Introduction

Single-nucleotide mutation is the basis of much genetic variation underpinning important agronomic traits in crop plants. Such mutations can result in amino acid substitutions or translation stop codons, which can change the function of the proteins. Therefore, it is desirable to produce novel alleles and improved traits by creating targeted point mutations. Traditional mutagenesis techniques are not targeted and require genome-scale screening, which is time-consuming, labour-intensive and may produce a limited number and type of point mutations. Homologous recombination (HR)-mediated DNA repair of CRISPR/Cas9 is inefficient for genome editing in plants (Li et al., 2013; Mao et al., 2013), and the delivery of DNA repair templates is also challenging, hindering the process of precise genome editing. Therefore, it is necessary to develop an alternative genome editing technology that enables genome-wide and target-specific editing.

Base-editing technology (‘Base editor’) is an emerging gene-targeting modification technology based on the CRISPR system. Base editor is a simple, broadly applicable and efficient technology developed initially by Komor et al. (2016). It does not require the generation of DNA double-strand breaks (DSBs) or DNA templates for efficiently replacing specific bases along the genome. This single-base-editing technique can be applied to achieve specific amino acid changes by precisely changing a single base or create a gene knockout by introducing a premature stop codon. The current base-editing system contains three major components: cytidine deaminase, Cas9 nickase (nCas9) or deactivated Cas9 (dCas9) and uracil glycosylase inhibitor (UGI). The nCas9 and dCas9 are generated by inactivating the enzymatic activity of RuvC or both the RuvC and HNH domains in Cas9 nuclease, which are responsible for cutting two strands of DNA. The nCas9 retains the ability to be programmed with sgRNA and then targets specific DNA sequences to nick one strand at single-stranded (ssDNA) regions. Subsequently, the cytidine (C) of a ssDNA is converted to uracil (U) via cytidine deaminase, and then, the converted uracil (U) is replaced with thymine (T) during DNA repair or replication process. Serial cytidine base editors, BE1, BE2 and BE3, in mammalian cells were subsequently developed (Komor et al., 2016). Several studies then reported successful applications of base-editing systems in plant species including rice, wheat, tomato and maize (Li et al., 2017b; Lu and Zhu, 2017; Ren et al., 2018; Shimatani et al., 2017; Zong et al., 2017). Currently, the most commonly used base-editing system is the third-generation base editor, BE3, which is armed with UGI, which inhibits endogenous base excision activity. The resulting base editor converts a cytidine on the nontarget strand to a thymine and cooperates with the mismatch repair system to complete a C•G conversion to a T•A (Standage-Beier et al., 2015).

Summary

The base-editing technique using CRISPR/nCas9 (Cas9 nickase) or dCas9 (deactivated Cas9) fused with cytidine deaminase is a powerful tool to create point mutations. In this study, a novel G. hirsutum-Base Editor 3 (GhBE3) base-editing system has been developed to create single-base mutations in the allotetraploid genome of cotton (Gossypium hirsutum). A cytidine deaminase sequence (APOBEC) fused with nCas9 and uracil glycosylase inhibitor (UGI) was inserted into our CRISPR/Cas9 plasmid (pRGEB32-GhU6.7). Three target sites were chosen for two target genes, GhCLA and GhPEBP, to test the efficiency and accuracy of GhBE3. The editing efficiency ranged from 26.67 to 57.78% at the three target sites. Targeted deep sequencing revealed that the C→T substitution efficiency within an ‘editing window’, approximately six-nucleotide windows of −17 to −12 bp from the PAM sequence, was up to 18.63% of the total sequences. The 27 most likely off-target sites predicted by CRISPR-P and Cas-OFFinder tools were analysed by targeted deep sequencing, and it was found that rare C→T substitutions (average < 0.1%) were detected in the editing windows of these sites. Furthermore, whole-genome sequencing analyses on two GhCLA-edited and one wild-type plants with about 100× depth showed that no bona fide off-target mutations were detectable from 1500 predicted potential off-target sites across the genome. In addition, the edited bases were inherited to T1 progeny. These results demonstrate that GhBE3 has high specificity and accuracy for the generation of targeted point mutations in allotetraploid cotton.

