Accepted 22 January 2013

Abstract

Aims To explore the association of HbA\textsubscript{1c} and educational level with risk of cardiovascular events and mortality in patients with Type 2 diabetes.

Methods A cohort of 32 871 patients with Type 2 diabetes aged 35 years and older identified by extracting data from electronic patient records for all patients who had a diagnosis of Type 2 diabetes and had glucose-lowering agents prescribed between 1999 and 2009 at 84 primary care centres in Sweden. Associations of mean HbA\textsubscript{1c} levels and educational level with risks of cardiovascular events and all-cause mortality were analysed.

Results The associations of HbA\textsubscript{1c} with risk of all-cause and cardiovascular mortality were J-shaped, with the lowest risk observed for cardiovascular mortality at an HbA\textsubscript{1c} level of 51 mmol/mol (6.8\%) for subjects on oral agents and 56 mmol/mol (7.3\%) in insulin-treated patients. The lowest risk observed for all-cause mortality was at an HbA\textsubscript{1c} level of 51 mmol/mol (6.8\%) for subjects on oral agents and 56 mmol/mol (7.3\%) in insulin-treated patients. There was an increased risk for cardiovascular death [hazard ratio 1.6 (1.2–2.1), \(P = 0.0008\)] at the lowest HbA\textsubscript{1c} decile for subjects in the low education category. For subjects with higher education there was no evident J curve for cardiovascular death [hazard ratio 1.2 (0.8–1.6), \(P = 0.3873\)].

Conclusions Our results lend support to the recent American Diabetes Association/European Association for the Study of Diabetes position statement that emphasizes the importance of additional factors, including the propensity for hypoglycaemia, which should influence HbA\textsubscript{1c} targets and treatment choices for individual patients.(Clinical Trials Registry No; NCT 01121315)

Diabet. Med. 30, e170–e177 (2013)

Introduction

In Type 2 diabetes, improved glycaemic control reduces the risk of microvascular complications, whereas the role of intensive glycaemic control in reducing macrovascular complications is less clear [1,2]. Benefits from early intervention to achieve glycaemic control are proven, but intensity of control has been debated [3]. In 2008, the results from three major cardiovascular outcome studies of intensive glycaemic control in patients with Type 2 diabetes were presented [1,4,5]. All three studies failed to show that achievement of intensified glycaemic control was associated with reduction of cardiovascular risk, and the Action to Control Cardiovascular Risk in Diabetes (ACCORD) study actually reported a 22\% increase in total deaths in the intensively treated group [5], which led to the conclusion that the findings identified a previously unrecognized harm of intensive glucose-lowering in high-risk patients with Type 2 diabetes. The harm associated with severe hypoglycaemia might counterbalance the potential benefit of intensive glucose-lowering treatment [6–8]. Since then some observational studies have reported a J- or U-shaped [9,10] association between HbA\textsubscript{1c} levels and mortality where low and high levels of HbA\textsubscript{1c} were linked with higher rates of death. This has been shown for subjects with Type 2 diabetes on a combination oral regimen with a sulphonylurea plus metformin and well as in subjects on insulin treatment [9] and in subjects who were aged \(\geq 60\) years.
[10]. However, a recent Swedish observational study showed a progressively increased total mortality with increasing HbA1c levels and no J-shaped risk curves [11].

Although not consistently, some previous results have suggested that there are important indicators of social deprivation, such as low education, which predict mortality over and above diabetic health status itself [12].

Our hypothesis was that the association between glycemic control and cardiovascular events may differ in different groups of educational level. Thus, in this cohort study of patients with Type 2 diabetes in primary care, the primary objective was to clarify if a linear or J-shaped association exists between HbA1c levels and cardiovascular morbidity and mortality. A second aim was to explore if such associations were dependent on socio-economic background in terms of educational achievement.

