CONSISTENCY OF SEMI-SUPERVISED LEARNING ALGORITHMS ON GRAPHS: PROBIT AND ONE-HOT METHODS

FRANCA HOFFMANN, BAMDAD HOSSEINI, ZHI REN, AND ANDREW M. STUART *

Abstract. Graph-based semi-supervised learning is the problem of propagating labels from a small number of labelled data points to a larger set of unlabelled data. This paper is concerned with the consistency of optimization-based techniques for such problems, in the limit where the labels have small noise and the underlying unlabelled data is well clustered. We study graph-based probit for binary classification, and a natural generalization of this method to multi-class classification using one-hot encoding. The resulting objective function to be optimized comprises the sum of a quadratic form defined through a rational function of the graph Laplacian, involving only the unlabelled data, and a fidelity term involving only the labelled data. The consistency analysis sheds light on the choice of the rational function defining the optimization.

Key words. Semi-supervised learning, classification, consistency, graph Laplacian, probit, spectral analysis.

1. Introduction. Semi-supervised learning (SSL) is the problem of labelling all the points in a dataset, by leveraging correlations and geometric information in the data points, together with explicit knowledge of a subset of noisily observed labels. The primary goal of this article is to analyze the probit and one-hot methods for transductive SSL. We elaborate conditions under which these methods consistently recover the correct labels attached to the unlabelled dataset. We do this in an idealized setting in which the unlabelled data is approximately clustered, and there is an unobserved latent variable which determines labels and which is observed in a small noise regime. We prove consistency in a limit in which the data becomes more clustered and the label noise goes to zero. The formulation and analysis demonstrates how ideas from unsupervised learning and, in particular spectral clustering, can be used as prior information; this prior information is enhanced, or sets up a competition with, labelled data. In so doing, our analysis also elucidates the role of parameter choices made when setting up the balance between labelled and unlabelled data. Furthermore, we exhibit useful properties of the probit and one-hot methods, including a representer theorem for the classifier, and a natural dimension reduction which follows from this theorem and is impactful in practice.

1.1. Background And Literature Review. We start by giving informal statements of the problem to be solved, and a brief literature review. Consider a set of nodes $Z = \{1, \ldots, N\}$ and an associated set of feature vectors $X = \{x_1, x_2, \ldots, x_N\}$. Each feature vector $x_j$ is assumed to be a point in $\mathbb{R}^d$. $X$ may thus be viewed as a function $X : Z \mapsto \mathbb{R}^d$ or as an element of $\mathbb{R}^{d \times N}$. We refer to $X$ as unlabelled data. Suppose there exists a function $l : Z \mapsto \{1, 2, \ldots, M\}$ that assigns one of $M$ distinct labels to each point in $Z$. That is, for every point $j \in Z$ the value $l(j) = m$ indicates that $j$ belongs to class $m$ or is labelled as $m$. Throughout this article we assume that every point in $Z$ belongs to one class only.

Now let $Z' \subseteq Z$ be a subset of the nodes with $|Z'| = J \leq N$ and define $y : Z' \mapsto \{1, 2, \ldots, M\}$ to be a noisily observed label of each point in $Z'$. We refer to $y$ as labelled data. With this setup we may define the SSL problem.

*Computing and Mathematical Sciences, Caltech, Pasadena, CA (fkoh@caltech.edu, bamdad@caltech.edu, zren@caltech.edu, astuart@caltech.edu).
Problem 1.1 (Semi-Supervised Learning). Suppose $Z, Z', X$ and $y$ are known. Find $l : Z \mapsto \{1, 2, \ldots, M\}$.

In order to solve this problem, which is highly ill-posed, it is necessary to introduce some form of regularity on the labels, guided by the correlations in $X$ for example, and to make assumptions about the errors in the labels provided. One approach, which we study here, is to assume that the labels on $Z$ are defined through a latent variable $u : Z \mapsto \mathbb{R}^M$, whose regularity is defined through the unlabelled data $X$, and a function $S : \mathbb{R}^M \mapsto \{1, 2, \ldots, M\}$. Specifically we assume that there is a ground truth function $u^\dagger : Z \mapsto \mathbb{R}^M$ for which

\begin{equation}
(1.1) \quad y(j) := S(u^\dagger(j) + \eta(j)), \quad j \in Z',
\end{equation}

where $\eta(j) \sim \psi$ and $\psi$ is the Lebesgue density of a zero-mean random variable on $\mathbb{R}^M$. We may now introduce the following relaxation of the SSL problem.

Problem 1.2 (Relaxed Semi-Supervised Learning). Suppose $Z, Z', X$ and $y$ are known, together with the function $S$ and the density $\psi$. Find $u : Z \mapsto \mathbb{R}^M$ and define $l = S \circ u : Z \mapsto \{1, 2, \ldots, M\}$.

In Problem 1.3 below we will define a class of optimization functionals for $u$, giving an explicit instantiation of Problem 1.2, and focus on the resulting optimization problems in our analysis. Before doing so we give a literature review explaining the context for this optimization approach.

The consistency of classification methods in the setting of supervised learning is well-developed; see [39] for a literature review and results applying to both binary and multi-class classification, as well as the preceding work in [36, 37, 44] which establishes the problem in the framework of Vapnik [40]. The paper [45] discusses the robustness of such supervised classification methods, allowing for a small fraction of adversarially labelled data points. There has been some recent analysis of logistic regression, and the reader may access the literature on this subject via the recent papers [11, 38]. All of this work on supervised classification focuses on the large data/large number of features setting, and often starts from assumptions that the unlabelled data is linearly separated. None of it leverages the power of graph-based techniques to extract geometric information in large unlabelled data sets. To make the connection to graph-based techniques we need to discuss unsupervised graph-based learning [3, 41]. This is a subject that has seen significant analysis in relation to consistency. The papers [34, 35] perform a careful analysis of the spectral gaps of graph Laplacians resulting from clustered data, studying recursive methods for multi-class clustering. The paper [25] introduced a way of thinking about, and analyzing, multi-class unsupervised learning based on perturbing a perfectly clustered case; we will leverage similar ideas in our work on SSL. The paper [42] introduced the idea of studying the consistency of spectral clustering in the limit of large i.i.d. data sets in which the graph Laplacian converges to a limiting integral operator; and the work [17, 18] has taken this further by working with localizing weight functions designed so that the limit of the graph Laplacian is a differential operator.

SSL is a methodology which combines the methods of unsupervised learning and of supervised classification. According to the definition in [22] “SSL can be categorized into two somewhat different settings, namely inductive and transductive learning... inductive SSL attempts to predict the labels on unseen future data, while transductive SSL attempts to predict the labels on unlabeled instances taken from the training set.” In this paper our focus is on transductive SSL. Initial attempts to solve
the SSL problem employed combinatorial algorithms [9], based on an explicit mathematical formulation stemming from Problem 1.1. Zhu and collaborators introduced a relaxation similar to Problem 1.2, leading to the influential papers [46, 47]. Their approach is most easily described in the binary case in which they assume \( S: \mathbb{R} \mapsto \mathbb{R} \) is the identity function and the labels are given in the form \( \pm 1 \). From a modeling viewpoint this approach is unnatural because the categorical data is assumed to also lie in the real-valued space of the latent variable. Bertozzi and Flenner [6] introduced an interesting relaxation of this assumption, by means of a Ginzburg-Landau penalty term which favours real-values close to \( \pm 1 \) but does not enforce the categorical values \( \pm 1 \) exactly. The probit approach to classification, described in the classic text on Gaussian process regression [28], does not make the unnatural modeling assumption underlying Zhu’s work; instead it is based on taking \( S \) to be the sign function. However the basic form of probit in [28] does not use unlabelled data to extend labels outside the labelled data set, but instead does so through regular Gaussian process regression: inductive SSL.

The extension of the probit method to graph-based transductive SSL is described in [8], where both Bayesian and optimization-based formulations are described; in that paper, (1.1) is also generalized to the level set form

\[
y(j) := S(u^t(j)) + \eta(j), \quad j \in \mathbb{Z}',
\]

and a Bayesian formulation of the Ginzburg-Landau relaxation of [6] is introduced. The close relationship between level set and probit formulations is discussed in [16]. The work of Belkin [2, 3, 5] demonstrates how both Gaussian process regression and graph-based SSL can be used simultaneously; in the sense of the definition in [22], transductive and inductive SSL are combined. All of the approaches which followed from the work of Zhu are readily generalized from the binary case to the multi-class setting, using the idea of one-hot encoding, explained in detail in subsection 3.1, in which each label is identified with a standard unit basis vector in \( \mathbb{R}^M \).

A large number of approaches to SSL have been developed in the literature and a detailed discussion of all of them is outside the scope of this article. We refer the reader to the review articles [48] and [22] for, respectively, the state-of-the-art in 2005 and a more recent appraisal of the field that categorizes various inductive and transductive approaches to SSL and semi-supervised regression. The idea of regularization by graph Laplacians for SSL was developed in different contexts such as manifold regularization [5], Tikhonov regularization [2] and local learning regularization [43]. However, while graph regularization methods are widely applied in practice the rigorous analysis of their properties, and in particular asymptotic consistency, is not well-developed within the context of SSL. Indeed, to the best of our knowledge the consistency analysis of the probit and one-hot methods has not been tackled before. SSL may be viewed as a method for boosting, refining or questioning unsupervised graph-based learning, through labelling information; our analysis sheds light on this process.