Keywords: cotton (Gossypium hirsutum), CRISPR/nCas9 (Cas9 nickase), cytidine deaminase (rAPOBEC1), base editing, off-target.
Appendix S1). This novel system has also been applied in several plant species (Hua et al., 2017) and the PCR product was inserted into the binary vector (Upland cotton) is a widely cultivated allotetraploid species (AtDt) valuable for the food and textile industries. Chloroplast development, and its mutant (GhCLA) has an albino phenotype (Mandel et al., 1996). VIGS and CRISPR/Cas9 editing of GhCLA can generate an albino phenotype in young cotton leaves that is similar to the cla1 mutant (Gao et al., 2013; Li et al., 2016; Wang et al., 2018). GhPEBP participates in the multiplex-branch developmental process (Chen et al., 2018), with a significant phenotype and important agronomic value. We developed an efficient and precise base editor system (GhBE3) consisting of a cytidine deaminase domain fused with nCas9 and UGI, for use in allotetraploid cotton, and which exhibits a high base-editing efficiency (up to 57.78%, which is comparable with the efficiency in rice and Arabidopsis) with no detectable off-targets effects.

Experimental procedures

Vector construction

In this study, the vector was modified from the vector pRGEB32-GhU6.7 previously used for cotton genome editing in our laboratory (Wang et al., 2018) and contains a neomycin phosphotransferase (NPTII) selection marker; sgRNA transcription was driven by a cotton U6 promoter (GhU6-7) with very high transcription efficiency. The plasmid pRGEB32-GhU6.7 was digested by BstBI and XbaI to delete the Cas9 and replaced by the base editor unit. We amplified cytidine deaminase (APOBEC), Cas9 nickase (nCas9) and uracil glycosylase inhibitor (UGI) units from template plasmid pCas9-PBE (Zong et al., 2017) and the PCR product was inserted into the binary vector pRGEB32-GhU6.7 using an In-Fusion Cloning Kit, thus generating G. hirsutum-Base Editor 3 (GhBE3) (Figure 1a and Appendix S1).

Since the nCas9 (D10A) gene has a BsaI restriction site, the sgRNA expression cassettes could not be introduced using this restriction site. Therefore, the GhBE3 plasmid was linearized with HpaI and SfiI double digestion, resulting in the deletion of the sgRNA-terminator fragment. The protocol for sgRNA construction is modified from a previous protocol used for pRGEB32-GhU6.7 (Wang et al., 2018). Two targets of GhCLA were designed to be integrated in a single vector, and the RNA-sgRNA unit with HpaI and SfiI double digestions was ligated to the same enzyme digested GhBE3 vector.

Agrobacterium-mediated cotton transformation

The base-editing vector was introduced into Agrobacterium strain GV3101 by electroporation. Elite cotton (Gossypium hirsutum) cultivar Jn668 (Li et al., 2019b) was used as the transformation receptor. Seeds were sterilized and cultured in a chamber without light for 6 days at 30 °C. Hypocotyls were cut into 5–10-mm segments and used as explants for Agrobacterium-mediated transformation following our previous methods (Sun et al., 2018; Wang et al., 2018).

On-target mutation analysis by Sanger sequencing

Genomic DNA was extracted from T0 transgenic and WT cotton plants using a DNAquick Plant System (TIANGEN Biotech, Beijing, China). Specific primers (nCas9 F/R and sgRNA F/R in Table S7) for nCas9 and sgRNA sequence were used to confirm transgenics. The target site was amplified with specific primers (CLA F/R and PEBP F/R in Table S7), and the amplicons were ligated into pGEMT-Easy vector with T4 DNA ligase (Promega, Madison, USA). The PCR products obtained were ligated into the pGEMT-Easy vector with T4 DNA ligase, the product was transformed into an E. coli strain using Top10, and positive clones were used for DNA Sanger sequencing.

