There are several methods for
sampling $\theta = (\theta_1, \ldots, \theta_m)$ from a Dirichlet
distribution with parameters $\alpha = (\alpha_1, \ldots, \alpha_m)$, with the
simplest being sampling $x_j$ from a Gamma($\alpha_j$) dis-
tribution for $j = 1, \ldots, m$ and then setting $\theta_j =
\frac{x_j}{\sum_{k=1}^{m} x_k}$ (Gentle, 2003).

4 Efficiently sampling from $P(t|w, \theta)$

This section completes the description of the Gibbs
sampler for $(t, \theta)$ by describing a dynamic program-
ing algorithm for sampling trees from the set of parses
for a string generated by a PCFG. This algorithm
appears fairly widely known: it was de-
scribed by Goodman (1998) and Finkel et al (2006)
and used by Ding et al (2005), and is very simi-
lar to other dynamic programming algorithms for
CFGs, so we only summarize it here. The algo-

Algorithm appears fairly widely known: it was de-
scribed by Goodman (1998) and Finkel et al (2006)
and used by Ding et al (2005), and is very simi-
lar to other dynamic programming algorithms for
CFGs, so we only summarize it here. The algo-

In this section we take $w$ to be a string of terminal
symbols $w = (w_1, \ldots, w_n)$ where each $w_i \in T$, and
define $w_{i,k} = (w_{i+1}, \ldots, w_k)$ (i.e., the sub-
string from $w_{i+1}$ up to $w_k$). Further, let $G_A =
(T, N, A, R)$, i.e., a CFG just like $G$ except that the
start symbol has been replaced with $A$, so, $P_{G_A}(t|\theta)$
is the probability of a tree $t$ whose root node is la-
beled $A$ and $P_{G_A}(w|\theta)$ is the sum of the probabili-
ties of all trees whose root nodes are labeled $A$ with
yield $w$.

The Inside algorithm takes as input a PCFG
$(G, \theta)$ and a string $w = w_0,n$ and constructs a
tale with entries $p_{A,i,k}$ for each $A \in N$ and $0 \leq
i < k \leq n$, where $p_{A,i,k} = P_{G_A}(w_{i,k}|\theta)$, i.e., the
probability of $A$ rewriting to $w_{i,k}$. The table entries
are recursively defined below, and computed by enu-
merating all feasible $i, k$ and $A$ in any order such that
all smaller values of $k - i$ are enumerated before any
larger values.

$$p_{A,k-1,k} = \theta_{A \rightarrow w_k}$$
$$p_{A,i,k} = \sum_{A \rightarrow B \; C \in R} \sum_{i < j < k} \theta_{A \rightarrow B} \; P_{B,i,j} \; P_{C,j,k}$$

for all $A, B, C \in N$ and $0 \leq i < j < k \leq n$. At the
end of the Inside algorithm, $P_G(w|\theta) = p_{S,0,n}$.

The second step of the sampling algorithm uses
the function SAMPLE, which returns a sample from
$P_G(t|w, \theta)$ given the PCFG $(G, \theta)$ and the inside
table $p_{A,i,k}$. SAMPLE takes as arguments a non-
terminal $A \in N$ and a pair of string positions
$0 \leq i < k \leq n$ and returns a tree drawn from
$P_{G_A}(t|w_{i,k}, \theta)$. It functions in a top-down fashion,
selecting the production $A \rightarrow BC$ to expand the $A$,
and then recursively calling itself to expand $B$ and
$C$ respectively.

function SAMPLE(A, i, k):
if k - i = 1 then return TREE(A, w_k)
(j, B, C) = MULTI(A, i, k)
return TREE(A, SAMPLE(B, i, j), SAMPLE(C, j, k))
MULTI is a function that produces samples from a multinomial distribution over the possible “split” positions \(j\) and nonterminal children \(B\) and \(C\), where:

\[
P(j, B, C) = \frac{\theta_{A\rightarrow BC} P_{G_B}(w_{i,j}|\theta) P_{G_C}(w_{j,k}|\theta)}{P_{G_A}(w_{i,k}|\theta)}
\]

5 A Hastings sampler for \(P(t|w, \alpha)\)

The Gibbs sampler described in Section 3 has the disadvantage that each sample of \(\theta\) requires reparsing the training corpus \(w\). In this section, we describe a component-wise Hastings algorithm for sampling directly from \(P(t|w, \alpha)\), marginalizing over the production probabilities \(\theta\). Transitions between states are produced by sampling parses \(t_i\) from \(P(t_i|w_i, t_{-i}, \alpha)\) for each string \(w_i\) in turn, where \(t_{-i} = (t_1, \ldots, t_{i-1}, t_{i+1}, \ldots, t_n)\) is the current set of parses for \(w_{-i} = (w_1, \ldots, w_{i-1}, w_{i+1}, \ldots, w_n)\). Marginalizing over \(\theta\) effectively means that the production probabilities are updated after each sentence is parsed, so it is reasonable to expect that this algorithm will converge faster than the Gibbs sampler described earlier. While the sampler does not explicitly provide samples of \(\theta\), the results outlined in Sections 2.3 and 3 can be used to sample the posterior distribution over \(\theta\) for each sample of \(t\) if required.

