This manuscript was compiled on March 13, 2019

Genomes computationally inferred from large metagenomic data sets are often incomplete and may be missing functionally important content and strain variation. We introduce an information retrieval system for large metagenomic data sets that exploits the sparsity of DNA assembly graphs to efficiently extract subgraphs surrounding an inferred genome. We apply this system to recover missing content from genome bins and show that substantial genomic sequence variation is present in a real metagenome. Our software implementation is available at https://github.com/spacegraphcats/spacegraphcats under the 3-Clause BSD License.

Metagenomics | sequence assembly | strain variation | bounded expansion | dominating set

Metagenomics is the analysis of microbial communities through shotgun DNA sequencing, which randomly samples many subsequences (reads) from the genomic DNA of each microbe present in the community (1).

A common problem in metagenomics is the reconstruction of individual microbial genomes from the mixture. Typically this is done by first running an assembly algorithm that reconstructs longer linear regions based on a graph of the sampled subsequences (2), and then binning assembled contigs together using compositional features and genic content (3, 4). These “metagenome-assembled genomes” are then analyzed for phylogenetic markers and metabolic function. In recent years, nearly 200,000 metagenome-assembled genomes have been published, dramatically expanding our view of microbial life (5–10).

Information present in shotgun metagenomes is often omitted from the binned genomes due to either a failure to assemble (11, 12) or a failure to bin. The underlying technical reasons for these failures include low coverage, high sequencing error, high strain variation, and/or sequences with insufficient compositional or genic signal. Recent work has particularly focused on the problem of strain confusion, in which high strain variation results in considerable fragmentation of assembled content in mock or synthetic communities (11, 12); the extent and impact of strain confusion in real metagenomes is still unknown but potentially significant - metagenome-assembled genomes may be missing 20–40% of true content (13–15).

Associating unbinned metagenomic sequence to inferred bins or known genomes is technically challenging. Some approaches use mapping or k-mer baiting, in which assembled sequences are used to extract reads or contigs from a metagenome or graph (16–20). These methods fail to recover genomic content that does not directly overlap with the query, such as large indels or novel genomic islands. Moreover, most assembly graphs undergo substantial heuristic error pruning and may not contain relevant content (11, 12). Graph queries have shown promise for recovering sequence from regions that do not assemble well but are graph-proximal to the query (21, 22). However, many graph query algorithms are NP-hard and hence computationally intractable in the general case; compounding the computational challenge, metagenome assembly graphs are frequently large, with millions of nodes, and require 10s to 100s of gigabytes of RAM for storage.

In this paper, we develop and implement a scalable graph query framework for extracting unbinned sequence from metagenome assembly graphs with millions of nodes. Crucially, we exploit the structural sparsity of compact De Bruijn assembly graphs in order to compute a succinct index data structure in linear time. We use this framework to perform neighborhood queries in large assembly graphs, which enables us to extract the genome of a novel bacterial species, recover missing sequence variation in amino acid sequences for genome bins, and identify missing content for metagenome-assembled genomes. Our query methods are assembly-free and avoid techniques that may discard strain information such as error correction. These algorithms are available in an open-source Python software package, spacegraphcats (23).

Results

Dominating sets enable efficient neighborhood queries in large assembly graphs. We designed and implemented (23) a set of algorithms for efficiently finding content in a metagenome that is close to a query as measured by distance in a compact De Bruijn graph (cDBG) representation of the sequencing data (Figure 1). To accomplish this, we organize the cDBG into pieces around a set of dominators that are collectively close to all vertices. In this context, the neighborhood of a query is the union of all pieces it overlaps; to enable efficient search, we build an invertible index of the pieces.

We compute dominators so that the minimum distance from every vertex in the cDBG to some dominator is at most \( r \) (an \( r \)-dominating set) using Algorithm 1, which is based on the linear-time approximation algorithm given by Dvořák and Reidl (24). Although finding a minimum \( r \)-dominating set is NP-hard (25–27) and an approximation factor below \( \log n \) is probably impossible (26) in general graphs, our approach guarantees constant-factor approximations in linear running time by exploiting the fact that (compact) De Bruijn graphs have bounded expansion, a special type of sparsity (28). Algorithm 1 first annotates the graph to determine the distances between all pairs of vertices at distance at most \( r \) (lines 1-3) and then uses these distances to ensure each vertex is close to a domina-

DM, MPO, FR, and BDS designed and implemented algorithms; CTB, DM, MPO, and FR developed software; CTB and TR conducted biological data analysis; CTB and BDS supervised work. All authors interpreted results, wrote text, created figures, and approved the submitted paper.

The core of the efficient distance computation is based on distance-truncated transitive fraternal (dtf) augmentations (24) which produce a directed graph in which each arc $uv$ is labeled with $\omega(uv)$, the distance from $u$ to $v$ in the original cDBG. Importantly, our implementation enhances the algorithm in (24) by computing only $r$-dominating sets (29) to compute an invertible index* between pieces and their sequence content in the metagenome.