On-target mutation analysis by targeted deep sequencing

For transgenic plants, a pair of 6 base combination was designed as the barcode tag for each single plant/sample. Each pair of markers was separately added to the 5' end of the forward and reverse primers for amplifying the target sequence. In total, 14 and 13 barcodes marker were designed for GHCLA and GHPPEBP, respectively (barcode primers of on-target in Table S5). The corresponding barcode primers were used for PCR amplification of independent samples, and the resulting PCR products were mixed in equal amounts and purified using a purification kit (OMEGA, D2500-02). One DNA library was applied to Illumina HiSeq 3000 System for paired-end 150 bp reads.

Raw data from high-throughput sequencing were analysed by using Trimmomatic software (version 0.32, MINLEN:75) (Bolger et al., 2014) to remove low-quality reads. According to specific barcode primers designed for a single strain, high-throughput data of target point mutation detection were sorted into each single strain. The high-throughput sequencing data of the target site detection were also sorted according to the forward and reverse specific primers of each target site. C→T substitution frequency was calculated using customized Perl script.

Off-target mutation analysis by targeted deep sequencing

The flanking 500 bp sequence of most potential off-targets was extracted by Perl script. The target sequences were amplified with barcoded primers (barcode primers of off-target in Table S6) from genomic DNA in each plant. The C→T substitution frequency in the editing window was calculated for each GhBE3-edited plant.
The genomic DNA was extracted from fresh young leaves (TIANGEN, Cat.#DP305-03). To identify potential off-target sites, the BatMis (Tennakoon et al., 2012) and Cas-OFFinder (Bae et al., 2014) algorithms were used to compare the two sgRNA target sites of \( \text{GhCLA} \) against the TM-1 reference genome. The most off-targets with high off-score, with C sites in the editing window, and located protein-coding regions, were identified according to target scores in human and mammalian cells (Hsu et al., 2013). Two base-edited plants (N17, N64) of \( \text{GhCLA} \) and one WT plant were sequenced with 100 X sequencing depth using the Illumina system (HiSeq X Ten). We analysed base-edited plant variations and compared with WT plants and negative plants to filter out background variations and somaclonal variations. The potential off-target site mutations were visualized in WT and nCas9-edited plants by IGV tools to confirm the GhBE3-induced mutations. All the mutations were visualized using the IGV tool (Robinson et al., 2011).

**Results and discussion**

**Detection of transgenes in the T0 plants**

To test the efficiency of the GhBE3 system in allotetraploid cotton, the endogenous \( \text{GhCLA} \) and \( \text{GhPEBP} \) genes were chosen as targets for base editing. In human cells, base editing accrues within an efficient deamination window (editing window): cytidines within approximately a five-nucleotide window of \(-16\) to \(-12\) bp from the PAM sequence (Komor et al., 2016). However, in plant species such as rice, wheat and maize, the C\(\rightarrow\)T conversions have been found to be induced at seven target sites, with an editing window spanning the position \(-16\) to \(-12\) bp from the PAM sequence (Zong et al., 2017). Based on these observations, we designed two sgRNAs (sgRNA1 and sgRNA2) for \( \text{GhCLA} \) and one sgRNA (sgRNA3) for \( \text{GhPEBP} \) (Figure 1a,b and Table S1). Our previous work reported that the cotton endogenous U6 promoter driving a tRNA-sgRNA transcription system (Wang et al., 2018) can enhance CRISPR/Cas9-mediated base editing of C\(\rightarrow\)G to T\(\rightarrow\)A in cotton.
Table 1 Summary of base-editing efficiency of GhCLA and GhPEBP genes

| Target gene | sgRNA    | The number of transgenic plants | The number of plants with base editing | Base-editing efficiency  |
|-------------|----------|---------------------------------|---------------------------------------|--------------------------|
| GhCLA       | sgRNA1   | 45                              | 12                                    | 26.67%                   |
| GhCLA       | sgRNA2   | 45                              | 26                                    | 57.78%                   |
| GhPEBP      | sgRNA3   | 40                              | 11                                    | 27.5%                    |