**Patients and methods**

**Study sample**

This observational study was based on patients with Type 2 diabetes in Swedish primary care based on the Retrospective Epidemiological Study to Investigate Outcome and Mortality with Glucose Lowering Drug Treatment in Primary Care (ROSE) study sample. For this study, data were extracted in 2010 from electronic patient records from 84 primary care centres in Sweden by the Pygarus Customized eXtraction Program [13]. The primary care centres were chosen to provide a good representation of Swedish primary care. All data between the years 1999 and 2009 were extracted for all 58 326 patients with a diagnosis of Type 2 diabetes [International Classification of Diseases (ICD)-9 code 250, ICD-10 codes E10-E14] and/or prescription of drug within Anatomic Therapeutic Chemical classification system class A10. We excluded patients who were not subjected to pharmacological treatment for diabetes (n = 16 973), were under the age of 35 years (n = 876) and patients who had incomplete data on HbA1c at baseline (n = 7606), rendering a final sample of 32 871 patients for further analyses.

**Baseline examinations**

Baseline was defined as the first time a patient was diagnosed with Type 2 diabetes or was prescribed an anti-diabetic drug. All baseline values were calculated as the mean of the values in a period of 6 months before to 6 months after the index date. Time-varying variables were determined as annually updated means—the baseline value was used for the period from the index date to 1 year; for the period from year i to i+1, the value used will be the mean of all values between year i–1 and year i.

Patients’ age and sex were determined using the unique personal identification number allocated to all Swedish citizens. Baseline data were extracted from electronic patient charts for the variables of systolic and diastolic blood pressure; total, LDL and HDL cholesterol; serum triglycerides; HbA1c values; lipid-lowering, glucose-lowering and blood pressure-lowering drugs; and estimated glomerular filtration rate (eGFR), calculated from serum creatinine, age and sex, assuming that all patients were Caucasian, using the Chronic Kidney Disease Epidemiology Collaboration (CKD-EPI) equation [14]. Data on HbA1c were retrieved according to the Mono-S method and were converted to the Diabetes Control and Complications Trial (DCCT) standard through \( \text{HbA1c}_{DCCT} = 0.923 \times \text{HbA1c}_{MonoS} + 1.345; R^2 = 0.998 \) [15]. Data on HbA1c are also reported in International Federation of Clinical Chemistry (IFCC) units (mmol/mol) Patients were categorized as treated with oral glucose-lowering agents alone or with insulin alone or in combination with oral agents.

Data on educational level were obtained by linking the personal identification number to data from the Swedish censuses. Educational level was categorized into two groups: compulsory (9-year comprehensive) school or upper school (including all types of secondary education as upper secondary education or tertiary education), which is the most frequent way of categorizing educational achievement with respect to the educational system in Sweden at that time.

Previous cardiovascular disease was determined by linkage to the Swedish national inpatient registry, using the personal identification number, as a hospitalization for acute myocardial infarction (ICD-10 code I21), heart failure (codes I11.0, I50) or stroke (codes I60, I61, I63.0-I63.5, I63.8-I63.9, I64; corresponding ICD-9 and -8 codes were used for all diagnoses).

**Follow-up and outcomes**

The primary endpoint was a composite endpoint of the first non-fatal or fatal event of hospitalization for acute myocardial infarction, heart failure, or stroke (ICD-10 codes as above) or cardiovascular mortality (I00-99). The second endpoints were all-cause mortality and cardiovascular mortality. This endpoint was determined with high validity [16] by linkage to the Swedish national cause-of-death and inpatient registries. Participants were followed from the index date to the first event of an endpoint, emigration or to 31 December 2009.

**Ethical approval**

The study, which complied with the declaration of Helsinki, was approved by the Regional Ethical Review Board in Uppsala, Sweden.

**Statistical analysis**

The relations of HbA1c to risk of the outcomes were investigated using Cox proportional hazard models, with
HbA1c modelled using restricted cubic splines with knots placed at 5th, 35th, 65th and 95th percentiles [17]. Covariates in the model were gender (fixed) and age, systolic blood pressure and LDL cholesterol as annually updated means. The time-dependent drug exposures (oral agents or insulin) were entered as a time-varying binary variable, together with an interaction with HbA1c (as restricted cubic spline). Baseline HbA1c, age, gender and treatment were required, whereas last observation was carried forward for missing values of annually updated means of HbA1c, systolic blood pressure and LDL. Proportional hazard assumptions were assessed by inspecting Schoenfeld residuals.

The value of HbA1c corresponding to lowest risk of an endpoint was searched for in the resulting function. An approximate 95% confidence interval was obtained using 0.025 and 0.975 quintiles of the distribution of optimal HbA1c values estimated by d-deletion Jackknife [18] using 500 resamples and letting d be half the number of patients.