One feature of this approach is that the dominating set and index only need to be computed once for a given metagenome, independent of the number and content of anticipated queries. Queries can then be performed using Algorithm 3 in time that scales linearly with the size of their neighborhood — all genomic content assigned to pieces that contain part of the query.

Our implementations of these algorithms in spacegraphcats can be run on metagenomic data with millions of DBG nodes (Table 1): indexing takes under an hour, enabling queries to complete in seconds to minutes (Table 2). See Appendix A for full benchmarking (including cDBG construction). This provides us with a tool to systematically investigate graph neighborhoods.

* an invertible function that defines both an index and the corresponding inverted index

Neighborhood queries enable recovery of relevant unknown genomic content. We first measured how well an inexact query can recover a target genome from a metagenome. For a benchmark data set, we used the podarV data set (30). This is a “mock” metagenome containing genomes from 65 strains and species of bacteria and archaea, each grown independently and rendered into DNA, then combined and sequenced as a metagenome. This metagenome is a commonly used benchmark for assembly (12, 31–33).

To evaluate the effectiveness of neighborhood query at recovering strain variants, we chose three target genomes from podarV—Porphyromonas gingivalis ATCC 33277, Treponema denticola ATCC 35405, and Bacteroides thetaiotaomicron VPI-5482—that have many taxonomically close relatives in GenBank. We then used these relatives to query the podarV mixture and measure the recovery of the target genome. The results, in Figure 2(a), show that graph neighborhood query can recover 35% or more of some target genomes starting from a relative with Jaccard similarity as low as 1%; even a small number of shared k-mers suffices to define a much larger neighborhood that contains related genomes.

We next applied neighborhood query to retrieve an unknown genome from podarV. Several papers have noted the presence of unexpected sequence in the assemblies of this data, and Awad et al. identify at least two species that differ from the intended mock metagenome contents (12, 31). One species variant has partial matches to several different Fusobacterium nucleatum genomes, while the other incompletely matches to three strains of Proteiniclasticum ruminis.

The complete genomes of these two variants are not in public databases and, for the Proteiniclasticum variant, cannot be entirely recovered with existing approaches: when we assemble the reads that share k-mers with the available genomes, a marker-based analysis with CheckM estimates that 98.8% of the Fusobacterium variant is recovered, while only 72.96% of the Proteiniclasticum variant is recovered. We therefore tried using neighborhood queries to expand our knowledge of the Proteiniclasticum variant.

We performed a neighborhood query into podarV with all three known Proteiniclasticum genomes from GenBank. We then extracted the reads overlapping this neighborhood and assembled them with MEGAHIT. The retrieved genome neighborhood for Proteiniclasticum contains 2264K novel k-mers (Figure 2(b)). The reads from the query neighborhood assembled into a 3.1 Mbp genome bin. The assembly is estimated by CheckM to be 100% complete, with 10.3% contamination. The mean amino acid identity between P. ruminis ML2 and the neighborhood assembly is above 95%, suggesting that this is indeed the genome of the Proteiniclasticum variant, and that neighborhood query retrieves a full draft genome sequence (see Supp. Material A).

Query neighborhoods in a real metagenome do not always assemble well. Real metagenomes may differ substantially from mock metagenomes in size, complexity, and content. In particular, real metagenomes may contain a complex mixture of species and strain variants (34) and the performance of assembly and binning algorithms on these data sets is challenging to
evaluate in the absence of ground truth. One recent comparison of single-cell genomes and metagenome-assembled genomes in an ocean environment found that up to 40% of single-cell genome content may be missing in metagenome-assembled genomes (15).

We first ask whether genome query neighborhood sizes in a real metagenome differ from mock metagenomes. We examined genomes inferred from the SB1 sample from the Hu et al. (2016) study, in which 6 metagenomic samples taken from various types of oil reservoirs were sequenced, assembled, binned, and computationally analyzed for biochemical function (35). Examining the 23 binned genomes in GenBank originating from the SB1 sample, we compared the HuSB1 neighborhood size distribution with the podarV data set (Figure 3(a)). We saw that more genome bins in HuSB1 have 1.5x or larger query neighborhoods than do the genomes in podarV. This suggests the presence of considerably more local neighborhood content in the real metagenome than in the mock metagenome.

We next investigated metagenomic content in the query neighborhoods. As with the unknown variants in podarV, we used CheckM to estimate genome bin completeness. The estimated bin completeness for many of the query genomes is low (Appendix A). To see if the query neighborhoods contain missing marker genes, we assembled reads from the query neighborhoods using MEGAHIT. However, we found little improvement in the completion metrics (Figure 3(b)).