Genome editing in cotton. Therefore, the sgRNAs targeting these endogenous genes were cloned into trRNA-sgRNA unit and inserted into the binary vector GhBE3. Several independent regenerated (T0) plants were obtained by Agrobacterium-mediated transformation (Figure 1c). For molecular analysis, a total of 46 and 42 independent T0 plants were selected for GhCLA (sgRNAs 1 and 2) and GhPEBP (sgRNA3), respectively. From PCR analysis using nCas9- and sgRNA-specific primers, 45 independent plants from sgRNA1 and sgRNA2 and 40 independent plants from sgRNA3 were positive transformatons, harbouring nCas9, sgRNA fragments (Figure S1), suggesting our cotton transformation system is very effective.

Detection of on-target mutations by Sanger sequencing

In order to test the viability and efficacy of GhBE3 in cotton, 45 independent transgenic T0 plants of GhCLA and 40 independent T0 plants of GhPEBP were analysed by Sanger sequencing. The sequencing data showed that 12 out of the 45 plants contained at least one C→T substitution at the sgRNA1 target region of GhCLA (with editing efficiency of 26.67%) and 26 out of the 45 plants exhibited at least one C→T substitution at the sgRNA2 target region of GhCLA (with editing efficiency of 57.78%) (Table 1). For the GhPEBP transgenic plants, Sanger sequencing data showed that 11 out of 40 plants contained at least one C→T substitution at the sgRNA target region (with editing efficiency of 27.5%) (Table 1). Among these T0 plants with the base editing, we found that there were three or four types of mutations in the editing window (Figure 2a–d). For sgRNA1, only one plant (CLA32) showed the single C→T substitution at position C6, whereas the other 11 plants harboured two or three substitutions (C6, C7 or C4, C6, C7). (Table 2 and Figure 2a). Among these 26 edited plants at the sgRNA2 target, there were only three plants that harbored the single C→T substitution, the remaining mutants occurring simultaneously at two or three sites, of these, 19/26 = triple substitutions; 4/26 = double substitutions (3 at C5 and C7; 1 at C7 and C8) and 3/26 = single substitution at C5 (Table 2 and Figure 2b). Among the 11 edited plants at the target sgRNA3, according to Figure 2c, 10/11 plants were single substitutions (7 at C4 and 3 at C8 positions, respectively) and only one (PEBP21) had double substitutions (Table 2 and Figure 2c).

The above data show that GhBE3 exhibits efficient base editing in cotton. The base substitution was detected within the editing window from C3 to C6 of the protospacer, which is consistent with editing windows reported in animals and other crops (Komor et al., 2016; Zong et al., 2017). We found that the C→T substitution efficiency reached up to 57.78%, which is comparable with the efficiency in rice, maize and wheat (Zong et al., 2017). Most common mutation types in the editing window of the GhCLA target were multiple substitutions, which are also consistent with results reported in other crops (Li et al., 2017b; Zong et al., 2017). However, the sgRNA3 target of this study showed a higher probability of single point mutation, which may be related to the particular sequence of the sgRNA. Although the editing efficiency was higher in GhCLA, the predicted phenotype (albino seedlings) of the transgenic plants did not show up in most T0 plants, and only one plant exhibited a chimeric phenotype (Figure 1d). The absence of the phenotype in the edited plants might be due to the possibility that the point mutation (base substitution) in the target site would only change a single amino acid (or not, if base editing occurred at the ‘wobble’, the 3rd base of a codon) and no frameshift happened. In this case, the resultant proteins will likely have full function, and so, no obvious phenotype would be detected. For the chimeric phenotype, we detected by deep sequencing about 8% indels (most are deletions) and speculate that the chimeric phenotype may be caused by frameshift mutation rather than base substitution (Figure S2).