There has been other analysis of SSL methods, not concerning consistency. In [16] the authors studied the large data and zero noise limits of the probit method. They derive a continuum inverse problem using the methodology of [17, 18] that characterizes SSL when the number of vertices of the graph and the number of observed labels is fixed, or goes to infinity in a manner insuring a fixed fraction of labels. The authors also study the zero noise limit of probit and level-set methods for SSL and show that both problems approach the same limit as the noise variance goes to zero. In forthcoming papers [21, 20] we will build on this body of work to study consistency of graph-based SSL in the limit of large unlabelled data sets.
1.2. Problem Setup And Preliminaries. Our focus in this paper is on the analysis of algorithms built from the introduction of real-(vector)-valued latent functions, leading to precise mathematical formulations of Problem 1.2. To make actionable algorithms we need to specify precisely how the unlabelled data $X$ and the labelled data $y$ are used. The approach we study here is to define the desired latent variable $u$ as the minimizer of a function comprised of two terms, one of which enforces correlations and geometric information in the unlabelled data $X$, and the other which enforces consistency with the label data $y$, on the assumption that they are related to $u$ as in (1.1). To this end we view $X$ as a point cloud in $\mathbb{R}^d$ and associate a weight matrix $W = (w_{ij})$ to tuples $(x_i,x_j)$ in $X \times X$. The weights $w_{ij}$, which are assumed to be non-negative, are chosen to measure affinities between $x_i$ and $x_j$. Since similarity between data points is a symmetric relationship, we assume $w_{ij} = w_{ji}$ so that $W$ is a symmetric matrix and define a proximity graph $G = \{X, W\}$ with vertices $X$ and edge weights $W$. From $W$ we will construct a covariance operator $C$ on spaces of functions $H = \{u : Z \to \mathbb{R}^M\}$, using a graph Laplacian implied by $W$. We also define a misfit function $\Phi(u; y) : H \times \{1, \ldots, M\} \to \mathbb{R}$ which encodes the assumption (1.1) about the relationship between the labels and the latent function. With these objects we then formulate the SSL problem as a regularized optimization problem.

**Problem 1.3 (Relaxed Semi-Supervised Learning As Optimization).** Suppose $Z, Z', X$ and $y$ are known, together with the function $S$, the covariance operator $C$ and the misfit $\Phi$. Find the function $u^*$ defined by

\[
(1.3) \quad u^* = \arg\min_{u \in H} \frac{1}{2} \langle u, C^{-1}u \rangle_H + \Phi(u; y).
\]

This optimization problem may be viewed as the MAP estimator associated to the Bayesian inverse problem of finding the distribution of $u|y$ when the prior on $u$ is a Gaussian random measure on $H$ with covariance $C$ and $\Phi(u; y)$ is the negative log-likelihood of $y$ conditioned on $u$, i.e.

\[
(1.4) \quad P(y|u) \propto \exp(-\Phi(u; y)), \quad \text{assuming} \quad y(j) = S(u(j) + \eta(j)).
\]

We refer to $\Phi$ as the **likelihood potential**.

1.3. Main Contributions. The key question at the heart of this article is to identify conditions under which the minimizer $u^*$ of Problem 1.3 correctly identifies the labels. To this end, we define the following notion of consistency.

**Definition 1.4 (SSL asymptotic consistency).** We say that Problem 1.3 is asymptotically consistent if, for all $j \in Z$,

\[
S(u^*(j)) \xrightarrow{\text{a.s.}} S(u^I(j)), \quad \text{as} \quad \text{std}(\eta(j)) \downarrow 0,
\]

where $u^I$ is the latent variable underlying the labelled data (1.1).

In the above and throughout the rest of the article $\xrightarrow{\text{a.s.}}$ denotes almost sure (a.s.) convergence with respect to a common probability space on which the measurement noise $\eta(j)$ are defined (see subsections 2.6 and 3.5 for a formal discussion of this mode of convergence). We primarily focus on the probit and one-hot methods for SSL, corresponding to specific choices of the function $S$. As mentioned earlier probit is an optimization approach for binary classification that formulates Problem 1.3 with
\( M = 2 \). The one-hot method is a generalization of probit for multi-class classification when \( M \geq 2 \). We outline these methods in detail in sections 2 and 3. We show that probit and one-hot methods are asymptotically consistent in the case where the graph \( G \) is nearly-disconnected in the following sense.

**Definition 1.5** (Nearly-disconnected graph). A weighted graph \( G = \{X, W\} \) is nearly-disconnected with \( k \) clusters if there exist connected components \( \tilde{G}_k = \{\tilde{X}_k, \tilde{W}_k\} \) for \( k \in \{1, \ldots, K\} \) so that the edges within each \( \tilde{G}_k \) are \( O(1) \), but the edges between elements in different \( \tilde{G}_k \) are \( O(\epsilon) \) for a small parameter \( \epsilon > 0 \). In other words, up to a reordering of the index set \( Z \), the matrix \( W \) is nearly block diagonal.

Working in such a setting is a natural way of representing nearly clustered data, and was exploited in the paper [25] concerning unsupervised learning. The number of clusters \( K \) is an inherent geometric property of the unlabelled data \( X \); determining a suitable choice of \( K \) in practice can be challenging and depends on the scale one is interested in. In the following informal statement of our main result we assume that each component \( \tilde{G}_k \) is associated with at least one pre-assigned label. The result shows that if \( G \) is nearly-disconnected and the ground truth function \( u^1 \) assigns the same label to all points within each component \( \tilde{G}_k \) then the probit and one-hot methods are asymptotically consistent for an appropriate choice of matrix \( C \) so long as at least one label is observed in each component \( \tilde{G}_k \). Below, \( L \) denotes the *graph Laplacian*, a discrete diffusion operator acting on functions defined on the graph \( G \), see section 2.3 for a precise definition.

**Theorem 1.6** (Consistency of probit and one-hot). Suppose \( G \) is a nearly-disconnected graph and let \( L \) be a graph Laplacian on \( G \). Define the matrix \( C = \tau^{2\alpha}(L + \tau^2 I)^{-\alpha} \) with parameters \( \tau^2, \alpha > 0 \). Assume \( S(u^1) \) is constant on the components \( \tilde{G}_k \) and at least one label is observed in each component \( \tilde{G}_k \). Then the probit and one-hot formulations are asymptotically consistent for any sequence \((\epsilon, \tau, \text{std}(\eta)) \downarrow 0 \) along which \( \epsilon = o(\tau^2) \).

**Remark 1.7.** Conceptually the parameter \( \epsilon \) should be thought of as an inherent measure of how clustered the unlabelled data is; in this paper we consider a specific set-up in which \( \epsilon \) is defined as a measure of the size of edge weights between clusters. We also connect the labelled and unlabelled data via a model involving an unobserved latent variable, perturbed by noise \( \eta \). Our consistency results are proven in the setting in which \( \epsilon \) and \( \text{std}(\eta) \) both tend to zero. This is a strong assumption which, whilst allowing a precise theory, may be difficult to apply directly in practice. We believe that similar consistency results will hold under different modeling assumptions which characterize clustering and label noise in more general ways. Furthermore our consistency results demonstrate the importance of choosing the hyperparameter \( \tau \) in a data-dependent fashion. Small \( \epsilon \) induces a spectral gap in \( L \) and for this to translate into a spectral gap in \( C \) we require \( \tau \) to be small too. However we also require \( \epsilon = o(\tau^2) \) so that the number of eigenvalues of \( C \) which are at, or close to, 1 is the same as the number of clusters in the data. We also give theory and numerical evidence showing that when \( \epsilon = \Theta(\tau^2) \) consistency may be lost. Our theoretical results are asymptotic in nature and therefore cannot apply directly to any one given data set. However our analysis provides insights into both algorithmic parameters choices, and algorithmic performance, in practical non-asymptotic set-ups. Indeed the papers [6, 8] demonstrate the use of optimization methodologies of the type introduced here in practical non-asymptotic set-ups for real data problems, and the papers [8, 12, 27] demonstrate analogous set-ups for related Bayesian approaches. An important
conclusion of the theory and numerical experiments is that careful choice of parameter \( \tau \) is crucial for effective SSL. The take-home message here is that the use of hierarchical Bayesian methods, which tune \( \tau \) automatically to the data, can be beneficial; as demonstrated in practical experiments in [12].

Formal statement and proof of the preceding main theorem is given in Theorem 2.15 (together with Corollaries 2.14 and 2.16) for the probit method and in Theorem 3.11 (together with Corollary 3.12) for the one-hot method.

As a secondary result, accompanying the preceding theorem, we identify a natural dimension reduction for probit and one-hot optimization problems. More precisely, we show that finding \( u^* \in H = \{ u : \mathcal{Z} \rightarrow \mathbb{R}^M \} \) is equivalent to a similar optimization problem for a function \( b^* \in H' = \{ b : \mathcal{Z}' \rightarrow \mathbb{R}^M \} \). Thus we can reduce the size of the optimization problems from \( N \times M \) to \( J \times M \). This result, which is a discrete representer theorem, has significant practical consequences when \( J \ll N \).

**Theorem 1.8 (Dimension reduction for probit and one-hot).** The problem of finding \( u^* \) is equivalent to an optimization problem of the form

\[
    b^* := \arg \min_{b \in H'} \frac{1}{2} (b, (C')^{-1}b)_{H'} + \Phi'(b; y),
\]

where \( C' \) is a submatrix of \( C \) after restriction of rows and columns to \( \mathcal{Z}' \), and \( \Phi' \) is defined from \( \Phi \).

