Abstract

Tree substitution grammars (TSGs) are a compelling alternative to context-free grammars for modelling syntax. However, many popular techniques for estimating weighted TSGs (under the moniker of Data Oriented Parsing) suffer from the problems of inconsistency and over-fitting. We present a theoretically principled model which solves these problems using a Bayesian non-parametric formulation. Our model learns compact and simple grammars, uncovering latent linguistic structures (e.g., verb subcategorisation), and in doing so far out-performs a standard PCFG.

1 Introduction

Many successful models of syntax are based on Probabilistic Context Free Grammars (PCFGs) (e.g., Collins (1999)). However, directly learning a PCFG from a treebank results in poor parsing performance, due largely to the unrealistic independence assumptions imposed by the context-free assumption. Considerable effort is required to coax good results from a PCFG, in the form of grammar engineering, feature selection and clever smoothing (Collins, 1999; Charniak, 2000; Charniak and Johnson, 2005; Johnson, 1998). This effort must be repeated when moving to different languages, grammar formalisms or treebanks. We propose that much of this hand-coded knowledge can be obtained automatically as an emergent property of the treebanked data, thereby reducing the need for human input in crafting the grammar.

We present a model for automatically learning a Probabilistic Tree Substitution Grammar (PTSG), an extension to the PCFG in which non-terminals can rewrite as entire tree fragments (elementary trees), not just immediate children. These large fragments can be used to encode non-local context, such as head-lexicalisation and verb subcategorisation. Since no annotated data is available providing TSG derivations we must induce the PTSG productions and their probabilities in an unsupervised way from an ordinary treebank. This is the same problem addressed by Data Oriented Parsing (DOP, Bod et al. (2003)), a method which uses as productions all subtrees of the training corpus. However, many of the DOP estimation methods have serious shortcomings (Johnson, 2002), namely inconsistency for DOP1 (Bod, 2003) and overfitting of the maximum likelihood estimate (Prescher et al., 2004).

In this paper we develop an alternative means of learning a PTSG from a treebanked corpus, with the twin objectives of a) finding a grammar which accurately models the data and b) keeping the grammar as simple as possible, with few, compact, elementary trees. This is achieved using a prior to encourage sparsity and simplicity in a Bayesian non-parametric formulation. The framework allows us to perform inference over an infinite space of grammar productions in an elegant and efficient manner. The net result is a grammar which only uses the increased context afforded by the TSG when necessary to model the data, and otherwise uses context-free rules.1 That is, our model learns to use larger rules when the CFG’s independence assumptions do not hold. This contrasts with DOP, which seeks to use all elementary trees from the training set. While our model is able, in theory, to use all such trees, in practice the data does not justify such a large grammar. Grammars that are only about twice the size of a

1While TSGs and CFGs describe the same string languages, TSGs can describe context-sensitive tree-languages, which CFGs cannot.
treebank PCFG provide large gains in accuracy. We obtain additional improvements with grammars that are somewhat larger, but still much smaller than the DOP all-subtrees grammar. The rules in these grammars are intuitive, potentially offering insights into grammatical structure which could be used in, e.g., the development of syntactic ontologies and guidelines for future treebanking projects.

2 Background and related work

A Tree Substitution Grammar (TSG) is a 4-tuple, $G = (T, N, S, R)$, where $T$ is a set of terminal symbols, $N$ is a set of non-terminal symbols, $S \in N$ is the distinguished root non-terminal and $R$ is a set of productions (a.k.a. rules). The productions take the form of elementary trees – tree fragments of depth $\geq 2$, where each internal node is labelled with a non-terminal and each leaf is labelled with either a terminal or a non-terminal. Non-terminal leaves are called frontier non-terminals and form the substitution sites in the generative process of creating trees with the grammar.

A derivation creates a tree by starting with the root symbol and rewriting (substituting) it with an elementary tree, then continuing to rewrite frontier non-terminals with elementary trees until there are no remaining frontier non-terminals. Unlike Context Free Grammars (CFGs) a syntax tree may not uniquely specify the derivation, as illustrated in Figure 1 which shows two derivations using different elementary trees to produce the same tree.

A Probabilistic Tree Substitution Grammar (PTSG), like a PCFG, assigns a probability to each rule in the grammar. The probability of a derivation is the product of the probabilities of its component rules, and the probability of a tree is the sum of the probabilities of its derivations.