Let \(P_D(\theta|\alpha)\) be a Dirichlet product prior, and let \(\Delta\) be the probability simplex for \(\theta\). Then by integrating over the posterior Dirichlet distributions we have:

\[
P(t|\alpha) = \int_\Delta P_G(t|\theta) P_D(\theta|\alpha) d\theta
\]

\[
= \prod_{A \in N} \frac{C(\alpha_A + f_A(t))}{C(\alpha_A)}
\]

(3)

where \(C\) was defined in Equation 2. Because we are marginalizing over \(\theta\), the trees \(t\) become dependent upon one another. Intuitively, this is because \(w_i\) may provide information about \(\theta\) that influences how some other string \(w_j\) should be parsed.

We can use Equation 3 to compute the conditional probability \(P(t_i|t_{-i}, \alpha)\) as follows:

\[
P(t_i|t_{-i}, \alpha) = \frac{P(t|\alpha)}{P(t_{-i}|\alpha)}
\]

Now, if we could sample from

\[
P(t_i|w_i, t_{-i}, \alpha) = \frac{P(w_i|t_i)P(t_i|t_{-i}, \alpha)}{P(w_i|t_{-i}, \alpha)}
\]

we could construct a Gibbs sampler whose states were the parse trees \(t\). Unfortunately, we don’t even know if there is an efficient algorithm for calculating \(P(w_i|t_{-i}, \alpha)\), let alone an efficient sampling algorithm for this distribution.

Fortunately, this difficulty is not fatal. A Hastings sampler for a probability distribution \(\pi(s)\) is an MCMC algorithm that makes use of a proposal distribution \(Q(s'|s)\) from which it draws samples, and uses an acceptance/rejection scheme to define a transition kernel with the desired distribution \(\pi(s)\). Specifically, given the current state \(s\), a sample \(s' \neq s\) drawn from \(Q(s'|s)\) is accepted as the next state with probability

\[
A(s, s') = \min \left\{ 1, \frac{\pi(s')Q(s|s')}{\pi(s)Q(s'|s)} \right\}
\]

and with probability \(1 - A(s, s')\) the proposal is rejected and the next state is the current state \(s\).

We use a component-wise proposal distribution, generating new proposed values for \(t_i\), where \(i\) is chosen at random. Our proposal distribution is the posterior distribution over parse trees generated by the PCFG with grammar \(G\) and production probabilities \(\theta'\), where \(\theta'\) is chosen based on the current \(t_{-i}\) as described below. Each step of our Hastings sampler is as follows. First, we compute \(\theta'\) from \(t_{-i}\) as described below. Then we sample \(t_i'\) from \(P(t_i|w_i, \theta')\) using the algorithm described in Section 4. Finally, we accept the proposal \(t_i'\) given the old parse \(t_i\) for \(w_i\) with probability:

\[
A(t_i, t_i') = \min \left\{ 1, \frac{P(t_i'|w_i, t_{-i}, \alpha)P(t_i|w_i, \theta')}{P(t_i|w_i, t_{-i}, \alpha)P(t_i'|w_i, \theta')} \right\}
\]

The key advantage of the Hastings sampler over the Gibbs sampler here is that because the acceptance probability is a ratio of probabilities, the difficult to
compute $P(w_i|t_{-i}, \alpha)$ is a common factor of both
the numerator and denominator, and hence is not re-
quired. The $P(w_i|t_i)$ term also disappears, being 1
for both the numerator and the denominator since
our proposal distribution can only generate trees for
which $w_i$ is the yield.

All that remains is to specify the production prob-
abilities $\theta'$ of the proposal distribution $P(t_i'|w_i, \theta')$.
While the acceptance rule used in the Hastings
algorithm ensures that it produces samples from
$P(t_i|w_i, t_{-i}, \alpha)$ with any proposal grammar $\theta'$
in which all productions have nonzero probability, the
algorithm is more efficient (i.e., fewer proposals are
rejected) if the proposal distribution is close to the
distribution to be sampled.