Investigating further, we found that the query neighborhood assemblies contain only between 4% and 56% of the neighborhood k-mer content (Appendix A), suggesting that MEGAHIT is not including many of the reads in the assembly of the query neighborhoods. This could result from high error rates and/or high strain variation in the underlying reads (11, 12).

To attempt the recovery of more gene content from the assemblies, we turned to the Plass amino acid assembler (36). Plass implements an overlap-based amino acid assembly approach that is considerably more sensitive than nucleotide assemblers and could be more robust to errors and strain variation (37).

When we applied Plass to the reads from the query neighborhoods, we saw a further increase in neighborhood completeness (Figure 3(b)). This suggests that the genome bin query neighborhoods contain real genes that are accessible to the Plass amino acid assembler. We note that these are unlikely to be false positives, since CheckM uses a highly specific Hidden Markov Model (HMM)-based approach to detecting marker genes (38).

Some query neighborhoods contain substantial strain variation. If strain variation is contributing to poor nucleotide assembly of marker genes in the query neighborhoods, then Plass should assemble these variants into similar amino acid sequences. Strain variation for unknown genes can be difficult to study due to lack of ground truth, but highly conserved proteins should be readily identifiable.

The gyrA gene encodes an essential DNA topoisomerase that participates in DNA supercoiling and was used by (35) as a phylogenetic marker. In the GenBank bins, we found that 15 of the 23 bins contain at least one gyrA sequence (with 18 gyrA genes total). We therefore used gyrA for an initial analysis of the Plass-assembled neighborhood content for all 23 bins. To avoid confounding effects of random sequencing error in the analysis and increase specificity at the cost of sensitivity, we focused only on high-abundance data; we truncated all reads in the query neighborhoods at any k-mer that appears fewer than five times, and ran Plass on these abundance-trimmed reads from each neighborhood. We then searched the gene assemblies with a gyrA-derived HMM, aligned all high-scoring matches, and calculated a pairwise similarity matrix from the resulting alignment.

When we examine all of the high-scoring gyrA protein matches in the hard-trimmed data, we see considerable se-
Much of this variation is present in fragmented Plass assemblies; when the underlying nucleotide sequences are retrieved and used to construct a compact De Bruijn graph, the variation is visible as spurs off of a few longer paths (insets in Figure 4(a)). When we count the number of well-supported amino acid variants in isolated positions (i.e., ignoring linkage between variants) we see that ten of the 23 neighborhoods have an increased number of gyrA genes, with four neighborhoods gaining a gyrA gene where none exists in the bin (Appendix A; see lowest inset in Figure 4(a) for one example). Only one neighborhood, *M. bacterium*, loses its gyrA gene due to the stringent k-mer abundance trimming. Collectively, the use of the Plass assembler on genome neighborhoods substantially increases the number of gyrA sequences associated with bins.

We see this same pattern for many genes, including *alaS, gyrB, rpb2* domain 6, *recA*, *rplB*, and *rpsC* (Appendix A). This shows that multiple variants of those proteins are present within at least some of the neighborhoods and implies the presence of underlying nucleotide strain variation. This strain variation may be one reason that nucleotide assembly performs poorly: on average, only 19.6% of Plass-assembled proteins are found within the nucleotide assemblies.

**Query neighborhoods assembled with Plass contain additional functional content.** In addition to capturing variants close to sequences in the bins, we identify many novel genes in the query neighborhoods. We used KEGG to annotate the Plass-assembled amino acid sequences, and subtracted all homolog already annotated in the genome bin. We also ignored homolog abundance such that each homolog is counted only once per neighborhood.

Novel functional content is distributed throughout pathways present in the genome bins, and increases functionality associated with binned genomes by approximately 13% (Figure 4(b)). This includes orthologs in biologically relevant pathways such as methane metabolism, which are important for biogeochemical cycling in oil reservoirs (35).

Genes in these neighborhoods contain important metabolic functionality expanding the pathways already identified in (35). We find 40 unique orthologs involved in nitrogen fixation across eight neighborhoods, four of which had no ortholog in the bin. Importantly, we find the ratio of observed orthologs approximately matches that noted in (35), where two thirds of nitrogen fixation functionality is attributable to archaea (29 of 40 orthologs). This is in contrast to most ecological systems where bacteria are the dominant nitrogen fixers (35).

**Discussion**

**Efficient graph algorithms provide novel tools for investigating graph neighborhoods.** Recent work has shown that incorporating the structure of the assembly graph into the analysis of metagenome data can provide a more complete picture of gene content (21, 22). While this has provided evidence that it is useful to analyze sequence that has small graph distance from a query (in a “neighborhood”), this approach has not been widely adopted. Naïvely, local expansion around many queries in the assembly graph does not scale to these types of analyses due to the overhead associated with searching in a massive graph. The neighborhood index structure described in this work overcomes this computational obstacle and enables rapid exploration of sequence data that is local to a query.