A formal statement and proof of this theorem is presented in Corollary 2.6 for probit and Proposition 3.6 for the one-hot method. These results also provide identities that relate \( b^* \) to \( u^* \) and vice versa. More precisely, pointwise values of the functions \( b^* \) and \( u^* \) coincide on the labelled set \( \mathcal{Z}' \). Conversely, \( u^* \) can be viewed as a smooth extension of \( b^* \) from the labelled set \( \mathcal{Z}' \) to the entire index set \( \mathcal{Z} \).

Finally we perform numerical experiments to illustrate the behavior of probit and one-hot methods beyond the theoretical setting. In particular we demonstrate that when \( \epsilon = \Theta(\tau^2) \) these methods are not always consistent. An interesting observation we make is a sharp phase transition in the accuracy of both methods. More precisely, we observe a curve in the \((\epsilon/\tau^2, \alpha)\)-plane across which the probit and one-hot methods transition rapidly from being consistent into inconsistent solutions based on majority label propagation, i.e., labelling all points in the dataset according to the label that is observed most often (see Figures 4.2 and 4.8). Intuitively this happens because, for larger values of \( \epsilon/\tau^2 \), it is cheaper to minimize the quadratic regularization term in the optimization problem of Theorem 1.8 than to minimize the misfit term \( \Phi \).

**1.4. Outline.** Section 2 is devoted to analysis of the probit method where \( M = 2 \). The problem is formulated as inference for a latent real-valued function on the nodes of a graph, with the sign determining the assignment of a binary label. An optimization approach is employed in which the graph Laplacian constructed from the unlabelled data is used for regularization, and a generic zero-mean log-concave label measurement noise is assumed; this results in a convex data misfit term. We study the properties of this optimization problem, showing that the related optimization functional is convex. We prove a representer theorem and then study asymptotic consistency of the method in Corollary 2.14, Theorem 2.15 and Corollary 2.16, the precise statements of Theorem 1.6 in the probit case.

Section 3 has the same structure as section 2 but focuses on the multi-class setting (i.e., \( M \geq 2 \)) and employs the one-hot method to link a real-vector-valued latent variable to the labels. The key results here are Corollary 3.10, Theorem 3.11 and
Corollary 3.12, the precise versions of Theorem 1.6 in case of the one-hot method. Section 4 contains numerical experiments confirming the key theoretical results from the two preceding sections, and illustrates the behavior of probit and one-hot methods beyond the theoretical setting. In section 5 we summarize and discuss future work.

1.5. Notation. Throughout we use \( Z \) to denote the nodes of a graph carrying a pre-assigned unlabelled data point at each node, and \( Z' \) the subset of nodes which also carry a label. We use \( G_0 = \{ X, W_0 \} \) to denote a disconnected graph with \( K \) disconnected subgraphs (clusters) \( \tilde{G}_k = \{ \tilde{X}_k, \tilde{W}_k \} \) for \( k = 1, \ldots, K \). The \( \tilde{X}_k \) are a subset of the points in \( X \) with indices \( \tilde{Z}_k \subset Z \) while \( \tilde{W}_k \) are submatrices of \( W_0 \). We also use \( \tilde{Z}_k' \) to denote the subset of labelled points within \( \tilde{Z}_k \). Subsequently we denote the graph Laplacian matrices of the subgraphs \( \tilde{G}_k \) by \( \tilde{L}_k \). We also introduce a nearly-disconnected graph \( G_\epsilon = \{ X, W_\epsilon \} \) with the weight matrix \( W_\epsilon \) that is considered to be a perturbation of \( W_0 \) and use \( L_\epsilon \) to denote the graph Laplacian on this nearly-disconnected graph. These concepts are introduced and discussed in subsection 2.5 and used extensively in the rest of the article.

We use \( u \) to denote real-(vector)-valued functions on \( Z \) which are acted upon by a nonlinear classifier to assign labels. We use \( \{ \cdot, \cdot \} \) to denote the cardinality of a set; \( \langle \cdot, \cdot \rangle \) denote the Euclidean inner-product and norm unless stated otherwise. We employ the standard \( \Theta, \mathcal{O} \) and \( o \) notations as in [15]: given positive functions \( f(s), g(s) \), we write

- \( f(s) = \Theta(g(s)) \) if there exist constants \( c_1, c_2, s_0 > 0 \) so that
  \[ 0 \leq c_1 g(s) \leq f(s) \leq c_2 g(s) \quad \forall s \in (0, s_0], \]
- \( f(s) = \mathcal{O}(g(s)) \) if there exists \( c, s_0 > 0 \) so that
  \[ 0 \leq f(s) \leq cg(s) \quad \forall s \in (0, s_0], \]
- \( f(s) = o(g(s)) \) if for any constant \( c > 0 \) there exists \( s_0(c) > 0 \) so that
  \[ 0 \leq f(s) < cg(s) \quad \forall s \in (0, s_0(c)]. \]

2. Binary Classification: The Probit Method. In subsection 2.1 we set up the probit methodology, noting that the binary classification problem \( (M = 2) \) can be formulated using a latent variable function which is \( \mathbb{R}^{M-1} \)-valued rather than \( \mathbb{R}^M \)-valued. In subsection 2.2 we study the likelihood contribution to the optimization problem, resulting from the labelled data, and in subsection 2.3 the quadratic regularization resulting from the unlabelled data. In subsection 2.4 we study the probit minimization problem, formulating the results via a discrete representer theorem, and in subsection 2.5 we study the properties of the representers via the properties of the eigenstructure of the covariance, exploiting the nearly-disconnected graph structure. subsection 2.6 concludes the analysis of the probit method, studying consistency in some detail.

2.1. Set-Up. We start with the case of binary classification where the nodes \( Z \) belong to only two classes. For simplicity we assume that \( l(j) \in \{ -1, +1 \} \) for all \( j \in Z \) rather than taking \( l(j) \in \{ 1, 2 \} \). This assumption is at odds with our notation in subsection 1.2 but allows for a simpler formulation of Problem 1.3. Since the classes are identified with the integers \( +1 \) and \( -1 \) a natural choice for the classifier function \( S \) is the sign function:

\[
S : \mathbb{R} \rightarrow \{ -1, +1 \}, \quad S(t) = \text{sgn}(t) := \begin{cases} +1, & \text{if } t \geq 0, \\ -1, & \text{if } t < 0. \end{cases}
\]
With the above choice for $S$ we can take the latent variable $u$ to be a real valued function on $Z$, i.e., $u : Z \rightarrow \mathbb{R}$. We can then naturally identify the function $u$ with a vector $u \in \mathbb{R}^N$ where $u = (u_1, u_2, \ldots, u_N)^T$ and $u_j = u(j)$ for $j \in Z$. This allows to view Problems 1.2 and 1.3 as the inverse problem of finding a vector $u^*$ in $\mathbb{R}^N$. In the remainder of this section we will utilize this vector notation for convenience.

### 2.2. The Probit Likelihood

Let us begin by deriving the likelihood potential $\Phi(u; y)$ for the probit method. Let $S$ be as in (2.1) and recall (1.1), then

$$y(j) = \text{sgn}(u_j + \eta_j), \quad \eta_j \text{iid } \psi, \quad j \in Z,$$

wherein we have identified the noise $\eta$ with a vector $\eta = (\eta_1, \ldots, \eta_N)^T \in \mathbb{R}^N$. Suppose $\psi$ is a symmetric probability density function on $\mathbb{R}$ and denote the cumulative distribution function (CDF) of $\psi$ by $\Psi$. Then,

$$P(y(j) = +1| u_j) = P(-u_j \leq \eta_j) = P(-u_j y(j) \leq \eta_j) = \Psi(u_j y(j)).$$

For more details on this calculation, see similar arguments for the multi-class case in section 3.2. Similarly,

$$P(y(j) = -1| u_j) = P(-u_j > \eta_j) = P(u_j y(j) > \eta_j) = \Psi(u_j y(j)).$$

From (1.4) it follows that the **probit likelihood** potential $\Phi(u; y)$ has the form

$$\Phi(u; y) = - \sum_{j \in Z'} \log \Psi(u_j y(j)). \quad (2.2)$$

### 2.3. Quadratic Regularization Via Graph Laplacians (Binary Case)

Let us now formulate a quadratic regularization term for the probit method. Recall our encoding of the nodes $Z$ and their similarities via a weighted graph $G = \{X, W\}$ with vertices at $x_j$ and edge weights $w_{ij} = w_{ji}$ for $i, j \in Z$. We denote by $d_i$ the degree of each node $i \in Z$ as

$$d_i := \sum_{j \in Z} w_{ij},$$

and further define the diagonal matrix $D := \text{diag}(d_i) \in \mathbb{R}^{N \times N}$. Finally, given constants $p, q \in \mathbb{R}$ we define the graph Laplacian operator on $G$

$$L := D^{-p}(D - W)D^{-q} \in \mathbb{R}^{N \times N}. \quad (2.3)$$

Different choices of $p$ and $q$ result in different normalizations of the graph Laplacian, see [4, 13, 14, 16, 17, 18, 31, 32, 41, 42] and the references therein as well as [21, Sec. 5] where a detailed discussion around various weightings of graph Laplacians and their connection to a family of elliptic operators is laid out. For example, $p = q = 0$ leads to the usual unnormalized graph Laplacian, when $p = q = 1/2$ we obtain the symmetric normalized graph Laplacian, and $p = 1$ and $q = 0$ gives the random walk graph Laplacian. Different normalizations of the graph Laplacian have been used for spectral clustering in the literature, but a thorough understanding of the advantages and disadvantages of certain parameter choices is still lacking, see [41]. Throughout we enforce $p = q$ in order to make $L$ symmetric with respect to the Euclidean inner-product, making no other assumptions regarding the value of $p, q$; however our results
can be generalized to \( p \neq q \) by using appropriate \( D \)-weighted inner-products. For \( p = q \), we can then write for any vector \( x \in \mathbb{R}^N \),

\[
(\mathbf{x}, \mathbf{L}\mathbf{x}) = \frac{1}{2} \sum_{i,j=1}^{N} w_{ij} \left| \frac{x_i}{d_i^p} - \frac{x_j}{d_j^q} \right|^2.
\]