To assess the robustness of the results, the same analyses were also performed for the subgroup of individuals with no history of cardiovascular disease and further for data sets with imputed data for missing baseline values using multiple imputation technique based on additive regression, bootstrapping and predictive mean matching.

We also investigated relations of HbA1c to risk using deciles of HbA1c. Hazard ratios for outcome were analysed by deciles of time, varying HbA1c stratified for time-dependent drug exposures for oral agents and insulin treatment, respectively, where the decile with lowest risk of event was used as the reference level.

The relations of HbA1c to risk using deciles of HbA1c. Hazard ratios for outcome were analysed by deciles of time, varying HbA1c stratified for time-dependent drug exposures for oral agents and insulin treatment, respectively, where the decile with lowest risk of event was used as the reference level.

The relations of HbA1c, primary endpoint and education were further investigated using the Cox proportional hazard model with annually updated HbA1c entered as restricted cubic splines with education level and treatment as fixed and time-varying predictors, respectively. Interaction terms between HbA1c and treatment and education were also entered in the model, which was further adjusted for age. R, version 2.13.1 [19] was used for all analyses.

## Results

### Baseline characteristics

During the study period, 19 760 (60%) individuals did not receive insulin and thus remained on oral agents. Table 1 shows the baseline characteristics by treatment category and by education level. Between the educational level categories, the most important difference was that subjects in the compulsory school category were older compared with individuals in the upper school category.

### Primary and secondary outcomes

Median follow-up time for the primary endpoint was 4.8 years. The primary outcome occurred in 8218 (25.0%) cases, total deaths 7814 (23.8%), cardiovascular deaths 5595 (17.0%) and 3575 (10.9%) cases of non-fatal myocardial infarction. The absolute event rates per 1000 person years were 52.7 (51.6–53.8), 33 (32.2–33.9) and 46.2 (45.1–47.2) for primary endpoint, cardiovascular death and all-cause death, respectively.

We further investigated the relation of education level to risk of the primary endpoint, all-cause mortality and cardiovascular mortality. Between the educational levels the location of the density of age differed. Cumulative hazard functions were therefore estimated with Kaplan-Meier stratified for education level as well as with Cox proportional hazard model adjusted for age. Low education defined as compulsory school as highest educational attainment had higher age-adjusted hazard ratio for the primary endpoint compared with subjects with higher education (Fig. 1).

In multivariable regression spline models adjusted for age, gender, systolic blood pressure and LDL cholesterol, the relations of HbA1c levels to risk of cardiovascular mortality and all-cause mortality were J-shaped, but not to risk of the primary endpoint (Fig. 2). The HbA1c level corresponding to lowest risk of the primary endpoint was 48 mmol/mol (6.5%) [upper confidence limit 50 (6.7)] in subjects on oral agents and 53 mmol/mol (7.0%) [51 (6.8) to 56 (7.3)] for insulin-treated patients. The corresponding figures for all-cause mortality were 51 mmol/mol (6.8%) [51 (6.8) to 53 (7.0)] for oral agents and 56 mmol/mol (7.3%) [54 (7.1) to 61 (7.7)] for insulin treatment; and for cardiovascular death 51 mmol/mol (6.8%) [49 (6.6) to 52 (6.9)] for oral agents and 56 mmol/mol (7.3%) [54 (7.1) to 61 (7.7)] for insulin treatment. All settings were adjusted for age, gender, systolic blood pressure and LDL cholesterol. In sensitivity analyses confined to patients with no history of previous cardiovascular disease, the HbA1c levels at nadir of risk were similar.

Insulin treatment was associated with an increased likelihood of progression to the primary endpoint [1.36 (1.26–1.45)], all-cause mortality [1.51 (1.4–1.62)] and cardiovascular death [1.46 (1.34–1.59)], all P < 0.0001 compared with subjects on oral agents, when adjusting for age, gender, systolic blood pressure, LDL and HbA1c. The associations between HbA1c and outcomes were further explored. Hazard ratios for outcome are given by deciles of time-varying HbA1c stratified for treatment, confirming an increased risk for cardiovascular mortality and all-cause mortality at both high and low levels of HbA1c in both treatment categories, but not for the primary endpoint and not for subjects in the upper school category (see also Supporting Information, Table S1 and Fig. S1).