Because a partition into pieces provides an implicit data reduction (the cDBG edge relationships are subsumed by piece membership), the query-independent nature of the index allows many queries to be processed quickly without loading the entire graph into memory. Our approach consequently provides a data exploration framework not otherwise available.

Exploiting the structural sparsity of cDBGs is a crucial com-
ponent of our algorithms. First, it is necessary to use graph structure to obtain a guarantee that Algorithm 2 finds a small number of pieces since the size of a minimum r-dominating set cannot be approximated better than a factor of \( \log n \) in general graphs\(^1\) unless NP \( \subseteq \) DTIME\((n^{O((\log \log n)^{\omega})})\) \((26)\). Without such a guarantee, we cannot be sure that achieving significant data reduction by grouping cDBG vertices into pieces. Being able to do this in linear time also ensures that indexing and querying can scale to very large data sets. Furthermore, because we utilize a broad structural characterization (bounded expansion) of cDBGs rather than a highly specialized aspect, our methods enable neighborhood-based information retrieval in any domain whose graphs exhibit bounded expansion structure; examples include some infrastructure, social, and communication networks \((24, 40, 41)\).

**Neighborhood queries extend genome bins.** In both the podarV and HnSB1 metagenomes, neighborhood queries were able to identify additional content likely belonging to query genomes. In the podarV mock metagenome, we retrieved a potentially complete genome for an unknown strain based on partial matches to known genomes. In the HnSB1 metagenome, we increased the estimated completeness of most genome bins – in some cases substantially, e.g., in the case of *P. bacterium 34_609* we added an estimated 20.9% to the genome bin. In both cases we rely solely on the structure of the assembly graph to expand the genome bins. We do not make use of sequence composition, contig abundance, or phylogenetic marker genes in our search. Thus graph proximity provides an orthogonal set of information for genome-resolved metagenomics that could be used to improve current binning techniques.

**Query neighborhoods from real metagenomes contain substantial strain variation that may block assembly.** Previous work suggests that metagenome assembly and binning approaches are fragile to strain variation \((11, 12)\). This may prevent the characterization of some genomes from metagenomes. The extent of this problem is unknown, although the majority of approaches to genome-resolved metagenomics rely on assembly and thus could be affected.

In this work, we find that some of the sequence missing from genome bins can be retrieved using neighborhood queries. For HnSB1, some genome bins are missing as many as 68.5% of marker genes from the original bins, with more than half of the 22 bins missing 20% or more; this accords well with evidence from a recent comparison of single-cell genomes and metagenome-assembled genomes \((15)\), in which it was found that metagenome-assembled genomes were often missing 20% to 40% of single-cell genomic sequence. Neighborhood query followed by amino acid assembly recovers additional content for all but two of the genome bins; this is likely an underestimate, since Plass may also be failing to assemble some content.

When we bioinformatically analyze the function of the expanded genome content from neighborhood queries, our results are consistent with the previous metabolic analyses by \((35)\), and extend the set of available genes by 13%. This suggests that current approaches to genome binning are specific, and that the main question is sensitivity, which agrees with a more direct measurement of lost content \((15)\).

**Neighborhood queries enable a genome-targeted workflow to recover strain variation.** The spacegraphcats analysis workflow described above starts with genome bins. The genome bins are used as a query into the metagenome assembly graph, following which we extract reads from the query neighborhood. We assemble these reads with the Plass amino acid assembler, and then analyze the assembly for gene content. We show that the Plass assembly contains strain-level heterogeneity at the amino acid level, and that this heterogeneity is supported by underlying nucleotide diversity. Even with stringent error trimming on the underlying reads, we identify at least thirteen novel gyrA sequences in ten genome neighborhoods.

Of note, this workflow explicitly associates the Plass assembled proteins with specific genome bins, as opposed to a whole-metagenome Plass assembly which recovers protein sequence from the entire metagenome but does not link those proteins to specific genomes. The binning-based workflow connects the increased sensitivity of Plass assembly to the full suite of tools available for genome-resolved metagenome analysis, including phylogenomic and metabolic analysis. However, spacegraphcats does not separate regions of the graph shared in multiple query neighborhoods; existing strain recovery approaches such as DESMAN or MSPminer could be used for this purpose \((16, 19)\).

One future step could be to characterize unbinned genomic content from metagenomes by looking at Plass-assembled marker genes in the metagenome that do not belong to any bin’s query neighborhood. This would provide an estimate of the extent of metagenome content remaining unbinned.

**Conclusions**

The neighborhood query approach described in this work provides an alternative window into metagenome content associated with binned genomes. We extend previous work showing that assembly-based methods are fragile to strain variation, and provide an alternative workflow that substantially broadens our ability to characterize metagenome content. This first investigation focuses on only two data sets, one mock and one real, but the neighborhood indexing approach is broadly applicable to all shotgun metagenomes.