High-throughput deep sequencing for on-target base editing in GhCLA- and GhPEBP-edited plants

Sanger sequencing for target sequence analysis is very reliable, but the rate of thoroughput of this method is very limited, and the cost is relatively high. Deep sequencing on the other hand is very reliable for the detection of various kinds of mutations, with high throughput and low cost. Barcode-based high-throughput sequencing has been applied for genotyping of a range of target genes in zebrafish and CRISPR/Cas9-edited plant species (Varshney et al., 2016; Wang et al., 2018). In this report, we designed a pair of specific barcodes to mark each independent transgenic plant and attached them to a pair of forward and reverse site-specific primers corresponding to the targeted genes, for PCR (Table S5). As shown in Figure 2e–g and Table S2, the C→T substitution efficiency reached up to 57.78%, which is comparable with the efficiency in rice, maize and wheat (Zong et al., 2017). Most common mutation types in the editing window of the GhCLA target were multiple substitutions, which are also consistent with results reported in other crops (Li et al., 2017b; Zong et al., 2017). However, the sgRNA3 target of this study showed a higher probability of single point mutation, which may be related to the particular sequence of the sgRNA. Although the editing efficiency was higher in GhCLA, the predicted phenotype (albino seedlings) of the transgenic plants did not show up in most T0 plants, and only one plant exhibited a chimeric phenotype (Figure 1d). The absence of the phenotype in the edited plants might be due to the possibility that the point mutation (base substitution) in the target site would only change a single amino acid (or not, if base editing occurred at the ‘wobble’, the 3rd base of a codon) and no frameshift happened. In this case, the resultant proteins will likely have full function, and so, no obvious phenotype would be detected. For the chimeric phenotype, we detected by deep sequencing about 8% indels (most are deletions) and speculate that the chimeric phenotype may be caused by frameshift mutation rather than base substitution (Figure S2).

(a) sgRNA1

(b) sgRNA2

(c) sgRNA3

(d) At_sgRNA1

(e) Dt_sgRNA1

(f) At_sgRNA2

(i) Dt_sgRNA2
substitution ratio within editing window of all sgRNAs ranged from 0.34% to 18.63% of the total DNA sequences. For the sgRNA2 site, 18.63%, 14.20% and 12.44% C→T substitutions at C5, C7 and C8 were detected from 101,000 reads. A higher editing efficiency ranging from 1.13 to 51.45% in At subgenome, while the editing efficiency ranging from 1.12 to 10.63% in At subgenome. The above data reveal that GhBE3 exhibits considerable editing efficiency. To detect any potential off-target effects of this system, we computationally predicted all off-target sites for the three sgRNAs and mapped their seed sequences to the TM-1 reference genome using CRISPR-P and Cas-OFFinder tools (seed sequences ≤ 5 mismatches with the sgRNA sequences) (Bae et al., 2014; Liu et al., 2017). We detected 1001, 499 and 1180 potential off-target sites for sgRNA1, sgRNA2 and sgRNA3, respectively (Table S4). Nine most likely off-target sites were selected for each sgRNA with a high off-score, and most sites were located in protein-coding regions (Figure 3a and Table S8). The base-editing frequency was analysed at these nine off-target sites for 26 edited plants using sgRNA1, 12 edited plants using sgRNA2 and 10 edited plants using sgRNA3 by deep sequencing. WT plants were also included as controls for deep sequencing and the subsequent analysis. The data indicate that the C→T substitution ratio in the editing window of the most likely off-target sites was lower than 0.1% (Figure 3b and Table S2). No difference in the off-target ratio between base-edited and WT plants was observed after statistical analysis.