Given a graph Laplacian \( \mathbf{L} \) and parameters \( \alpha, \tau^2 > 0 \) we define a family of covariance operators

\[
C_\tau = \tau^{2\alpha}(L + \tau^2 I)^{-\alpha} \in \mathbb{R}^{N \times N},
\]

where \( I \in \mathbb{R}^{N \times N} \) denotes the identity matrix. We then use this covariance matrix to define the quadratic regularization term in Problem 1.3. To this end note that in the binary case we may identify \( H = \mathbb{R}^N \); we make this identification in what follows in this section, and \( \langle \cdot, \cdot \rangle \) then denotes the standard Euclidean inner-product.

**Remark 2.1.** We use the term covariance operator to refer to the matrix \( C_\tau \) following the connection between optimization problems of the form (1.3) and MAP estimators within the Bayesian formulation of probit given in [8]. In the Bayesian perspective \( C_\tau \) is the covariance operator of a Gaussian prior measure on \( u \), and \( u^* \) coincides with the MAP estimator of \( u^\dagger \). We note that the covariance \( C_\tau \) may be viewed as a form of discrete Matérn covariance, in the framework of [24]. The scaling of \( C_\tau \) that we adopt ensures that the spectrum of \( C_\tau \) lies in \([0, 1]\) and hence controls the total variance of samples \( u \) from the prior: \( \mathbb{E}^{N(0, C_\tau)} \| u \|^2 = K \), where \( K \) is the number of clusters in the disconnected or nearly-disconnected graph setting. Further study of the connections between \( C_\tau \) and Matérn kernels is outside the scope of this article and is postponed to our companion papers [20, 21] where the continuum limits of graph Laplacian and covariance matrices such as \( C_\tau \) are studied when the elements of \( X \) are drawn i.i.d. at random from a probability measure, and \( N \to \infty \), building on [18].

**2.4. Properties Of The Probit Minimizer.** With the likelihood \( \Phi \) and covariance matrix \( C_\tau \) identified we can now discuss properties of the *probit functional*

\[
J(u) := \frac{1}{2}(u, C_\tau^{-1}u) + \Phi(u; y), \quad u \in \mathbb{R}^N.
\]

**Remark 2.2.** In the following we will study the problem of minimizing \( J \). We highlight the fact that related optimization problems for objective functions of the form

\[
J(u) := \frac{1}{2}(u, \mathbf{L}u) + \Upsilon(u; y), \quad u \in \mathcal{E}
\]

have been defined and studied in [6, 8, 46], although asymptotic consistency has not been investigated there. In order to give these methods a Bayesian interpretation we need to define a covariance \( C = \mathbf{L}^{-1} \), noting that \( \mathbf{L} \) is invertible on the set \( \mathcal{E} = \{ u \in \mathbb{R}^N : \langle u, D^p_0 1 \rangle = 0 \} \), where \( 1 \in \mathbb{R}^N \) denotes the vector of ones. \( \mathbf{L} \) is invertible on \( \mathcal{E} \) because \( D^p_0 1 \) spans the null-space of \( \mathbf{L} \) when the graph is pathwise connected. Introduction of \( C_\tau \) with \( \tau > 0 \) not only circumvents the need to work on \( \mathcal{E} \) but also allows for consistent prior modeling of the situation in which multiple clusters have the same prior label. Furthermore the parameter \( \alpha \) is needed when the large data limit \( N \to \infty \) is considered; see [21].
Our first task is to prove existence and uniqueness of the minimizers of $J$ by proving it is strictly convex. The following proposition follows directly from [1, Thm. 1] and states that the CDF of a log-concave probability distribution function (PDF) is also log-concave.

**Proposition 2.3 (Convexity of the likelihood potential $\Phi$).** Let $\psi$ be a continuously differentiable, symmetric and strictly log-concave PDF with full support on $\mathbb{R}$. Then $\Psi$ is also strictly log-concave and so $\Phi(\cdot; y) : \mathbb{R}^N \mapsto \mathbb{R}$ is strictly convex.

Convexity of the quadratic regularization term in (2.6) follows directly from Lemma A.1 that establishes that the matrix $C_\tau$ is strictly positive-definite whenever $\tau^2, \alpha > 0$. With the convexity of both terms in the definition of $J$ established we can now characterize its minimizer.

**Proposition 2.4 (Representer theorem for the probit functional).** Let $G = \{X, W\}$ be a weighted graph and let $\psi$ be a PDF that is continuously differentiable, symmetric and strictly log-concave with full support on $\mathbb{R}$. Suppose the likelihood potential $\Phi$ is given by (2.2) and the matrix $C_\tau$ is given by (2.5) with parameters $\tau^2, \alpha > 0$. Then the following hold.

(i) The probit functional $J$ has a unique minimizer $u^* \in \mathbb{R}^N$.

(ii) The minimizer $u^*$ satisfies the Euler-Lagrange (EL) equations

\begin{equation}
C_\tau^{-1} u^* = \sum_{j \in Z'} F_j(u^*_j) e_j,
\end{equation}

where $e_j$ is the $j$-th standard coordinate vector in $\mathbb{R}^N$ and

\begin{equation}
F_j(s) := \frac{y(j) \psi(sy(j))}{\Psi(sy(j))}.
\end{equation}

(iii) The minimizer $u^*$ has a sparse representation

\begin{equation}
u^* = \sum_{j \in Z'} \tilde{a}_j c_j,
\end{equation}

where $C_\tau e_j =: c_j = (c_{1j}, \ldots, c_{Nj})^T$ are a subset of the column space of $C_\tau = (c_{ij})_{i,j \in Z}$ and $\tilde{a}_j \in \mathbb{R}$.

(iv) The vector $u^*$ defined in (2.10) solves (2.8) if and only if the coefficients $\tilde{a}_j$ satisfy the non-linear system of equations

\[\tilde{a}_j = F_j \left( \sum_{k \in Z'} \tilde{a}_k c_{jk} \right), \quad \forall j \in Z'.\]

**Proof.** (i) Since $\Psi$ is the CDF of a random variable on $\mathbb{R}$ with full support then $\Psi(s) \in (0, 1)$. Thus, $-\log \Psi \geq 0$ and so $\Phi$ is bounded from below. Furthermore, $\Phi$ is convex following Proposition 2.3. On the other hand, the matrix $C_\tau^{-1}$ is strictly positive definite following Lemma A.1 and so the quadratic term $\frac{1}{2} \langle w, C_\tau^{-1} w \rangle$ is strictly convex and positive. Thus, since the functional $J$ is bounded from below and is the sum of strictly convex functions then $J$ is strictly convex and has a unique minimizer.

(ii) Since $\psi$ is $C^1(\mathbb{R})$ the CDF $\Psi$ is $C^2(\mathbb{R})$ and $\psi/\Psi$ is $C^1(\mathbb{R})$ and locally bounded since $\psi$ has full support. Then $J : \mathbb{R}^N \mapsto \mathbb{R}$ is differentiable and the minimizer $u^*$ satisfies the first order optimality condition $\nabla J(u^*) = 0$. The statement now follows by directly computing the gradient of $J(u)$ with respect to $u$. 

10
(iii–iv) Multiply (2.8) by \( C_\tau \) to get
\[
\mathbf{u}^* = \sum_{j \in Z'} F_j(u_j^*)C_\tau \mathbf{e}_j = \sum_{j \in Z'} \tilde{a}_j \mathbf{c}_j,
\]
where we set \( \tilde{a}_j = F_j(u_j^*) \) for \( j \in Z' \). Now substitute the expansion of \( \mathbf{u}^* \) into the definition of \( \tilde{a}_j \) to get
\[
(2.11) \quad \tilde{a}_j = F_j \left( \sum_{k \in Z'} \bar{a}_k \mathbf{c}_k \right),
\]
This establishes the “only if” statement in (iv). In order to establish the converse, suppose the \( \tilde{a}_j \) satisfy (2.11). Multiply this equation by \( c_k \) and sum over \( j \in Z' \) to get
\[
\sum_{j \in Z'} \tilde{a}_j \mathbf{c}_j = \sum_{j \in Z'} F_j \left( \sum_{k \in Z'} \bar{a}_j c_{jk} \right) \mathbf{c}_j.
\]
now define \( \mathbf{u}^* = \sum_{j \in Z'} \tilde{a}_j \mathbf{c}_j \) to get
\[
\mathbf{u}^* = \sum_{j \in Z'} F_j(u_j^*) \mathbf{c}_j.
\]
The claim follows by multiplying this equation by \( C_\tau^{-1} \).

**Remark 2.5 (Connection to kernel regression).** We note that Proposition 2.4 is closely related to the representer theorem in Gaussian process and kernel regression [28, Sec. 6.2]. Similar result to ours can be found in [33, Thm. 1] and [30].