## Associations of HbA1c with risk by levels of socio-economic status

The risk for outcomes by deciles of time-varying HbA1c were analysed and stratified for education level, where the decile with lowest risk of event was used as the reference
Table 1 Baseline characteristics, by (a) treatment category and (b) educational level, in the Retrospective Epidemiological Study to Investigate Outcome and Mortality with Glucose Lowering Drug Treatment in Primary Care (ROSE) study, 1999–2009

(a) Total sample Oral agents Insulin

level and adjusted for age, systolic blood pressure and LDL cholesterol and gender (not in Table S1). There was an increased hazard ratio for the primary endpoint [1.3 (1.0–1.6), \( P = 0.0216 \)], all-cause mortality [1.6 (1.3–2.0), \( P < 0.0001 \)] and cardiovascular death [1.6 (1.2–2.1), \( P = 0.0008 \)] at the lowest HbA1c decile for subjects in the low education category. For subjects with higher education, the J-shape curve was evident only for all-cause mortality [1.3 (1.0–1.8), \( P = 0.0266 \)].

In multivariable regression spline models exploring the association between HbA1c and hazard ratios for primary and secondary endpoints adjusted for age, the J-shaped curve was most evident in patients with low education (Fig. 3). The nadir of risk for the primary endpoint was observed at a slightly higher HbA1c level for subjects with compulsory school as highest educational achievement: 50 mmol/mol (6.7%) [43 (6.1) to 51 (6.8)] vs. 46 mmol/mol (6.4%) [upper confidence limit 50 (6.7)] in the oral agent treatment category as well as in insulin-treated subjects: 53 mmol/mol (7.0%) [upper confidence limit 57 (7.4)] vs. 51 mmol/mol (6.8%) [upper confidence limit 55 (7.2)], compared with patients with higher educational level.

**Discussion**

We found a non-linear relationship between glycaemic control and cardiovascular mortality and all-cause mortality, with elevated risk at both high and low HbA1c levels among patients treated with glucose-lowering medication in primary care. The J-shaped curve was clear in both treatment categories. Furthermore, the J-shaped curve was most marked in patients with low educational level, who also had higher risk for the primary endpoint compared with subjects with higher education. The non-linear associations were confirmed by using both cubic splines and deciles when exploring the relationship between HbA1c and outcome in this retrospective cohort of patients with Type 2 diabetes in primary care.

The observational nature of this study confers a risk of selection bias, and residual or unmeasured confounding may exist, which may limit the validity. Data were missing for smoking status, hence analyses were not adjusted for smoking status; smoking status is known to be socially patterned and may therefore explain some of the observed association between educational level and mortality. Information on diabetes duration was not available, but, using directed acyclic graphs, that was not identified as a crucial confounder. Of note, even if the observed J-shaped relations could partly be explained by confounding, the observed relations were robust across several analyses and subgroups and represent important knowledge as current diabetes and prevention guidelines do not differentiate between reasons for having a particular glucose level.

The main advantage of randomized clinical trials over observational studies is the randomization per se. Meta-analyses of clinical trial study databases, such as investigations of risk in relation to achieved glycaemic control [6,20],

have a range of limitations, including heterogeneity of populations and interventions, but retain the advantage of well-matched treatment groups.

The present study also extends those findings to persons who would not match the inclusion criteria of the trials included in those meta-analyses. This is important, as it is well known that patients included in clinical trials differ considerably from those eventually treated with the same drugs in clinical practice [21].

We used low education defined as compulsory school as highest educational attainment as marker for an underprivileged socio-economic group in society. However, other potential markers such as income, type of work, being unemployed or marital status may be equal or more important markers for low socio-economic status. It may also be appropriate to consider the potential roles of comorbidity, reverse causality and ethnicity (immigrant ethnic groups may have lower educational levels, higher HbA1c and higher mortality than Swedish born groups) in interpreting our findings.