These results reveal that the GhBE3 has a low off-target efficiency in cotton. It has been reported that base-editing systems have varying levels of off-target effects in different species. Kim et al. (2017) used digested-genome sequencing (Digenome-seq) to assess the specificity of base editor in the human genome and detected a substitution frequency of 0.1% at the off-target sites. In another report, deep sequencing analysis detected approximately 0.14–0.38% off-target mutations in a base-edited tomato genome (Shimatani et al., 2017). Comparing the off-target effects in previous reports, the GhBE3 system used in this report is highly precise for cotton genome editing. The negligible C→T conversions at these off-target sites in this report may be due to sequencing errors or inherent genetic and/or somaclonal variations during the tissue culture process, which is consistent with our recent report regarding the off-target evaluation of CRISPR/Cas9-edited cotton plants (Li et al., 2019a).

Whole-genome sequencing analysis of off-target effects of GhBE3 in cotton

To assess GhBE3 off-target effects in cotton plants on a genome-wide scale, whole-genome sequencing (WGS) was performed for two base-edited plants (N17, N64) for the GhCLA gene and one WT plant, with 100 × sequencing depth. Furthermore, two WT plants and three T0 negative (Ne) plants (following tissue culture and plant generation but without T-DNA insertion, that is no CRISPR/Cas9 component) identified in our recent reports were also included in this analysis since they share a very similar genetic background with the WT and GhBE3-edited plants (Li et al., 2019a). We identified all potential off-targets of these three sgRNAs at a whole-genome scale through bioinformatics analysis. In total, 499 off-targets for sgRNA1 and 1001 off-targets for sgRNA2 were identified, based on Cas-OFFinder analysis (Table S4 and Figure 4c). Firstly, we checked the on-target base editing at sgRNA1 and sgRNA2 target sites using Integrative Genomics

### Table 2 Details of base-editing profile at three sgRNA target sites

| Gene Target | Plants number | Base-editing position in the editing window | Base-editing type |
|-------------|---------------|--------------------------------------------|------------------|
| GhCLA sgRNA1 | CLA32         | 6                                         | C→T             |
|             | CLA7, CLA10, CLA15 | 6, 7                                       | C→T             |
|             | CLA23, CLA26, CLA27, N17, N64 | 4, 6, 7 | C→T |
| GhCLA sgRNA2 | CLA24, CLA25, CLA29, CLA30, CLA31, CLA32 | 5 | C→T |
|             | CLA15, CLA32, CLA36, CLA37, CLA38, CLA39, CLA40, CLA41, N17, N64 | 5, 7 | C→T |
|             | CLA12, CLA18, CLA21, CLA22, CLA27, CLA30, CLA35, CLA37, CLA38, CLA39, CLA40, N17, N64 | 5, 7, 8 | C→T |
| GP/PEBP sgRNA3 | PEBP7, PEBP17, PEBP18, PEBP28, PEBP31, PEBP32, PEBP35, PEBP36 | 4 | C→T |
|             | PEBP22, PEBP28, PEBP31, PEBP32, PEBP35, PEBP36 | 4 | C→T |
|             | PEBP32, PEBP35, PEBP36 | 8 | C→T |

T0 plants with multiple editing types are highlighted in red.
Figure 3  The evaluation of off-target effect of GhBE3 in edited cotton plants by targeted deep sequencing. (a) Scores (high off-target score and the seed sequences ≤ 5 mismatches with the sgRNA sequences) for the most potential off-target sites. The number of mismatches shown in the figure is from both sgRNA and PAM sequences (23 nt in length). (b) No off-target mutation was detected at most potential off-target sites in sgRNA1, sgRNA2 and sgRNA3 by targeted deep sequencing. There were 12, 26 and 10 edited plants in sgRNA1, sgRNA2 and sgRNA3 used to detect off-target and 3 WT plants used for analysis in this experiment. Error bar = 3.

Mismatch bases of sgRNA between the WT and off-target sequences are marked with lowercase letters, and all C bases in editing window of off-target are highlighted in red font.
Viewer (IGV), and results showed many C→T substitutions in the editing window of sgRNA1 target regions (Figure 4a), consistent with the Sanger sequencing data shown in Figure 2. Similarly, C→T mutations were also detected at the editing window of the sgRNA2 target region, but the ratio was lower than that in the sgRNA1 target region, although many C→G mutations were detected at this site (Figure 4b). Similar results have been detected in rice (G→C or G→T mutations) (Li et al., 2017b).
and it is not clear how these kinds of unintended base mutations were generated.