In this initial investigation of neighborhood indexing, we have focused on using neighborhood queries with a genome bin. We recognize that this approach is of limited use in regions where no genome bin is available; spacegraphcats is flexible and performant enough to support alternative approaches such as querying with k-mers belonging to genes of interest.

Potential applications of spacegraphcats in metagenomics include developing metrics for genome binning quality, analyzing pangenome neighborhood structure, exploring r-dominating sets for \( r > 1 \), extending analyses to colored De Bruijn graphs, and investigating de novo extraction of genomes based on neighborhood content. We could also apply spacegraphcats to analyze the neighborhood structure of assembly graphs overlayed with physical contact information (from e.g. HiC), which could yield new applications in both metagenomics and genomics \((42, 43)\).

More generally, the graph indexing approach developed here may be applicable well beyond metagenomes and sequence analysis. The exploitation of bounded expansion to efficiently compute r-dominating sets on large graphs makes this technique applicable to a broad array of problems.

\(^1\) That is, graphs about which we make no structural assumptions.
Materials and Methods

Data. We use two data sets: SRR606249 from podarY (44) and SRR1760948 (sample SB1) from hu (39). Each data set was first preprocessed to remove low-abundance k-mers as in (45), using trim-low-abund.py from khmer v2.1.2 (46) with the parameters -C 3 -Z 18 -M 20e6 -V -k 31. We build compact De Bruijn graphs using BCALM v2.2.0 (47). Stringent read trimming at low-abundance k-mers was done with trim-low-abund.py from khmer, with the parameters -C 5 -S -M 20e9 -k 31.

Software. The source code for the index construction and search is available at https://github.com/spacegraphcats/spacegraphcats (23). It is implemented in Python 3 under the 3-Clause BSD License. Version 1.1.1, used in this paper, is archived at DOI: 10.5281/zenodo.2505206.

Snakemake (48) workflows to reproduce all of the analysis are available at https://github.com/spacegraphcats/2018-paper-spacegraphcats/, and Jupyter Notebooks to recreate Figures 1, 2, 3, and 4(b) are in that same repository (49).

Graph denoising. For each data set, we built a compact De Bruijn graph (cDBG) for k=31 by computing the set of unitigs with BCALM (57), removing all vertices of degree one with a mean k-mer abundance of 1 or less, and then contracting long degree-two paths when possible.

Neighborhood indexing and search. We used spacegraphcats to build an r-dominating set for each denoised cDBG and index it. We then performed neighborhood queries with spacegraphcats, which produces a set of cDBG nodes and reads that contributed to them. The full list of query genomes for the Proteiniclasticum query is available in Supp Material A, and the NCBI accession numbers for the P. gingivalis, T. denticola, and B. thetaiotaomicron queries are in the directory pipeline-base of the paper repository, files spacegraphcats/strain-gingivalis.txt, strain-denticola.txt, and strain-bacteroides.txt, respectively.

Search results analysis. Query neighborhood size, Jaccard containment, and Jaccard similarity were estimated using modulo hash signatures with a k-mer size of 31 and a scaled factor of 1000, as implemented in sourmash v2.0.9 (58).

Assembly and genome bin analysis. We assembled reads using MEGAHT v1.1.3 (31) and Plass v2-c7e35 (36), treating the reads as single-ended. Bin completeness was estimated with CheckM 1.0.11, with the -reduced_tree argument (38). Amino acid identity between bins and genomes was calculated using CompareM commit 7cd51276 (https://github.com/dparks1134/CompareM).

Gene targeted analysis. Analysis of specific genes was done with HM- MER v3.2.1 (59). Plass amino acid assemblies were queried with HMMER hmmbuild using the PFAM domains listed in Supp Material A, and the NCBI accession numbers for the P. gingivalis, T. denticola, and B. thetaiotaomicron queries are in the directory pipeline-base of the paper repository, files pipeline-base/strains/strain-gingivalis.txt, strain-denticola.txt, and strain-bacteroides.txt, respectively.

KEGG Analysis. We annotated the Plass assemblies using Kyoto Encyclopedia of Genes and Genomes (KEGG) v2.0 (60). To assign KEGG ortholog function, we used methods implemented at https://github.com/edgearham/KoalaParser release 1.1.

A. Appendix

Approximation guarantee. Let us introduce some notation for the analysis of Algorithm 1. We first partition the vertices of $D$ according to whether they were added in line 10 (denoted by $D_1$) or in line 15 (denoted by $D_2$). Let $v_1, \ldots, v_k$ be the vertex-order in which they are iterated over in the loop starting at line 6. We will use the notation $D'_1$, $D'_2$, $d'_i$, and $c'$ to represent the states of the respective sets and data structures during the $i$th iteration of said loop. Let $\tau := \text{doseThreshold}(r)$ be the chosen threshold (we discuss a good value for $\tau$ on CDBGs below).