Given the observations above about the corre-
spondence between terms in $P(t_i|t_{-i}, \alpha)$ and the
relative frequency of the corresponding productions
in $t_{-i}$, we set $\theta'$ to the expected value $E[\theta|t_{-i}, \alpha]$ of
$\theta$ given $t_{-i}$ and $\alpha$ as follows:

$$\theta'_r = \frac{f_r(t_{-i}) + \alpha_r}{\sum_{r' \in R_A} f_{r'}(t_{-i}) + \alpha_{r'}}$$

6 Inferring sparse grammars

As stated in the introduction, the primary contribu-
tion of this paper is introducing MCMC methods
for Bayesian inference to computational linguistics.
Bayesian inference using MCMC is a technique of
generic utility, much like Expectation-Maximization
and other general inference techniques, and we be-
lieve that it belongs in every computational linguist’s
toolbox alongside these other techniques.

Inferring a PCFG to describe the syntac-
tic structure of a natural language is an obvi-
sous application of grammar inference techniques,
and it is well-known that PCFG inference is
using maximum-likelihood techniques such as the
Inside-Outside (IO) algorithm, a dynamic program-
ing Expectation-Maximization (EM) algorithm for
PCFGs, performs extremely poorly on such tasks.
We have applied the Bayesian MCMC methods
described here to such problems and obtain results
very similar to those produced using IO. We be-
lieve that the primary reason why both IO and the
Bayesian methods perform so poorly on this task
is that simple PCFGs are not accurate models of
English syntactic structure. We know that PCFGs

that represent only major phrasal categories ignore
a wide variety of lexical and syntactic dependen-
cies in natural language. State-of-the-art systems
for unsupervised syntactic structure induction sys-
tem uses models that are very different to these kinds
of PCFGs (Klein and Manning, 2004; Smith and
Eisner, 2006).

Our goal in this section is modest: we aim merely
to provide an illustrative example of Bayesian infer-
ce using MCMC. As Figure 2 shows, when the
Dirichlet prior parameter $\alpha_r$ approaches 0 the prior
probability $P_D(\theta_r|\alpha)$ becomes increasingly concen-
trated around 0. This ability to bias the sampler
toward sparse grammars (i.e., grammars in which
many productions have probabilities close to 0) is
useful when we attempt to identify relevant produc-
tions from a much larger set of possible productions
via parameter estimation.

The Bantu language Sesotho is a richly agglutina-
tive language, in which verbs consist of a sequence
of morphemes, including optional Subject Markers
(SM), Tense (T), Object Markers (OM), Mood (M)
and derivational affixes as well as the obligatory
Verb stem (V), as shown in the following example:

\begin{verbatim}
re -a-di -bon-a
SM T OM V M
“We see them”
\end{verbatim}

\footnote{It is easy to demonstrate that the poor quality of the PCFG
models is the cause of these problems rather than search or other
algorithmic issues. If one initializes either the IO or Bayesian
estimation procedures with treebank parses and then runs the
procedure using the yields alone, the accuracy of the parses uni-
formly decreases while the (posterior) likelihood uniformly in-
creases with each iteration, demonstrating that improving the
(posterior) likelihood of such models does not improve parse
accuracy.}
We used an implementation of the Hastings sampler described in Section 5 to infer morphological parses \( t \) for a corpus \( w \) of 2,283 unsegmented Sesotho verb types extracted from the Sesotho corpus available from CHILDES (MacWhinney and Snow, 1985; Demuth, 1992). We chose this corpus because the words have been morphologically segmented manually, making it possible for us to evaluate the morphological parses produced by our system. We constructed a CFG \( G \) containing the following productions:

\[
\begin{align*}
\text{Word} & \rightarrow V \\
\text{Word} & \rightarrow VM \\
\text{Word} & \rightarrow SM VM \\
\text{Word} & \rightarrow SM TVM \\
\text{Word} & \rightarrow SM T OM VM
\end{align*}
\]

together with productions expanding the terminals \( SM, T, OM, V \) and \( M \) to each of the 16,350 distinct substrings occurring anywhere in the corpus, producing a grammar with 81,755 productions in all. In effect, \( G \) encodes the basic morphological structure of the Sesotho verb (ignoring factors such as derivation morphology and irregular forms), but provides no information about the phonological identity of the morphemes.

Note that \( G \) actually generates a finite language. However, \( G \) parameterizes the probability distribution over the strings it generates in a manner that would be difficult to succinctly characterize except in terms of the productions given above. Moreover, with approximately 20 times more productions than training strings, each string is highly ambiguous and estimation is highly underconstrained, so it provides an excellent test-bed for sparse priors.