To evaluate potential off-target mutations of GhBE3 at a whole genome-wide scale, two variant caller tools with strict parameter settings were applied to get the high concordance variations (Table S9). In total, 976, 280, 11,124,776 and 1,138,453 SNPs, and 134,097, 139,787 and 140,733 indels were detected in WT, N17 and N64 plants, respectively, compared with the TM-1 reference genome. We used two negative control plants and two WT plants from a previous study to eliminate somaclonal variations or germ-line background variations (Table 3) (Li et al., 2019a). According to the analysis, the GhBE3-induced mutations (on-target editing) are solely present in GhBE3-edited plants, but not in WT and negative control plants. Finally, a total of 20 193 and 16 770 SNPs and 9471 and 8756 indels were detected in N17 and N64 plants, respectively (Figure 4c and Table 3). These variations were annotated by ANNOVAR tools. The 21.5% functional variations were detected where the exonic region contained a high ratio (Figure 4d). 5689 SNPs and 3189 indels were shared between the N17 and N64 plants (Figure 4c). After filtering the shared variations, the remaining individual variations (14 504 and 11 081 SNPs and 6280 and 5565 indels in the N17 and N64 plants, respectively) were filtered for further detection of GhBE3-induced off-target mutations (Table 3). These variations overlapped with the 1500 predicted potential off-target sites by Cas-OFFinder. No bona fide off-target mutations were detected at these potential off-target sites. The targeted deep sequencing and WGS data therefore suggest that GhBE3 did not cause detectable off-target mutations on a whole genome-wide scale and was highly precise for cotton genome editing.

The base editing produced by GhBE3 was genetically inheritable from T0 to T1 progeny

The above analysis allowed us to evaluate the base-editing efficiency and accuracy in stable transgenic cotton T0 plants using Sanger sequencing, target deep sequencing and whole-genome sequencing. In order to test the inheritance of base editing induced by GhBE3 from T0 to T1 progeny, the T1 plants generated from N1, N2 and N64 T0 plants of GhCLA were analysed by PCR amplification and Sanger sequencing. T1 seeds and their seedlings were obtained from T0 positive parental seedlings, as shown in Figure 5a,b. The N64 T1 plantlets exhibited a complete albino phenotype as expected (Figure 5b), whereas other T1 plantlets from two lines N1 and N2 remained green. All the T1 plantlets were checked with nCas9- CLA-specific primers (Table S7) to identify positive transformants and target amplifications (Figure 5c). The results showed that C→T substitutions at sgRNA targets were detected in T1 generation plants from three T0 parental plants. Furthermore, several newly generated base-editing types at the base-editing window of sgRNA2 site were detected from T1 progenies of N1, N2 and N64 T0 plantlets (Figure 5d). These results confirmed that the base editing was heritable (Figure 5). In addition to the predicted mutations inherited from T0 plants, several new mutations were detected in T1 plants but not in T0 plants. New mutations generated in the T1 progeny at the target sites indicate that the base editor (GhBE3) can continue to induce base editing in the progeny containing the T-DNA insertion. This means that, to ensure stability of edited progeny, it will be necessary to screen for offspring without T-DNA insertions, so that the mutations in the parental generation will be faithfully inherited to the next generation while preventing the occurrence of additional mutations. Recently, a report showed that base editing mediated by the rBE3 system could be stably and faithfully inherited to the T1 generation in rice, and homozygous mutants without exogenous T-DNA could be obtained in T1 generation (Ren et al., 2017).