Lemma 1. After the for-loop at line 7 has finished,
\[
d'_i[v_i] = \begin{cases} \text{dist}_G(v_i, D'_i) & \text{if dist}_G(v_i, D'_i) \leq \tau, \text{ and} \\ \infty & \text{otherwise}.\end{cases}
\]

Proof. The statement trivially holds while $D^i = \emptyset$, so assume otherwise. Let $u_h \in D^i$ be the vertex closest to $v_h$ and let $h < i$ be the iteration in which $u_h$ was added to $D$ (either in line 10 or line 15 of that iteration).

If $d := \text{dist}_G(v_i, u_h) > r$, then $d'_i[v_i]$ has not been changed yet and is still set to $\infty$. Otherwise, consider the three possible scenarios promised by the distance-property of dist augmentations:

Case 1: $v_i u_h \in \tilde{G}_d$. Then $\omega(v_i u_h) = d$ and in iteration $h$ the value of $d'_i[v_i]$ is set to the correct value at line 8. By assumption this distance remains minimal until iteration $i$ and hence $d'_i[v_i] = d = d'_i[v_i]$.

Case 2: $u_h, v_i \in \tilde{G}_d$. Then $\omega(v_i u_h) = d$ and in iteration $i$ the value of $d'_i[v_i]$ is set to the correct value at line 8.

Case 3: $x u_h, x v_i \in \tilde{G}_d$ with $\omega(x u_h) + \omega(x v_i) = d$. During iteration $h$ the value of $d'_i[x]$ is set to $\omega(x u_h)$ at line 8 and subsequently retrieved in iteration $i$ when $d'_i[v_i]$ is set to $d'_i[x] + \omega(x u_h) = \omega(x v_i) + \omega(x v_i) = d$.

We conclude that after the execution of the loop at line 8, $d'_i[v_i]$ is set to $\infty$ if $v_i$ is not dominated by $D_1$ and is otherwise set to $\text{dist}_G(v_i, D'_i)$, as claimed.

As an immediate consequence, we see the conditional statement at the end of the loop at line 8 accurately determines whether $v_i$ is dominated by $D_1$ or not. Accordingly, line 15 of the loop is only executed if $v_i$ is not dominated by $D_1$. Another consequence is that all vertices in $D_1$ have large distance to each other:

Corollary 1. The set $D_1$ is $(r + 1)$-scattered in $G$.

We need one more important property of the algorithm in order to derive the approximation factor.

Lemma 2. For every $w \in G$ it holds that $|D_1 \cap N^c_r(w)| \leq \tau + 1$.

Proof. Assume towards a contradiction that $\tau + 2$ such vertices $v_{i_1}, \ldots, v_{i_{\tau+2}}$, $i_1 < i_2 < \cdots < i_{\tau+2}$ exist in $D_1 \cap N^c_r(w)$. Since every such vertex $v_i$, $i \in \{i_1, \ldots, i_{\tau+2}\}$, was added to $D$ in part (2), part (3) of the algorithm was executed during iteration $i$ as well. Thus $c[w]$ was increased in each iteration $i$ and during iteration $i_{\tau+1}$ we have that $c[w] \geq \tau + 1$ after the increment of $c[w]$. Therefore part (4) must have been executed for $w$, including $w$ into $D$. Hence $w \in D^i$ for $s > i_{\tau+1}$ and in particular $w \in D^{i_{\tau+2}}$. But then $v_{i_{\tau+2}}$ was dominated by $w$ at the beginning of iteration $i_{\tau+2}$ since we assumed that $\omega(v_{i_{\tau+2}}) \leq \tau$, thus $v_{i_{\tau+2}}$ would not have been included in $D$ at step (2). This contradicts our assumption of $v_{i_{\tau+2}} \in D_1$ so the claim must hold.

Lemma 3. There exists a subset $A \subseteq D_1$ such that $A$ is $(2r + 1)$-scattered in $G$ and
\[
|A| \geq \frac{|D|}{2(\tau + 2)\Delta^-(\tilde{G}_d)\Delta^-({G})}.
\]

Proof. We construct an auxiliary graph $H$ with vertices $D_1$ by adding arcs $v_i v_j$ for $v_i, v_j \in D_1$ with $i < j$ whenever $\text{dist}_G(v_i, v_j) \leq 2r$. Let $\tilde{G}_{2r}$ be a $2r$th dist-augmentation of $G$ and let us create a digraph $H$ by orienting every edge $vw \in H$ as follows:

1. If of $w, v \in \tilde{G}_{2r}$, then orient $vw$ in $H$ according to the corresponding arc in $\tilde{G}_{2r}$ (if both arcs exist choose an arbitrary orientation).