As we mentioned in the introduction, work within the DOP framework seeks to induce PTSGs from treebanks by using all possible subtrees as rules, and one of a variety of methods for estimating rule probabilities. Our aim of inducing compact grammars contrasts with that of DOP; moreover, we develop a probabilistic estimator which avoids the shortcomings of DOP1 and the maximum likelihood estimate (Bod, 2000; Bod, 2003; Johnson, 2002). Recent work on DOP estimation also seeks to address these problems, drawing from estimation theory to solve the consistency problem (Prescher et al., 2004; Zollmann and Sima’an, 2005), or incorporating a grammar brevity term into the learning objective (Zuidema, 2007). Our work differs from these previous approaches in that we explicitly model a prior over grammars within a Bayesian framework.

Models of grammar refinement (Petrov et al., 2006; Liang et al., 2007; Finkel et al., 2007) also aim to automatically learn latent structure underlying treebanked data. These models allow each non-terminal to be split into a number of subcategories. Theoretically the grammar space of our model is a sub-space of theirs (projecting the TSG’s elementary trees into CFG rules). However, the number of non-terminals required to recreate our TSG grammars in a PCFG would be exorbitant. Consequently, our model should be better able to learn specific lexical patterns, such as full noun-phrases and verbs with their sub-categorisation frames, while theirs are better suited to learning subcategories with larger membership, such as the terminals for days of the week and noun-adjective agreement. The approaches are orthogonal, and we expect that combining a category refinement model with our TSG model would provide better performance than either approach alone.

Our model is similar to the Adaptor Grammar model of Johnson et al. (2007b), which is also a kind of Bayesian nonparametric tree-substitution grammar. However, Adaptor Grammars require that each sub-tree expands completely, with only terminal symbols as leaves, while our own model permits non-terminal frontier nodes. In addition, they disallow recursive containment of adapted non-terminals; we impose no such constraint.

3 Model

Recall the nature of our task: we are given a corpus of parse trees $t$ and wish to infer a tree-substitution grammar $G$ that we can use to parse new data. Rather than inferring a grammar directly, we go through an intermediate step of inferring a distribution over the derivations used to produce $t$, i.e.,

a distribution over sequences of elementary trees $e$ that compose to form $t$. We will then essentially read the grammar off the elementary trees, as described in Section 5. Our problem therefore becomes one of identifying the posterior distribution of $e$ given $t$, which we can do using Bayes’ Rule:

$$P(e|t) \propto P(t|e)P(e)$$  \hspace{1cm} (1)

Since the sequence of elementary trees can be split into derivations, each of which completely specifies a tree, $P(t|e)$ is either equal to 1 (when $t$ and $e$ are consistent) or 0 (otherwise). Therefore, the work in our model is done by the prior distribution over elementary trees. Note that this is analogous to the Bayesian model of word segmentation presented by Goldwater et al. (2006); indeed, the problem of inferring $e$ from $t$ can be viewed as a segmentation problem, where each full tree must be segmented into one or more elementary trees. As in Goldwater et al. (2006), we wish to favour solutions employing a relatively small number of elementary units (here, elementary trees). This can be done using a Dirichlet process (DP) prior. Specifically, we define the distribution of elementary tree $e$ with root non-terminal symbol $c$ as

$$G_c|\alpha_c, P_0 \sim \text{DP}(\alpha_c, P_0(\cdot|c))$$

$$e|c \sim G_c$$

where $P_0(\cdot|c)$ (the base distribution) is a distribution over the infinite space of trees rooted with $c$, and $\alpha_c$ (the concentration parameter) controls the model’s tendency towards either reusing elementary trees or creating novel ones as each training instance is encountered (and consequently, the tendency to infer larger or smaller sets of elementary trees from the observed data). We discuss the base distribution in more detail below.

Rather than representing the distribution $G_c$ explicitly, we integrate over all possible values of $G_c$. The resulting distribution over $e$, conditioned on $e = e_1 \ldots e_i$ and the root category $c$ is:

$$p(e_i|e_{<i}, c, \alpha_c, P_0) = \frac{n_{e_i,c}^c + \alpha_c P_0(e_i|c)}{n_{<i,c}^c + \alpha_c}$$  \hspace{1cm} (2)

where $n_{e_i,c}^c$ is the number of times $e_i$ has been used to rewrite $c$ in $e_{<i}$, and $n_{<i,c}^c = \sum_{e} n_{e_i,c}^c$ is the total count of rewriting $c$.