Part (iv) of Proposition 2.4 suggests that the problem of minimizing \( J \) is analogous to a low-dimensional optimization problem. To this end we now define a one-to-one reordering
\[
(2.12) \quad \pi : Z' \mapsto \{1, 2, \cdots, J\}, \quad \pi^{-1} : \{1, 2, \cdots, J\} \mapsto Z',
\]
that allows us to associate the coefficients \( \{\tilde{a}_j\}_{j \in Z'} \) with a vector \( \mathbf{a} = (a_1, \cdots a_J)^T \in \mathbb{R}^J \) via
\[
a_{\pi(j)} = \tilde{a}_j, \quad j \in Z',
\]
and define submatrix \( C' \in \mathbb{R}^{J \times J} \) by the identity
\[
(2.13) \quad (C'_\pi)^{i(j)} = c_{ij}, \quad i, j \in Z'.
\]
That is, \( C'_\pi \) is the matrix \( C_\tau \) with the rows and columns of the indices in \( Z \setminus Z' \) removed. Finally, we define \( \mathbf{b} := C'_\pi \mathbf{a} \). We then have the following natural dimension reduction for the probit optimization problem.

**Corollary 2.6 (Probit dimension reduction).** Suppose the conditions of Proposition 2.4 are satisfied. Then the following hold.

(i) The problem of finding the minimizer \( \mathbf{u}^* \in \mathbb{R}^N \) of the functional \( J \) is equivalent to the problem of finding the vector \( \mathbf{b}^* \in \mathbb{R}^J \) that solves
\[
(2.14) \quad (C'_\pi)^{-1} \mathbf{b}^* = F'(\mathbf{b}^*),
\]
where the map $F': \mathbb{R}^J \rightarrow \mathbb{R}^J$ is defined as
\[
F'(v) = (f_1(v_1), \ldots, f_J(v_J))^T, \quad f_k(v_k) := F_{\pi^{-1}(k)}(v_k)
\]
and $F_j$ are defined in (2.9).

(ii) Moreover, the vector $b^*$ solves the optimization problem
\[
b^* = \arg \min_{v \in \mathbb{R}^J} J'(v),
\]
where
\[
J'(b) := \frac{1}{2} (b, (C_\tau')^{-1}b) + \Phi'(b; y),
\]
and
\[
\Phi'(b; y) = - \sum_{j=1}^J \log \Psi\left(b_j \pi^{-1}(j)\right).
\]

(iii) The two solutions $b^* \in \mathbb{R}^J$ and $u^* \in \mathbb{R}^N$ satisfy the relationship
\[
u^* = \sum_{j \in Z'} \left( (C_\tau')^{-1}b^* \right)_{\pi(j)} c_j,
\]
and
\[
b_k^* = u_{\pi^{-1}(k)}^*, \quad k = \{1, 2, \ldots, J\}.
\]

Proof. This result follows from Proposition 2.4 and direct computations.

Remark 2.7 (Variable Elimination And Gaussian Process Regression). There is a simple explanation for the finite dimensional representer theorem which underlies Proposition 2.4 and Proposition 2.6. If we re-order the variables in $u$ into components $u^+$ in $Z'$ and $u^-$ in $Z \setminus Z'$, and re-order the components of the precision matrix $P = C_\tau^{-1}$ then setting the gradient of $J$ to 0 in this re-ordered set of variables gives equations of the form
\[
\begin{pmatrix}
P^{++} & P^{+-} \\
P^{-+} & P^{--}
\end{pmatrix}
\begin{pmatrix}
u^+ \\
u^-
\end{pmatrix}
= \begin{pmatrix}
g(u^+) \\
0
\end{pmatrix}.
\]
This follows from the fact that $\Phi(u)$ does not depend on $u^-$; the term $g(u^+)$ results from the gradient of $\Phi(u)$ with respect to $u^+$. From this re-ordering of the equations several things are apparent: (i) the bottom row provides a linear mapping from $u^+$ to $u^-$ since $P^{--}$ is invertible whenever $C_\tau$ is; (ii) using this linear mapping it is possible to obtain a closed nonlinear equation for $u^+$ only, from the top row, and the linear part of this equation has a Schur complement form; (iii) the unknown $u^-$ is recovered by solving a linear equation; (iv) the nonlinear equation for $u^+$ may be viewed as the equation for a critical point of a functional of $u^+$ only. These four points are encapsulated in the previous two theorems, where they are rendered in a form familiar from Gaussian process regression and representer theorems [28]. Ideas analogous to those described in this remark underlie all representer theorems, but are not so transparent in the infinite-dimensional setting. We present the results in the abstract form of Proposition 2.4 and Proposition 2.6 to highlight the formal analogies with our companion papers [20, 21] which study the limiting continuum optimization problems that arise in the $N \rightarrow \infty$ limit.

\[\diamond\]
The expansion (2.10) indicates that the minimizer \( u^* \in \text{span} \{ c_j \}_{j \in \mathbb{Z}'} \); we refer to the \( c_j \) as representers. In other words, the minimizer \( u^* \) belongs to a subspace of the column space of the covariance matrix \( C_\tau \). Recall that by definition \( C_\tau = \tau^{2\alpha}(L + \tau^2 I)^{-\alpha} \) and so we can compute the vectors \( c_j \) by solving the linear equations,

\[
(L + \tau^2 I)^{\alpha}c_j = \tau^{2\alpha}e_j, \quad j \in \mathbb{Z}',
\]

that cost \( J \) linear solves involving an \( N \times N \) matrix. With the \( \{ c_j \}_{j \in \mathbb{Z}'} \) at hand we can extract the matrix \( C'_\tau \) and solve the nonlinear system (2.14) for \( b^* \) and in turn compute the solution \( u^* \) by (2.15); note that \( F_j \) is defined in Proposition 2.4(ii). Then, whenever \( J \ll N \) solving the dimension reduced problem (2.14) is typically much faster than solving the full nonlinear system (2.8). We present evidence of this improved efficiency in subsection 4.3 in the context of the one-hot method for multi-class classification.

We now proceed to exploit the geometry in the problem dictated by the nearly-disconnected graph structure that forms the basic assumption underlying our consistency analysis. It is clear that the geometry of \( u^* \) is dictated by the geometry of the vectors \( c_j \). It is then natural for us to try to identify the geometry of the \( c_j \). By Lemma A.2 we have the expansion

\[
c_j = \sum_{k=1}^{N} \frac{1}{\lambda_k}(\phi_k)_j \phi_k,
\]

where \( \{ \lambda_k, \phi_k \} \) are the eigenpairs of \( C_\tau^{-1} \). Therefore, by analyzing the spectrum of \( C_\tau \) we can identify the geometry of the vectors \( c_j \) which together with the vector \( b^* \) allow us to identify the minimizer \( u^* \) and eventually prove consistency of the probit minimizer. Spectral analysis of \( C_\tau \) is outlined in Appendix A, and in the next subsection we present the main propositions and assumptions that are used in the remainder of the article.

### 2.5. Perturbation Theory For Covariance Operators.

Consider a disconnected graph \( G_0 = \{ X, W_0 \} \) consisting of \( K < N \) connected components \( \tilde{G}_k \), i.e., the subgraphs \( \tilde{G}_k \) are connected but there exist no edges between pairs of components \( \tilde{G}_i, \tilde{G}_k \) with \( i \neq k \). Without loss of generality assume the nodes in \( Z \) are ordered so that \( Z = \{ \tilde{Z}_1, \tilde{Z}_2, \ldots, \tilde{Z}_K \} \) and the \( \tilde{Z}_k \) collect the nodes in the \( k \)-th subgraph \( \tilde{G}_k \). We refer to the \( \tilde{Z}_k \) as clusters. Thus, the weight matrix \( W_0 = (w_{ij}^{(0)}) \) satisfies

\[
\begin{align*}
w_{ij}^{(0)} & \geq 0 & \text{if } i \neq j \text{ and } i, j \in \tilde{Z}_k \text{ for some } k, \\
w_{ij}^{(0)} & = 0 & \text{if } i = j \text{ or } i \in \tilde{Z}_k, j \in \tilde{Z}_\ell \text{ for } k \neq \ell.
\end{align*}
\]

We will show that when \( \tau \) is small the geometry of \( c_j \) is dominated by indicator functions of the clusters \( \tilde{Z}_k \). First, let us collect some assumptions on the graph \( G_0 \).

#### Assumption 1.

The graph \( G_0 = \{ X, W_0 \} \) satisfies the following conditions with \( K < N \):

(a) The weight matrix \( W_0 \) satisfies (2.18) and has a block diagonal form \( W_0 = \text{diag}(\tilde{W}_1, \ldots, \tilde{W}_K) \) where \( \tilde{W}_k \) are the weight matrices of the subgraphs \( \tilde{G}_k \).

(b) Let \( \tilde{L}_k \) be the graph Laplacian matrices of the subgraphs \( \tilde{G}_k \), i.e.,

\[
\tilde{L}_k := \tilde{D}_k^{-1/2}(\tilde{D}_k - \tilde{W}_k)\tilde{D}_k^{-1/2}
\]
with $\tilde{D}_k$ denoting the degree matrix of $\tilde{W}_k$. There exists a uniform constant $\theta > 0$ so that for $j = 1, \cdots, K$ the submatrices $\tilde{L}_j$ have a uniform spectral gap, i.e.,

$$\langle x, \tilde{L}_j x \rangle \geq \theta \langle x, x \rangle,$$

for all vectors $x \in \mathbb{R}^{N_k}$ and $x \perp \tilde{D}_k^p \mathbf{1}_k$ where $\mathbf{1}_k \in \mathbb{R}^{N_k}$ are vectors of ones.