The benefit from intensified glycaemic control nevertheless remains controversial as management recommendations tend to be based on extrapolation from surrogate endpoints. Furthermore, intensified glucose lowering is more difficult to achieve and has greater negative impact on quality of life than lowering cholesterol or blood pressure [22]. However, recent trials have questioned the lower-the-better hypothesis for glycaemic control. In the ACCORD trial, high-risk patients with diabetes who were submitted to intensive glycaemic control with an HbA1c target < 6.0% had higher mortality than those with a target of 7.0–7.9% [5]. This increased risk was, even if not confirmed, most likely attributable to the increased risk for severe hypoglycaemia in the intensively treated group. Decreased survival in patients achieving low mean percentages of HbA1c might be related to hypoglycaemia—a common complication of intensive blood-glucose control [23]. In the Veterans Affairs study [20], more than one episode of severe hypoglycaemia was associated with an 88% higher relative risk for sudden death.

From our study, it is not clear that the J-shaped curve is caused by more frequent hypoglycaemic events in patients with tight glycaemic control. An alternative explanation to the J-shape of the curve may be attributable to reverse causation, i.e. that pre-existing illness explains both the tight glycaemic control and the increased mortality. Furthermore, if pharmacologically induced hypoglycaemia is more dangerous to patients with Type 2 diabetes than previously recognized, this would of course only be relevant to treatment with the potential of inducing hypoglycaemia, i.e. sulphonylureas, meglitinides and insulin. In contrast, metformin, which was the most frequently prescribed oral agent in this study, does not tend to cause hypoglycaemia and the evidence of benefit in terms of reduction in risk of cardiovascular events and mortality is quite strong [24]. However, the medication changed as drugs were added, combined or removed continuously during the follow-up time in the study cohort. For this reason, it was not possible to draw conclusions on potential associations between the utilization of a particular class of glucose-lowering agents and outcome, nor was this the scope of the study.

**FIGURE 3** Age-adjusted hazard ratio for (a) primary composite endpoint of major cardiovascular events (acute myocardial infarction, heart failure, stroke or cardiovascular death), (b) cardiovascular death and (c) all-cause mortality. Upper panels are oral agent treatment and lower panels are insulin treatment.
Our results, with a J-shaped association between HbA₁c and all-cause mortality and cardiovascular mortality for subjects on oral agents and insulin treatment are in line with a similar recent observational study by Currie et al. [9] where data were obtained from routine general practice in the UK. In the present study, the J-curve was not evident for the primary composite endpoint, which primarily consisted of non-fatal (56%) cardiovascular events. This finding is in agreement with the results from the ACCORD trial, where no increased risk for non-fatal cardiovascular events in the intensively treated group was reported [5].

The nadir for the HbA₁c level associated with the lowest risk for all-cause mortality and cardiovascular mortality for insulin-treated patients in our study was approximately 7.3%, which is very close to the corresponding nadir of 7.5% in the study from primary care in the UK [9]. However, for subjects on oral agents, the nadir for all-cause mortality was lower (6.8%) in our study compared with the study from the UK (7.5%).

While a relationship between socio-economic deprivation and health in the general population is well established, the situation for people with Type 2 diabetes is less clear and a weaker or lesser than expected effect of socio-economic deprivation in patients with diabetes is reported [25–27].

We conclude from this observational retrospective cohort study that we were able to confirm some previous results reporting that low and high mean HbA₁c values were associated with increased risk for all-cause mortality and cardiovascular mortality in subjects with Type 2 diabetes. Furthermore, the J-shaped curve was most clear in individuals with low educational level. Our results lend support to the recent American Diabetes Association/European Association for the Study of Diabetes position statement that emphasizes the importance of additional factors that should influence HbA₁c targets set for individual patients. These include patient attitudes and their expected therapeutic involvement, risk of hypoglycaemia, disease duration, life expectancy, the presence of co-morbidity and patient access to resources and support systems [28].

**Supporting Information**

Additional Supporting Information may be found in the online version of this article:

**Table S1.** Hazard ratios for outcome by deciles of time-varying HbA1c stratified for treatment with oral agents and insulin treatment, where the decile with lowest risk of event was used as the reference level within treatment category.

**Figure S1.** Estimated Cox regression, with deciles of HbA1c as annual updated mean exposure, with age, systolic blood pressure and LDL cholesterol as annual updated mean and gender as covariates.