As with other DP models, ours can be viewed as a cache model, where $e_i$ can be generated in one of two ways: by drawing from the base distribution, where the probability of any particular tree is proportional to $\alpha_c P_0(e_i|c)$, or by drawing from a cache of previous expansions of $c$, where the probability of any particular expansion is proportional to the number of times that expansion has been used before. This view makes it clear that the model embodies a “rich-get-richer” dynamic in which a few expansions will occur with high probability, but many will occur only once or twice, as is typical of natural language. Our model is similar in this way to the Adaptor Grammar model of Johnson et al. (2007a).

We still need to define $P_0$, the base distribution over tree fragments. We use two such distributions. The first, $P_0^M$ generates each elementary tree by a series of random decisions: whether to expand a non-terminal, how many children to produce and their identities. The probability of expanding a non-terminal node labelled $c$ is parameterised via a binomial distribution, $\text{Bin}(\beta_c)$, while all other decisions are chosen uniformly at random. The second base distribution, $P_0^C$, has a similar generative process but draws non-terminal expansions from a treebank-trained PCFG instead of a uniform distribution.

Both choices of $P_0$ have the effect of biasing the model towards simple rules with a small number of internal nodes. The geometric increase in cost discourages the model from using larger rules; for this to occur these rules must yield a large increase in the data likelihood. As $P_0^C$ incorporates PCFG probabil-
Figure 2: Gibbs state \( e \) specifying the derivation in Figure 1a. Each node is labelled with its substitution indicator variable.

4 Training

To train our model we use Gibbs sampling (Geman and Geman, 1984), a Markov chain Monte Carlo method in which variables are repeatedly sampled conditioned on the values of all other variables in the model. After a period of burn-in, each sampler state (set of variable assignments) is a sample from the posterior distribution of the model. In our case, we wish to sample from \( P(e) \) from the posterior distribution of the model. In our plier state (set of variable assignments) is a sample of the model. After a period of burn-in, each sample, and Geman, 1984), a Markov chain Monte Carlo method in which variables are repeatedly sampled conditioned on the values of all other variables in the model. After a period of burn-in, each state of the sampler. Figure 2 shows an example tree with its substitution variables, corresponding to the TSG derivation in Figure 1a.

Our Gibbs sampler works by sampling the value of each substitution variable, one at a time, in random order. If \( d \) is the node associated with the substitution variable \( s \) under consideration, then the two possible values of \( s \) define two options for \( e \): one in which \( d \) is internal to some elementary tree \( e_M \), and one in which \( d \) is the substitution site connecting two smaller trees, \( e_A \) and \( e_B \). In the example in Figure 2, when sampling the VP node, \( e_M = (S \text{ NP } (VP \text{ (V hates) } \text{ NP})), e_A = (S \text{ NP } VP) \), and \( e_B = (VP \text{ (V hates) } \text{ NP}) \). To sample a value for \( s \), we compute the probabilities of \( e_M \) and \( (e_A, e_B) \), conditioned on \( e^- \): all other elementary trees in the training set that share at most a root or frontier non-terminal with \( e_M, e_A \), or \( e_B \). This is easy to do because the DP is exchangeable, meaning that the probability of a set of outcomes does not depend on their ordering. Therefore, we can treat the elementary trees under consideration as the last ones to be sampled, and apply Equation 2, giving us

\[
P(e_M | e) = \frac{n_{e_M, e} + \alpha_{e_M} P_0(e_M | e)}{n_{e_M} + \alpha_{e_M}}
\]

\[
P(e_A, e_B | e_A) = \frac{n_{e_A, e} + \alpha_{e_A, e} P_0(e_A | e_A)}{n_{e_A} + \alpha_{e_A}} \times \frac{n_{e_B, e} + \delta(e_A, e_B) + \alpha_{e_B, e} P_0(e_B | e_B)}{n_{e_B} + \delta(e_A, e_B) + \alpha_{e_B}}
\]