Note that the preceding assumption means that the clusters $\tilde{G}_k$ are pathwise connected. Further, condition (2.19) excludes the possibility of outliers, that is, nodes of zero degree. This means that the inner product as expressed in (2.4) is well defined.

In the following and throughout the remainder of the article we introduce the following notation: We define the graph Laplacian in terms of the weight matrix $W_0$ and the associated degree matrix $D_0$:

$$L_0 := D_0^{-p}(D_0 - W_0)D_0^{-p} \in \mathbb{R}^{N \times N}.$$  

Let $Z = \{\tilde{Z}_1, \tilde{Z}_2, \cdots, \tilde{Z}_K\}$ and define the weighted indicator functions

$$(\chi_k)_j := \begin{cases} (d_0^{(j)})^p, & \text{if } j \in \tilde{Z}_k, \\ 0, & \text{otherwise}, \end{cases} \quad \text{and} \quad \bar{\chi}_k := \frac{1}{|\chi_k|} \chi_k.$$  

Similarly, the weighted indicator function on $Z$ is denoted by

$$\chi := D_0^p \mathbf{1}, \quad \text{and} \quad \bar{\chi} := \frac{1}{|\chi|} \chi.$$  

The next proposition, whose proof is given in appendix A.1, identifies the geometry of the covariance matrix constructed from $L_0$. The key take away is that, for small $\tau$, the covariance matrix is nearly block diagonal which implies negligible correlation outside clusters.

**Proposition 2.8.** Let $G_0 = \{X, W_0\}$ satisfy Assumption 1 and let $L_0$ be a graph Laplacian of form (2.20) on $G_0$ and define the covariance matrix $C_{\tau,0}$ on $G_0$ for $\tau^2, \alpha > 0$

$$C_{\tau,0} := \tau^{2\alpha} (L_0 + \tau^2 I)^{-\alpha}.$$  

Then as $\tau \downarrow 0$,

$$\|c_{j,0} - (\bar{x}_k)_j \bar{\chi}_k\| \leq \Xi \tau^{4\alpha} \quad \forall j \in \tilde{Z}_k,$$

where $c_{j,0} = (c_{1j}, \cdots, c_{Nj})^T$ is the $j$-th column of $C_{\tau,0}$, and $\Xi > 0$ is a uniform constant.

Thus, when $\tau^{2\alpha}$ is small the vectors $c_{j,0}$ have a similar geometry to the set functions $\bar{\chi}_k$. We now show that this result remains true when the graph $G_0$ is perturbed.

Consider a perturbation of the matrix $W_0$ by modifying some of the entries $w_{ij}^{(0)}$ and possibly making the graph connected. More precisely, let $G_\epsilon = \{X, W_\epsilon\}$ where

$$W_\epsilon = W_0 + \sum_{h=1}^{\infty} \epsilon^h W^{(h)}.$$  

We need to collect some assumptions on the perturbed matrix $W_\epsilon$ to restrict the type of perturbations that are allowed.
Assumption 2. The graph $G_\epsilon = \{X,W_\epsilon\}$ satisfies the following assumptions:
(a) The weight matrix $W_\epsilon$ satisfies expansion (2.24) with $W_0$ satisfying (2.18).
(b) The sequence of matrix norms satisfies $\{|W^{(h)}|_2|\in \ell_\infty$, and for each $h \in \mathbb{Z}$, $W^{(h)} = (w_{ij}^{(h)})$ is self-adjoint and satisfies
\begin{equation}
\left\{ \begin{array}{ll}
w_{ij}^{(h)} \geq 0, & \text{if } w_{ij}^{(0)} = 0 \text{ for } i,j \in \mathbb{Z}, i \neq j, \\
& \text{if } w_{ij}^{(0)} > 0.
\end{array} \right.
\end{equation}
Note that $w_{ij}^{(h)}$ may be negative for indices $i,j$ such that $w_{ij}^{(0)} > 0$.

Associated to the weight matrix $W_\epsilon$ is a graph Laplacian and covariance matrix
\begin{equation}
L_\epsilon := D^{-\rho}(D_\epsilon - W_\epsilon)D^{-\rho}, \quad C_{\tau,\epsilon} := \tau^{2\alpha}(L_\epsilon + \tau^2 I)^{-\alpha},
\end{equation}
where $\tau^2, \alpha > 0$ and $p \in \mathbb{R}$. We then have the following result stating that if $\epsilon = o(\tau^2)$, then the geometry of the column space of $C_{\tau,\epsilon}$ remains close to the set functions $\chi_k$, whilst if $\epsilon = \Theta(\tau^2)$ then prior correlation between clusters is introduced. The proof is given in appendix A.2.

**Proposition 2.9.** Suppose $G_0$ satisfies Assumption 1 and $G_\epsilon$ satisfies Assumption 2. For $\tau^2, \alpha > 0$ define the covariance matrix $C_{\tau,\epsilon}$ as in (2.26) and denote the $j$-th column of $C_{\tau,\epsilon}$ by $c_{j,\epsilon} = (c_{1,j}^{(\epsilon)}, \ldots, c_{N,j}^{(\epsilon)})^T$. Then
(a) If $\epsilon = o(\tau^2)$, then there exists a constant $\Xi > 0$ independent of $\epsilon$ and $\tau$ so that
\begin{equation}
\|c_{j,\epsilon} - (\hat{X}_k)_{j} \hat{X}_k\|^2 \leq \Xi \left(\epsilon^2/\tau^2 + \tau^{2\alpha} + \epsilon^2\right), \quad \forall j \in \hat{Z}_k.
\end{equation}
(b) If $\epsilon/\tau^2 = \beta > 0$ is constant, then there exist constants $\Xi', \Xi > 0$ independent of $\epsilon$ and $\tau$ so that
\begin{equation}
\|c_{j,\epsilon} - [(1 - \tilde{\beta})(\hat{X})_j \hat{X} + \tilde{\beta} (\hat{X}_k)_j \hat{X}_k]\|^2 \leq \Xi \left(\epsilon^2 + \tau^{2\alpha}\right), \quad \forall j \in \hat{Z}_k,
\end{equation}
and where $\tilde{\beta} = (1 + \Xi'/\beta)^{-\alpha}$.

### 2.6. Consistency Of The Probit Method

Throughout this section we consider a graph $G_0 = \{X,W_0\}$ consisting of $K$ components, along with perturbed graphs $G_\epsilon = \{X,W_\epsilon\}$ as introduced in the previous subsection. As before, we use $Z' \subset \hat{Z}$ to denote the set of points where labels are observed and assume the usual ordering $\hat{Z} = \hat{Z}_1 \cup \hat{Z}_2 \cup \cdots \cup \hat{Z}_K$ where $\hat{Z}_k$ denotes the $k$-th cluster in $\hat{Z}$. Recall the probit assumption on the labelled data, namely that
\begin{equation}
y(j) = \text{sgn}(u^T_j + \eta_j), \quad j \in Z',
\end{equation}
where $u^T = (u_1^T, \ldots, u_K^T)$ is the vector isomorphic to the ground truth function $u^T$.

The additive noises $\eta_j$ are assumed to be a rescaling of a sequence of i.i.d. samples from a reference density $\psi$. That is, for all $j \in Z'$,
\begin{equation}
\eta_j = \gamma \hat{\eta}_j, \quad \hat{\eta}_j \overset{i.i.d.}{\sim} \psi,
\end{equation}
where $\psi$ is the PDF of a centered random variable with unit standard deviation, and thus $\gamma > 0$ is the standard deviation of the $\eta_j$. Thus the $\eta_j$ are i.i.d and have distribution
\begin{equation}
\psi_\gamma(t) = \frac{1}{\gamma} \psi\left(\frac{t}{\gamma}\right).
\end{equation}
We recall a useful result stating that log-concave random variables have exponential tails [10, Thm. 4.3.7].

**Lemma 2.10.** Let $\psi(t)$ be a log-concave PDF on $\mathbb{R}$. Then there is $\omega_c > 0$ such that, for all $\omega \in [0, \omega_c)$, $\int_\mathbb{R} \exp(\omega |t|) \psi(t) dt < +\infty$.

With this lemma we can estimate the probability of the event where the observed labels $y(j)$ have the same value as $\text{sgn}(u_j^\dagger)$, i.e., the event where the data is exact.

**Lemma 2.11.** Let $\psi(t)$ be a log-concave PDF on $\mathbb{R}$. Then there exist constants $\omega_1, \omega_2 > 0$ depending only on $\psi$, so that

$$
\mathbb{P}(y(j) = \text{sgn}(u_j^\dagger), \text{ for all } j \in Z') \geq \prod_{j \in Z'} \left[ 1 - \omega_2 \exp\left( -\frac{\omega_1}{\gamma} |u_j^\dagger| \right) \right].
$$

That is, when $\gamma > 0$ is small the data $y$ is exact with high probability.