We estimated the morphological parses \( t \) in two ways. First, we ran the IO algorithm initialized with a uniform initial estimate \( \theta_0 \) for \( \theta \) to produce an estimate of the MLE \( \hat{\theta} \), and then computed the Viterbi parses \( \hat{t} \) of the training corpus \( w \) with respect to the PCFG \( (G, \hat{\theta}) \). Second, we ran the Hastings sampler initialized with trees sampled from \( (G, \theta_0) \) with several different values for the parameters of the prior. We experimented with a number of techniques for speeding convergence of both the IO and Hastings algorithms, and two of these were particularly effective on this problem. Annealing, i.e., using \( P(t|w)^{1/\tau} \) in place of \( P(t|w) \) where \( \tau \) is a “temperature” parameter starting around 5 and slowly adjusted toward 1, sped the convergence of both algorithms. We ran both algorithms for several thousand iterations over the corpus, and both seemed to converge fairly quickly once \( \tau \) was set to 1. “Jittering” the initial estimate of \( \theta \) used in the IO algorithm also sped its convergence.

The IO algorithm converges to a solution where \( \theta_{\text{Word}} \rightarrow V = 1 \), and every string \( w \in w \) is analysed as a single morpheme \( V \). (In fact, in this grammar \( P(w_i|\theta) \) is the empirical probability of \( w_i \), and it is easy to prove that this \( \theta \) is the MLE).

The samples \( t \) produced by the Hastings algorithm depend on the parameters of the Dirichlet prior. We set \( \alpha_r \) to a single value \( \alpha \) for all productions \( r \). We found that for \( \alpha > 10^{-2} \) the samples produced by the Hastings algorithm were the same trivial analyses as those produced by the IO algorithm, but as \( \alpha \) was reduced below this \( t \) began to exhibit nontrivial structure. We evaluated the quality of the segmentations in the morphological analyses \( t \) in terms of unlabeled precision, recall, f-score and exact match (the fraction of words correctly segmented into morphemes; we ignored morpheme labels because the manual morphological analyses contain many morpheme labels that we did not include in \( G \)). Figure 3 contains a plot of how these quantities vary with \( \alpha \); obtaining an f-score of 0.75 and an exact word match accuracy of 0.54 at \( \alpha = 10^{-5} \) (the corresponding values for the MLE \( \hat{\theta} \) are both 0). Note that we obtained good results as \( \alpha \) was varied over several orders of magnitude, so the actual value of \( \alpha \) is not critical. Thus in this application the ability to prefer sparse grammars enables us to find linguistically meaningful analyses. This ability to find linguistically meaningful structure is relatively rare in our experience with unsupervised PCFG induction.

We also experimented with a version of IO modified to perform Bayesian MAP estimation, where the Maximization step of the IO procedure is replaced with Bayesian inference using a Dirichlet prior, i.e., where the rule probabilities \( \theta_r^{(k)} \) at iteration \( k \) are estimated using:

\[
\theta_r^{(k)} \propto \max(0, \mathbb{E}[f_r|w, \theta_r^{(k-1)}] + \alpha - 1).
\]

Clearly such an approach is very closely related to the Bayesian procedures presented in this article,
and in some circumstances this may be a useful estimator. However, in our experiments with the Sesotho data above we found that for the small values of \( \alpha \) necessary to obtain a sparse solution, the expected rule count \( E[f_r] \) for many rules \( r \) was less than \( 1 - \alpha \). Thus on the next iteration \( \theta_r = 0 \), resulting in there being no parse whatsoever for many of the strings in the training data. Variational Bayesian techniques offer a systematic way of dealing with these problems, but we leave this for further work.

7 Conclusion

This paper has described basic algorithms for performing Bayesian inference over PCFGs given terminal strings. We presented two Markov chain Monte Carlo algorithms (a Gibbs and a Hastings sampling algorithm) for sampling from the posterior distribution over parse trees given a corpus of their yields and a Dirichlet product prior over the production probabilities. As a component of these algorithms we described an efficient dynamic programming algorithm for sampling trees from a PCFG which is useful in its own right. We used these sampling algorithms to infer morphological analyses of Sesotho verbs given their strings (a task on which the standard Maximum Likelihood estimator returns a trivial and linguistically uninteresting solution), achieving 0.75 unlabeled morpheme f-score and 0.54 exact word match accuracy. Thus this is one of the few cases we are aware of in which a PCFG estimation procedure returns linguistically meaningful structure. We attribute this to the ability of the Bayesian prior to prefer sparse grammars.

We expect that these algorithms will be of interest to the computational linguistics community both because a Bayesian approach to PCFG estimation is more flexible than the Maximum Likelihood methods that currently dominate the field (c.f., the use of a prior as a bias towards sparse solutions), and because these techniques provide essential building blocks for more complex models.