where \( e_x \) is the root label of \( e_x, x \in \{A, B, M\} \), the counts \( n^- \) are with respect to \( e^- \), and \( \delta(\cdot, \cdot) \) is the Kronecker delta function, which returns 1 when its arguments are identical and 0 otherwise. We have omitted \( e^-, t, \alpha \) and \( \beta \) from the conditioning context. The \( \delta \) terms in the second factor of (4) account the changes to \( n^- \) that would occur after observing \( e_A \), which forms part of the conditioning context for \( e_B \). If the trees \( e_A \) and \( e_B \) are identical, then the count \( n_{e_A, e_B} \) would increase by one, and if the trees share the same root non-terminal, then \( n_{e_B} \) would increase by one.

In the previous discussion, we have assumed that the model hyperparameters, \( (\alpha, \beta) \), are known. However, selecting their values by hand is extremely difficult and fitting their values on heldout data is often very time consuming. For this reason we treat the hyper-parameters as variables in our model and infer their values during training. We choose vague priors for each hyper-parameter, encoding our lack of information about their values. We treat the concentration parameters, \( \alpha \), as being generated by a vague gamma prior, \( \alpha_c \sim \text{Gamma}(0.001, 1000) \). We sample a new value \( \alpha_c' \) using a log-normal distribution with mean \( \alpha_c \) and variance 0.3, which is then accepted into the distribution \( p(\alpha_c | \alpha, \beta) \) using the Metropolis-Hasting algorithm. We use a Beta prior for the binomial specification parameters, \( \beta_c \sim \text{Beta}(1, 1) \). As the Beta distribution is conjugate to the binomial, we can directly resample the \( \beta \) parameters from the posterior, \( p(\beta | \alpha, \beta) \). Both the concentration and substitution parameters are resampled after every full Gibbs sampling iteration over the training trees.
5 Parsing

We now turn to the problem of using the model to parse novel sentences. This requires finding the maximiser of

\[
p(t|w, t) = \int p(t|w, e, \alpha, \beta) p(e, \alpha, \beta|t) \, de \, d\alpha \, d\beta
\]

(5)

where \(w\) is the sequence of words being parsed and \(t\) the resulting tree, \(t\) are the training trees and \(e\) their segmentation into elementary trees.

Unfortunately solving for the maximising parse tree in (5) is intractable. However, it can approximated using Monte Carlo techniques. Given a sample of \((e, \alpha, \beta)\) we can reason over the space of possible trees using a Metropolis-Hastings sampler (Johnson et al., 2007a) coupled with a Monte Carlo integral (Bod, 2003). The first step is to sample from the posterior over derivations, \(p(d|w, e, \alpha, \beta)\). This is achieved by drawing samples from an approximation grammar, \(\tilde{p}(d|w)\), which are then accepted to the true distribution using the Metropolis-Hastings algorithm. The second step records for each sampled derivation the CFG tree. The counts of trees constitute an approximation to \(p(t|w, e, \alpha, \beta)\), from which we can recover the maximum probability tree.

A natural proposal distribution, \(\tilde{p}(d|w)\), is the maximum a posterior (MAP) grammar given the elementary tree analysis of our training set (analogous to the PCFG approximation used in Johnson et al. (2007a)). This is not practical because the approximation grammar is infinite: elementary trees with zero count in \(e\) still have some residual probability under \(P_{\theta}\). In the absence of a better alternative, we discard (most of) the zero-count rules from MAP grammar. This results in a tractable grammar representing the majority of the probability mass, from which we can sample derivations. We specifically retain all zero-count PCFG productions observed in the training set in order to provide greater robustness on unseen data.

In addition to finding the maximum probability parse (MPP), we also report results using the maximum probability derivation (MPD). While this could be calculated in the manner as described above, we found that using the CYK algorithm (Cocke, 1969) to find the Viterbi derivation for \(\tilde{p}\) yielded consistently better results. This algorithm maximises an approximated model, as opposed to approximately optimising the true model. We also present results using the tree with the maximum expected count of CFG rules (MER). This uses counts of the CFG rules applied at each span (compiled from the derivation samples) followed by a maximisation step to find the best tree. This is similar to the MAX-RULE-SUM algorithm of Petrov and Klein (2007) and maximum expected recall parsing (Goodman, 2003).