**Proof.** By Lemma 2.10 there exists a sufficiently small $\omega_1 > 0$ and constant $\omega_2 > 0$ so that for $\gamma > 0$,

$$
\omega_2 = \int_\mathbb{R} \exp\left( \frac{\omega_1}{\gamma} |t| \right) \psi(\gamma t) dt < +\infty.
$$

Let $\eta_j \sim \psi_\gamma$, then by Markov’s inequality for $\theta > 0$

$$
\mathbb{P}(\eta_j \geq \theta) \leq \omega_2 \exp\left( -\frac{\omega_1}{\gamma} \theta \right).
$$

But $y(j) \neq \text{sgn}(u^\dagger(j))$ whenever

$$
\eta_j < -|u_j^\dagger| \quad \text{if} \quad u_j^\dagger > 0,
$$

$$
\eta_j \geq |u_j^\dagger| \quad \text{if} \quad u_j^\dagger < 0.
$$

The result now follows from the symmetry of the $\psi_\gamma$ and independence of the $\eta_j$.  

**Lemma 2.12.** Suppose (2.27) and (2.28) hold, $\psi$ is log-concave and $|u_j^\dagger| > \theta > 0$ for all $j \in Z'$. Then for any sequence $\gamma \downarrow 0$, $y(j) \xrightarrow{a.s.} \text{sgn}(u_j^\dagger)$ a.s. with respect to $\prod_{j \in Z'} \psi(t_j)$ the law of the i.i.d. sequence $\{\tilde{\eta}_j\}_{j \in Z'}$.

**Proof.** Since $\psi$ is log-concave it has exponential tails by Lemma 2.10 and $|\tilde{\eta}_j| < \infty$ a.s.  

Recall that value of $\eta_j = \gamma \tilde{\eta}_j$. Then for any fixed $\tilde{\eta}_j \in (-\infty, \infty)$, if $\gamma < \theta/|\tilde{\eta}_j|$ then $y(j) = \text{sgn}(u_j^\dagger)$. Since $\tilde{\eta}_j$ are a.s. finite the result follows.

Now consider a probit likelihood potential of the form

$$
\Phi_\gamma(u,y) := \sum_{j \in Z'} -\log \Psi_\gamma(u_j y(j)),
$$

where

$$
\Psi_\gamma(s) = \int_{-\infty}^s \psi_\gamma(t) dt, \quad s \in \mathbb{R}.
$$

For $\epsilon, \tau^2, \gamma > 0$ we study the consistency of minimizers of the functionals

$$
\mathcal{J}_{\tau, \epsilon, \gamma}(u) := \frac{1}{2} \langle u, C_{\tau, \epsilon}^{-1} u \rangle + \Phi_\gamma(u,y), \quad u \in \mathbb{R}^N.
$$

This functional is of the same form as (2.6), and so the results in section 2.4 apply.

Footnote 3: In fact the proof reveals that all we need is that the $\tilde{\eta}_j$ are a.s. finite, for which log-concavity suffices.
2.6.1. Probit Consistency With A Single Observed Label. We start with the simple case of a single observed label. Without loss of generality assume \( Z' = \{1\} \), that is the observed label is the first point in the first cluster \( \tilde{Z}_1 \) and \( u_1^* > 0 \).

**Proposition 2.13.** Consider the single observation setting above and suppose Assumptions 1 and 2 are satisfied by \( G_0 \) and \( G_e \). Let \( u^* \) denote the minimizer of \( J_{\tau,\epsilon,\gamma} \) and let \( \gamma > 0 \).

(a) If \( \epsilon = o(\tau^2) \) as \( \tau \to 0 \) then \( \exists \tau_0 > 0 \) so that \( \forall (\tau, \gamma) \in (0, \tau_0) \times (0, \infty) \) and \( \forall j \in \tilde{Z}_1 \)

\[
\mathbb{P}\left( \text{sgn}(u_j^*) = +1 \right) \geq 1 - \omega_2 \exp\left( -\frac{\omega_1}{\gamma} |u_j^*| \right),
\]

where \( \omega_1, \omega_2 > 0 \) are uniform constants depending only on \( \psi \).

(b) If \( \epsilon = \Theta(\tau^2) \) then the above statement holds for all \( j \in Z \).

**Proof.** (a) By Corollary 2.6 we have that \( u_1^* = b \) where \( b \) solves

\[
b = (C_{\tau,\epsilon})_{11} F_{1,\gamma}(b).
\]

where we recall \( F_{1,\gamma}(s) = y(1) \psi_\gamma(s y(1)) / \psi_\gamma(s y(1)) \). Furthermore, by Proposition 2.9(a) and equivalence of \( \ell_\infty \) and \( \ell_2 \) norms we infer that there exists \( \tau_0 > 0 \) so that \( \forall \tau \in (0, \tau_0) \) we have

\[
(c_{j,\epsilon})_{1} = \begin{cases} (\bar{x}_1)_{j} (\bar{x}_1)_1 + \mathcal{O}(\epsilon/\tau^2 + \tau^{2\alpha} + \epsilon), & j \in \tilde{Z}_1, \\ \mathcal{O}(\epsilon/\tau^2 + \tau^{2\alpha} + \epsilon), & j \notin \tilde{Z}_1. \end{cases}
\]

Thus, we can rewrite (2.34) up to leading order in the form

\[
b = |(\bar{x}_1)_1|^2 F_{1,\gamma}(b).
\]

Now consider the event where \( y(1) = +1 \), i.e., the measurement is exact. Then \( b > 0 \) since \( F_{1,\gamma} > 0 \) and \( (\bar{x}_1)_1 > 0 \). Finally, by Corollary 2.6(iii) we can write

\[
u^* = F_{1,\gamma}(b) c_{1,\epsilon} = F_{1,\gamma}(b) (\bar{x}_1)_1 \bar{x}_1 + \mathcal{O}(\epsilon/\tau^2 + \tau^{2\alpha} + \epsilon).
\]

Thus, when \( \epsilon/\tau^2, \tau \) and \( \epsilon \) are sufficiently small and the data is exact, \( u^* \) is positive on \( \tilde{Z}_1 \). The claim now follows by Lemma 2.11. The statement in (b) follows by an identical argument except that in this case

\[
c_{1,\epsilon} = [(1 - \bar{b})(\bar{x})_1 \bar{x} + \bar{b}(\bar{x}_1)_1 \bar{x}_1] + \mathcal{O}(\tau^{2\alpha} + \epsilon)
\]

with \( \bar{b} \in (0,1) \). Thus in the event that \( y(1) = +1 \) the minimizer \( u^* \) is positive on all of \( Z \).

The following corollary shows that the relationship between \( \tau \) (which is user-specified) and \( \epsilon \) (which is a property of the unlabelled data) is crucial in determining how the probit algorithm assigns labels to the entire data set in the small noise limit; case (a) is neutral about \( Z \setminus \tilde{Z}_1 \) whilst case (b) leads to \( Z \setminus \tilde{Z}_1 \) being labelled the same as \( \tilde{Z}_1 \). The reason for the difference is that the limit process in (a) corresponds, asymptotically, to a setting where a priori different clusters have no correlation whilst under the limit process (b) there is positive correlation; thus, under (b), the one given label is propagated to the entire set of nodes. When more clusters are labelled then similar effects are present under the limit process (b), but are harder to express analytically because they set-up a competition between potentially conflicting prior information and observed label information. This is investigated numerically in section 4.
Corollary 2.14. Consider the single observation setting as above. Suppose Proposition 2.13 is satisfied and $|u'_j| > 0$ for all $j \in Z'$. Then the following holds with a.s. convergence in the sense of Lemma 2.12:
(a) For any sequence $\gamma, \tau, \epsilon \downarrow 0$ along which $\epsilon = o(\tau^2)$ it holds that
$$\text{sgn}(u'_j) \overset{a.s.}{\longrightarrow} \text{sgn}(u_j), \quad \forall j \in \tilde{Z}_1.$$  
(b) For any sequence $\gamma, \tau, \epsilon \downarrow 0$ along which $\epsilon = \Theta(\tau^2)$ the above statement holds for all $j \in Z$.

Proof. In the the proof of Proposition 2.13(a) we showed that $\text{sgn}(u'_j) = +1$ on $\tilde{Z}_1$ so long as the data $y(1) = +1$ independent of $\gamma > 0$. In light of this, (a) follows directly from Lemma 2.12 implying that the data $y(j) \to \text{sgn}(u_j)$ a.s. as $\gamma \downarrow 0$. Statement (b) follows in the same way but using the proof of Proposition 2.13(b).

2.6.2. Probit Consistency with Multiple Observed Labels. Let us now consider the setting where multiple labels are observed, i.e. $|Z'| = J \geq 2$. We need to make an additional assumption on the ground truth function $u^\dagger$.

Assumption 3. Let $\tilde{Z}_k$ be a cluster within which a label has been observed, i.e., $\tilde{Z}_k \cap Z' \neq \emptyset$. Then $\text{sgn}(u^\dagger)$ does not change within $\tilde{Z}_k$.

It is helpful in the following to define $Z''$ to be the index set of nodes within all clusters $\tilde{Z}_k$ where a label has been observed, i.e.,

$$Z'' := \bigcup_{(k: \tilde{Z}_k \cap Z' \neq \emptyset)} \tilde{Z}_k.$$

Theorem 2.15. Consider the multiple observation setting above and suppose Assumptions 1, 2 and 3 are satisfied by $G_0, G_e$ and $u^\dagger$. Let $u^\star$ be the minimizer of $J_{\tau, e, \gamma}$. If $\epsilon = o(\tau^2)$ as $\tau \to 0$ then $3\tau_0 > 0$ so that $\forall (\tau, \gamma) \in (0, \tau_0) \times (0, \infty)$ and $\forall j \in Z''$

$$\mathbb{P}\left(\text{sgn}(u'_j) = \text{sgn}(u_j)\right) \geq \prod_{i \in Z''} \left[1 - \omega_2 \exp\left(-\frac{\omega_1}{\gamma} |u'_j|\right)\right], \quad \forall j \in Z'',$$

where $\omega_1, \omega_2 > 0$ are uniform constants depending only on $\psi$.