In conclusion, GhBE3 can efficiently perform C to T substitutions on sgRNA targets in the cotton genome, and successful base editing of two endogenous genes prompted us to apply this system to future functional genomics studies. More importantly, no off-target C→T substitutions were detected at potential off-target sites in a genome-wide scale analysis. Therefore, it is a feasible and effective tool for targeted base editing in cotton and

| Plants VS Ref | Plants VS Ref/WT | Plants VS Ref/WT/Ne | Individual variations |
|----------------|-----------------|-------------------|----------------------|
| Description | SNP | indel | SNP | indel | SNP | indel | SNP | indel |
| WT (s195) | 976 280 | 134 097 | – | – | – | – | – | – |
| WT (s79)* | 1 211 622 | 149 327 | – | – | – | – | – | – |
| WT (s191)* | 1 210 509 | 148 567 | – | – | – | – | – | – |
| Negative (s65)* | 1 203 206 | 149 636 | 319 900 | 19 300 | – | – | – | – |
| Negative (s66)* | 1 217 124 | 148 842 | 329 233 | 18 456 | – | – | – | – |
| Negative (s67)* | 1 209 155 | 135 845 | 339 335 | 29 969 | – | – | – | – |

| nCas9-CLA (N64) | 1 138 453 | 140 733 | 351 187 | 21 541 | 16 770 | 8756 | 11 081 | 5565 |

The ‘Plants vs Ref’ represents the high confidence variations of per plant compared with TM-1 reference genome (Table S9). The ‘Plants vs Ref/WT’ represents the variations of per plant compared with TM-1 and wild type (WT). Similarly, the ‘Plants vs Ref/WT/Ne (unique variation)’ represents the variations of per GHBE3-edited plants compared with TM-1, WT and negative plants. The individual variations indicated that two base-edited plants have the similar genotype as three negative plants, but differ from each other and contain specific variations, which may include the GhBE3-induced off-target mutations. Sample-specific variations (including pre-existing variations, and/or inherent variations and/or nCas9-induced mutations) were annotated by ANNOVAR (Figure 4c). The ‘*’ indicates the genome data from these samples were cited from our previous report (Li et al., 2019a).
will provide important technical support for the functional analysis of cotton genome, genetic improvement of crops and breeding of new varieties. The combination of adenine and cytidine base editors can now generate all four base transition mutations, and it has now been shown that adenine and cytidine base editing can be achieved simultaneously in rice (Hua et al., 2019) and will also be applied in cotton in the near future.

Acknowledgements
We appreciate Dr. Caixia Gao of Institute of Genetics and Developmental Biology, CAS, for her kind gift of plasmid pCas9-PBE for this research. This work was supported by grant from National R&D Project of Transgenic Crops of Ministry of Science and Technology of China (2016ZX08010001-006), National Key Research and Development Plan (2016YFD0100203-9) and Fundamental Research Funds for the Central Universities (2013PY064, 2662015PY028, 2662015PY091 and 0900206328) to Dr. Shuangxia Jin.

Figure 5 Base editing of GhCLA was genetically inheritable to T1 progenies. (a,b) Seeds and their young seedlings from WT, N1, N2 and N64 T0 parental plants. (c) PCR analysis to detect nCas9 and GhCLA genes in WT, N1, N2 and N64 T1 progenies. (d) Genotyping of independent T0 plants and their T1 progeny at the sgRNA2 of GhCLA gene. The WT and T0 plants are highlighted in orange and purple background colour, respectively. Base-editing sites are highlighted in red font, and PAMs are highlighted in blue font.

Author contributions
S.X.J. and X.L.Z. designed the Project. L.Q. performed experiments and wrote the manuscript. J.Y.L., Q.Q.W. and Z.P.X. performed genotype data and WGS data analysis. S.X.J., J.Y.L., M.A., H.M and K.L. revised the manuscript. All authors read and approved the final manuscript.

Conflict of interest
The authors have declared that no competing interests exist in this manuscript.

Data availability
The target deep sequencing and WGS data have been submitted to the NCBI Sequence Read Archive (SRA) BioProject ID: PRJNA380842.