2. otherwise there exists $w \in N^c_{2r}(u) \cap N^c_{2r}(v)$ with $\omega_{2r}(w) + \omega_{2r}(v) = \text{dist}_G(w, v) \leq 2r$. Orient the edge $vw$ towards that vertex $x \in \{w, v\}$ for which $\omega_{2r}(x)$ is larger.

We now argue that $\Delta^-(H)$ is small. Consider any vertex $v \in H$. Every in-arc in $H$ either is of type 1, of which we have at most $\Delta(\tilde{G}_{2r})$, or of type 2. Consider a group of in-arcs $v_i, v_{i+1}, \ldots, v_{i+k}$ of type 2 that are all present because of a common vertex $w$. Since $w \in N^c_{2r}(u)$, we have at most $\Delta(\tilde{G}_{2r})$ such groups. By construction, $\omega_{2r}(w v_i) \leq \omega_{2r}(w v)$ and since both weights sum to less than $2r$, this means that $\omega_{2r}(w v_i) \leq r$. Lemma 2 now tells us that $\ell \leq r + 1$. Therefore $v$ has at most $(\tau + 1)\Delta^-({G})$ in-arcs of type 2 and we conclude that

$\Delta^-(H) \leq \Delta^-({G}) + (\tau + 1)\Delta^-(\tilde{G}_d) = (\tau + 2)\Delta^-({G})$.

This finally implies that $H$ is $2(\tau + 2)\Delta^-({G})$-degenerate and therefore contains an independent set $A \subseteq V(H)$ of size at least $|A| \geq |H|/(2(\tau + 2)\Delta^-({G}))$. Together taken with the fact that $|H| = |D_1| \geq |D|/\Delta^-({G})$ (every vertex added to $D_1$ will cause at most $\Delta^-({G})$ many vertices to be added to $D_2$ in the loop at line 11 and $D = D_1 \cup D_2$), we find that
\[
|A| \geq \frac{|D|}{2(\tau + 2)\Delta^-({G})\Delta^-({G})}
\]

By construction of $H$ we conclude that $A$ is $(2r + 1)$-scattered in $G$ of the claimed size.

Since a $(2r + 1)$-scattered set provides a lower bound for an $r$-dominating set, we conclude that Algorithm 1 computes a $2(\tau + 2)\Delta^-({G})\Delta^-({G})$-approximation of an optimal $r$-dominating set, which is a constant-factor approximation in graphs of bounded expansion.

In practice one could, depending on the value of $\Delta^-({G})$ and $\Delta^-({G})$, compute the optimal value for $\tau$. However, this would necessitate the computation of $2r$ augmentation, the expensive step we want to avoid. Alternatively, we can choose a ‘good enough’ value for $\tau$ that still guarantees a constant-factor approximation while being easy to determine in practice. In the context of CDBGs, we found that $\tau := (2r)^2$ yields reliably good results.

Computational Runtimes. See “Benchmarking” in Materials and Methods for benchmarking methods.

The podarV data set was retrieved from the NCBI SRA using accession SRR606249. The full build and indexing of the 103 million error-trimmed reads (10.3 Gbp in total) took approximately 23 minutes and required 12.8 GB of RAM. Loading the indices for search required 4.3 GB of RAM and a search with a 3 Mbp genome took approximately 32 seconds.

The HaSBr data set was retrieved from the NCBI SRA using accession SRR1976948. The full build and indexing of the 34 million error-trimmed reads (8.5 Gbp in total) required approximately 217 minutes and required 24.4 GB of RAM. Loading the indices for search required 18 GB of RAM and a search with a 3 Mbp genome took approximately 80 seconds.

For data set complexity (number of k-mers, number of cDBG nodes) please see Table 1.

spacegraphcats pipeline overview. spacegraphcats follows a series of steps when run on sequencing data, see Figure 5. In detail, we perform the following steps.

BCALM. Use BCALM to generate a CDBG. Then convert a BCALM unmitigs.fa output (a CDBG) into spacegraphcats files. Outputs an undirected graph, a file containing the sequences, and a .info. eaf file containing information about the contig. Also outputs sourmash k=31, scaled=1000 signatures for both input and output files.

spacegraphcats.cdbg.label_cdbg. Build an index that can be used to retrieve individual reads or contigs by CDBG node ID; produce a SQLite database for fast retrieval. Briefly, this script
creates a sqlite database with a single table, sequences, where a query like select distinct sequences.offset from sequences where label ... can be executed to return the offset of all sequences with the given label; the offsets refer to BGZF coordinates in the gzipped sequence collection. Here, 'label' is the cDBG ID to which the sequence belongs.

The script extract_reads_by_frontier_sqlite.py is a downstream script to extract the reads with a frontier search. Specifically: 1. walk through the contigs assembled from the cDBG; 2. build a DBG cover using kmmer tags, such that every k-mer in the DBG is within distance d=40 of a tag; 3. label each tag with the cDBG node ID from the contig; 4. save for later use.