6 Experiments

Synthetic data Before applying the model to natural language, we first create a synthetic problem to confirm that the model is capable of recovering a known tree-substitution grammar. We created 50 random trees from the TSG shown in Figure 3. This produces binary trees with \(A\) and \(B\) internal nodes and ‘a’ and ‘b’ as terminals, such that the terminals correspond to their grand-parent non-terminal (\(A\) and a or \(B\) and b). These trees cannot be modelled accurately with a CFG because expanding \(A\) and \(B\) nodes into terminal strings requires knowing their parent’s non-terminal.

We train the model for 100 iterations of Gibbs sampling using annealing to speed convergence. Annealing amounts to smoothing the distributions in (3) and (4) by raising them to the power of \(\frac{1}{T}\). Our annealing schedule begins at \(T = 3\) and linearly decreases to reach \(T = 1\) in the final iteration. The sampler converges to the correct grammar, with the 10 rules from Figure 3.

Penn-treebank parsing We ran our natural language experiments on the Penn treebank, using the standard data splits (sections 2–21 for training, 22 for development and 23 for testing). As our model is parameter free (the \(\alpha\) and \(\beta\) parameters are learnt in training), we do not use the development set for pa-
rameter tuning. We expect that fitting these parameters to maximise performance on the development set would lead to a small increase in generalisation performance, but at a significant cost in runtime. We replace tokens with count \( \leq 1 \) in the training sample with one of roughly 50 generic unknown word markers which convey the token’s lexical features and position in the sentence, following Petrov et al. (2006). We also right-binarise the trees to reduce the branching factor in the same manner as Petrov et al. (2006). The predicted trees are evaluated using EVALB\(^6\) and we report the F1 score over labelled constituents and exact match accuracy over all sentences in the testing sets.

In our experiments, we initialised the sampler by setting all substitution variables to 0, thus treating every full tree in the training set as an elementary tree. Starting with all the variables set to 1 (corresponding to CFG expansions) or a random mix of 0s and 1s considerably increases time until convergence. We hypothesise that this is due to the sampler getting stuck in modes, from which a series of locally bad decisions are required to escape. The CFG solution seems to be a mode and therefore starting the sampler with maximal trees helps the model to avoid this mode.

**Small data sample** For our first treebank experiments, we train on a small data sample by using only section 2 of the treebank. Bayesian methods tend to do well with small data samples, while for larger samples the benefits diminish relative to point estimates. The models were trained using Gibbs sampling for 4000 iterations with annealing linearly decreasing from \( T = 5 \) to \( T = 1 \), after which the model performed another 1000 iterations with \( T = 1 \). The final training sample was used in the parsing algorithm, which used 1000 derivation samples for each test sentence. All results are the average of five independent runs.

Table 1 presents the prediction results on the development set. The baseline is a maximum likelihood PCFG. The TSG model significantly outperforms the baseline with either base distribution \( P^M_0 \) or \( P^C_0 \). This confirms our hypothesis that CFGs are not sufficiently powerful to model syntax, but that the increased context afforded to the TSG can make a large difference. This result is even more impressive when considering the difference in the sizes of grammar in the PCFG versus TSG models. The TSG using \( P^M_0 \) achieves its improvements with only double as many rules, as a consequence of the prior which encourages sparse solutions. The TSG results with the CFG base distribution, \( P^C_0 \), are more accurate but with larger grammars.\(^7\) This base distribution assigns proportionally higher probability to larger rules than \( P^M_0 \), and consequently the model uses these additional rules in a larger grammar.

Surprisingly, the MPP technique is not systematically better than the MPD approach, with mixed results under the F1 metric. We conjecture that this is due to sampling variance for long sentences, where repeated samples of the same tree are exceedingly rare. The MER technique results in considerably better F1 scores than either MPD or MPP, with a margin of 1.5 to 3 points. This method is less affected by sampling variance due to its use of smaller tree fragments (PCFG productions at each span).

For comparison, we trained the Berkeley split-merge (SM) parser (Petrov et al., 2006) on the same data and decoded using the Viterbi algorithm (MPD) and expected rule count (MER a.k.a. MAX-RULE-SUM). We ran two iterations of split-merge training, after which the development F1 dropped substantially (in contrast, our model is not fit to the development data). The result is an accuracy slightly below that of our model (SM\(_{\tau=2}\)). To be fairer to their model, we adjusted the unknown word threshold to their default setting, i.e., to apply to word types occurring 5 times or more.