Table 3. Accession numbers for Proeinasticulum search. See Table 3.

Amino Acid Identity results for Proeinasticulum. See Table 4.

HuSB1 analysis pipeline overview. See Figure 6. We implemented three workflows to analyze the plass-assembled HuSB1 query neighborhoods.

Genome bin completeness improvements for HuSB1. See Table 5.

K-mer inclusion of reads by MEGAHIT assemblies. See Table 7. We estimated the number of k-mers in each query neighborhood that were contained in the MEGAHIT assembly of that query neighborhood. We used sourmash compare to calculate signatures with k-size of 31 and a scaled value of 2000. We then used sourmash estimate to estimate containment in MEGAHIT assemblies. The query neighborhood with the smallest containment, M. harundinacea isolate 57_489, had the largest query neighborhood, while the query neighborhood with the largest containment, M. bacterium 39_7, had the smallest query neighborhood.

| Name          | NCBI accession        |
|---------------|-----------------------|
| P. ruminis GCMCC | GCA_900099635.1      |
| P. ruminis DSM  | GCA_000701905.1      |
| P. ruminis ML2  | GCA_900115135.1      |

Table 3. Accession numbers for genomes used in Proteinasticulum neighborhood query.

gyrA alignment. See Figure 7. The MDS plot in the left panel of figure 4 shows distinct gyrA sequences identified in the Plass assemblies using HMMPR. To visualize the sequences within these clusters and in other query neighborhoods, we constructed a multiple sequence alignment. However, because many sequences assembled by Plass were fragmented (see Results: Some query neighborhoods contain substantial strain variation), we first clustered the sequences at 95% similarity using CD-HIT. We then aligned the centroid sequences using MAFFT with default settings. To produce the multiple sequence alignment visualization, we calculated an unrooted neighbor joining tree using the MAFFT alignment. Then we used the function msaplot in the R package ggtree to plot the alignment.

gyrA by neighborhood. See Table 6. As can be seen in the left panel of figure 4 in the main text, we observe many unique amino acid sequences per single copy ortholog per query neighborhood. Although we observe many possible traversal paths in compact De Brujin graphs built from reads that give rise to these sequences, we have no way to ascertain whether we observed combinatorial complexity by assembling variants that would never be linked in nature. Therefore, we sought to conservatively estimate the number of positions per amino acid sequence that contained variants using MAFFT alignments. First, we subsetted the alignment to sequences from one query neighborhood. Then we identified all aligned non-gap characters for each position in the alignment (gaps were induced in some neighborhoods by the presence of amino acid residues in other query neighborhood amino acid sequences). For each of these positions, we counted the number of unique amino acid sequences per position, and the number of times each occurred at that position. We then eliminated any variant that occurred fewer than 10 times. Lastly, we counted the number of well-supported distinct characters. We did this for gyrA, as well as the amino acid sequences for the other genes we tested (see other genes). Table 6 shows that we see increased number of gyrA sequences in many neighborhoods even with this conservative approach.

Other genes. See bin and neighborhood content results for alaS in Table 9, gyrB in Table 10, recA in Table 11, rpb2d6 in Table 12, rplB in Table 13, and rpsC in Table 14. We selected gyrB and recA because they were used by HuSB1 to assign taxonomy to binned genomes. We selected other genes used as single copy orthologs by programs like CheckM, and with longer PFAM domains.

| Genome A          | Genome B          | Orthologous Genes | Mean AAI |

Table 6. Bin and neighborhood gyrA protein content. gyrA count for each bin is the number of gyrA amino acid sequences that are part of the original bin. gyrA count by Plass is the minimum number of gyrA amino acid sequences supported by at least one position with at least 10 copies of each variant, e.g. “3” indicates that there is at least one position in the multiple sequence alignment of gyrA sequences for that neighborhood that has 3 distinct variants in 10 distinct sequences.
Fig. 6. Three workflows implemented to analyze the plass-assembled HuSB1 query neighborhoods. The first three steps, depicted in blue, were common across all workflows. The green boxes depict the KEGG GhostKOALA annotation workflow, the results of which can be seen in Figure 4. The orange boxes depict steps in common between the clustering and variant workflows used to generate Figure 4. The red boxes depict steps used to generate the MDS clustering plot and the multiple sequence alignment (see Figure 7). The gold boxes depict the steps of the variant workflow used to generate the assembly graphs.
Fig. 7. A multiple sequence alignment and neighbor joining tree of representative gyrA amino acid fragments assembled by Plass from the genome neighborhoods in HuSB1. Protein sequences that originated from the genome bin are prepended with "Bin." All other sequences were assembled by Plass.

Table 7. Containment of neighborhood k-mer content in MEGAHIT nucleotide assemblies.

| Species                           | MEGAHIT assembly containment |
|-----------------------------------|------------------------------|