---

\(^6\)See http://nlp.cs.nyu.edu/evalb/.

\(^7\)The grammar is nevertheless far smaller than the full DOP grammar on this data set, which has 700K rules.

| Grammar | F1  | EX  | # rules |
|---------|-----|-----|---------|
| PCFG    | 60.20 | 4.29 | 3500 |
| TSG \( P^M_0 \): MPD | 72.17 | 11.92 | 6609 |
| MPP     | 71.27 | 12.33 | 6609 |
| MER     | 74.25 | 12.30 | 6609 |
| TSG \( P^C_0 \): MPD | 75.24 | 15.18 | 14923 |
| MPP     | 75.30 | 15.74 | 14923 |

Table 1: Development results for models trained on section 2 of the Penn tree-bank, showing labelled constituent F1 and exact match accuracy. Grammar sizes are the number of rules with count \( \geq 1 \).
Figure 4: Grammar statistics for a TSG $P_{0}^{M}$ model trained on section 2 of the Penn treebank, showing a histogram over elementary tree depth, number of nodes, terminals (lexemes) and frontier non-terminals (vars).

The TSG rules vary in depth from two to nine levels with the majority between two and four. Most rules combine a small degree of lexicalisation and a variable or two. This confirms that the model is learning local structures to encode, e.g., multi-word units, subcategorisation frames and lexical agreement. The few very large rules specify full parses for sentences which were repeated in the training corpus. These complete trees are also evident in the long tail of node counts (up to 27; not shown in the figure) and counts for highly lexicalised rules (up to 8).

To get a better feel for the types of rules being learnt, it is instructive to examine the rules in the redundant M0 model.

Full treebank We now train the model using $P_{0}^{M}$ on the full training partition of the Penn treebank, using sections 2–21. We run the Gibbs sampler for 15,000 iterations while annealing from $T = 5$ to $T = 1$, after which we finish with 5,000 iterations at $T = 1$. We repeat this three times, giving an average F1 of 84.0% on the testing partition using the maximum expected rule algorithm and 83.0% using the Viterbi algorithm. This far surpasses the MLPCFG (F1 of 70.7%), and is similar to Zuidema’s (2007) DOP result of 83.8%. However, it still well below state-of-the-art parsers (e.g., the Berkeley parser trained using the same data representation scores 87.7%). But we must bear in mind that these parsers have benefited from years of tuning to the Penn-treebank, where our model is much simpler and is largely untuned. We anticipate that careful data preparation and model tuning could greatly improve our model’s performance.

7 Discussion

So what kinds of non-CFG rules is the model learning? Figure 4 shows the grammar statistics for a TSG model trained on the small data sample. This model has 5611 CFG rules and 1008 TSG rules. The TSG rules vary in depth from two to nine levels with the majority between two and four. Most rules combine a small degree of lexicalisation and a variable or two. This confirms that the model is learning local structures to encode, e.g., multi-word units, subcategorisation frames and lexical agreement. The few very large rules specify full parses for sentences which were repeated in the training corpus. These complete trees are also evident in the long tail of node counts (up to 27; not shown in the figure) and counts for highly lexicalised rules (up to 8).

Table 3: Most frequent lexicalised expansions for noun and verb phrases, excluding auxiliary verbs.
Table 2: Top fifteen expansions sorted by frequency (most frequent at top), taken from the final sample of a model trained on the full Penn treebank. Non-terminals shown with an over-bar denote a binarised sub-span of the given phrase type.

8 Conclusion

In this work we have presented a non-parametric Bayesian model for inducing tree substitution grammars. By incorporating a structured prior over elementary rules our model is able to reason over the infinite space of all such rules, producing compact and simple grammars. In doing so our model learns local structures for latent linguistic phenomena, such as verb subcategorisation and lexical agreement. Our experimental results show that the induced grammars strongly out-perform standard PCFGs, and are comparable to a state-of-the-art parser on small data samples. While our results on the full treebank are well shy of the best available parsers, we have proposed a number of improvements to the model and the parsing algorithm that could lead to state-of-the-art performance in the future.