Proof. Our proof follows a similar approach to the single observation case. The main difference is that now the dimension reduced system (2.14) takes the form

$$(C'_{\gamma, \tau})^{-1} b^\star = F'_\gamma(b^\star).$$

Where $C'_{\gamma, \tau}$ is now the submatrix of $C_{\gamma, \tau}$ with the rows and columns of the indices $Z \setminus Z'$ removed. It follows from Proposition 2.9 that for small $\tau$ the matrix $C'_{\gamma, \tau} = (c'_{ij})$ approaches a block diagonal matrix and so

$$c'_{ij} = \begin{cases} (\hat{x}_k)_{\pi^{-1}(i)} (\hat{x}_k)_{\pi^{-1}(j)} + \mathcal{O}\left(\epsilon/\tau^2 + \tau^{2\alpha} + \epsilon\right), & \text{if } \pi^{-1}(i), \pi^{-1}(j) \in \tilde{Z}_k, \\ \mathcal{O}\left(\epsilon/\tau^2 + \tau^{2\alpha} + \epsilon\right), & \text{if } \pi^{-1}(i) \in \tilde{Z}_k, \pi^{-1}(j) \in \tilde{Z}_\ell, k \neq \ell. \end{cases}$$

Without loss of generality assume that observations are made in the clusters $\tilde{Z}_1, \ldots, \tilde{Z}_{K'}$. Note that $K' \leq K$ since we do not need to assume observations are made in every cluster. Let $\tilde{Z}'_1, \ldots, \tilde{Z}'_{K'}$ denote the indices of the labelled nodes in the corresponding clusters and define $J_k := |\tilde{Z}'_k|$. Then (2.37) approximately decouples between the
clusters and up to leading order we can write

\[(\hat{x}_k)^{-1}b^*_{\pi(j)} = \sum_{i \in \tilde{Z}'_k} (\hat{x}_k)_{i} F_{i,\gamma}(b^*_{\pi(i)}), \quad \text{for } j \in \tilde{Z}'_k \text{ and } k \in \{1, \ldots, K'\}.
\]

Observe that the right hand side is independent of \(j\) and so, writing \(b^*_\ell = u^*_{x_{\pi^{-1}(\ell)}}\) for \(\ell \in \{1, 2, \ldots, J\}\) as in Corollary 2.6(iii), it follows that \(D_0^* u^*\) is a constant vector on the index sets \(\tilde{Z}'_k\). Thus, we can further simplify this equation to get

\[(\hat{x}_k)^{-1}u^*_j = \sum_{i \in \tilde{Z}'_k} (\hat{x}_k)_{i} F_{i,\gamma}(u^*_j), \quad \text{for } j \in \tilde{Z}'_k \text{ and } k \in \{1, \ldots, K'\},
\]

which we only need to solve once on every cluster. Finally, observe that \(\text{sgn}(u^t)\) does not change on \(\tilde{Z}_k\) following Assumption 3 and so in the event that \(y\) is exact we have

\[u^*_j = (\hat{x}_k)_{j} \left( \sum_{i \in \tilde{Z}'_k} (\hat{x}_k)_{i} \right) \frac{\text{sgn}(u^t_j) \psi_{\gamma}(\text{sgn}(u^t_j)u^*_j)}{\Psi_{\gamma}(\text{sgn}(u^t_j)u^*_j)}, \quad \text{for } j \in \tilde{Z}'_k \text{ and } k \in \{1, \ldots, K'\}.
\]

To this end, \(\text{sgn}(u^t)\) agrees with \(\text{sgn}(u^t)\) on the observation nodes. Once again using Corollary 2.6(iii) we see that

\[u^* = \sum_{j \in \tilde{Z}'_k} \frac{\text{sgn}(u^t_j) \psi_{\gamma}(\text{sgn}(u^t_j)b^*_{\pi(j)})}{\Psi_{\gamma}(\text{sgn}(u^t_j)\hat{x}_k)_{j}} \chi_{\gamma}, \quad c_{j,\epsilon} = \sum_{k=1}^{K'} \tilde{a}_k \hat{x}_k,
\]

where the last identity is once more up to leading order following Proposition 2.9 and for coefficients

\[\tilde{a}_k := \sum_{j \in \tilde{Z}'_k} \frac{\text{sgn}(u^t_j) \psi_{\gamma}(\text{sgn}(u^t_j)b^*_{\pi(j)})}{\Psi_{\gamma}(\text{sgn}(u^t_j)\hat{x}_k)_{j}} (\hat{x}_k)_{j},
\]

such that \(\text{sgn}(\tilde{a}_k)\) agrees with \(\text{sgn}(u^t)\) on \(\tilde{Z}_k\) for \(k = 1, \ldots, K'\). Finally, the claim follows by applying Lemma 2.11 to compute the probability of the event where the data is exact.

Similarly to Corollary 2.14 the next corollary follows from the proof of Theorem 2.15 and Lemma 2.12.

**Corollary 2.16.** Suppose Theorem 2.15 is satisfied and \(|u^t_j| > 0\) for \(j \in \tilde{Z}'\). Then for any sequence \(\gamma, \tau, \epsilon \downarrow 0\) along which \(\epsilon = o(\tau^2)\) it holds that,

\[\text{sgn}(u^*_j) \xrightarrow{a.s.} \text{sgn}(u^t_j) \quad \forall j \in \tilde{Z}'\,
\]

with a.s. convergence in the sense of Lemma 2.12.

**3. Multi-Class Classification: The One-Hot Method.** In the multi-class setting \(M > 2\) we can no longer use the \(\text{sgn}(\cdot)\) function to reduce the dimension of the latent variable to \(\mathbb{R}^{M-1}\) as we did for binary \(M = 2\) classification in section 2. Instead we use one-hot encoding and work directly with latent variables taking value in \(\mathbb{R}^{M}\). We set up the one-hot methodology in subsection 3.1 assuming that \(M \geq 2\), though it would be un-necessary to use it for \(M = 2\) and Gaussian label noise when it reduces to probit. In subsection 3.2 we study the form of the one-hot likelihood that appears
in the optimization problem, resulting from the labelled data. In subsection 3.3 we introduce a quadratic regularization term for the one-hot method that uses the covariance matrix $C_\tau$ of (2.5) and is analogous to the quadratic penalty used in the probit method. In subsection 3.4 we study the one-hot minimization problem, formulating a discrete representer theorem for the one-hot method. Subsection 3.5 concludes the analysis of the one-hot method, studying consistency in some detail by putting together the results of previous subsection with the spectral theory introduced in section 2.5.

3.1. Set-Up. We now turn our attention to the multi-class classification problem, i.e., where the label function $l : Z \mapsto \{1, \cdots, M\}$ assigns one of $M \geq 1$ classes to each point in $X$. In this case the sign function from section 2 is no longer an appropriate classifying function and we need a different method. We shall utilize the one-hot mapping

$$S(\mathbf{v}) = \arg \max_k v_k, \quad \mathbf{v} = (v_1, \cdots, v_M) \in \mathbb{R}^M.$$  

In the case of two maximal elements $v_{k_1} = v_{k_2}$, we take the smallest index. As with probit, the case of a near-tie is prone to misclassification by perturbation. For the purpose of consistency analysis, we later make assumptions that ensure a tie for the maximal element cannot occur.

The latent variable $u : Z \mapsto \mathbb{R}^M$ is isomorphic to a matrix $U = (u_{mj}) \in \mathbb{R}^{M \times N}$. We use $\mathbf{u}_j$ to denote the $j$-th column of $U$ as a vector in $\mathbb{R}^M$. With this notation at hand we consider the following model for observed labels $y$:

$$y(j) = S(\mathbf{u}_j + \eta_j), \quad j \in Z',$$

where

$$\eta_j = (\eta_{1j}, \cdots, \eta_{Mj})^T \in \mathbb{R}^M, \quad \text{and} \quad \eta_{mj} \overset{iid}{\sim} \psi.$$  

Here $\psi$ is a probability density function on $\mathbb{R}$ as before.

Remark 3.1. Note that the assumption that $\eta_{mj}$ are i.i.d. is not needed in general and one can consider correlations in the observation noise both between different classes and also amongst different points in the dataset. However, for simplicity we only consider i.i.d. noise and leave the correlated noise setting for future study.

3.2. The One-Hot Likelihood. We begin by identifying the likelihood potential $\Phi$ for the model (3.2). For $j \in Z'$ and $m, \ell \in \{1, \cdots, M\}$ we have

$$P[y(j) = m|U] = P[u_{mj} + \eta_{mj} \geq u_{\ell j} + \eta_{\ell j}, \quad \forall \ell \in \{1, \cdots, M\}]$$

$$= P[\eta_{\ell j} \leq \eta_{mj} + u_{mj} - u_{\ell j}, \quad \forall \ell \in \{1, \cdots, M\}]$$

$$= E\left[ P[\eta_{\ell j} \leq \eta_{mj} + u_{mj} - u_{\ell j}, \quad \forall \ell \in \{1, \cdots, M\}] \bigg| \eta_{mj} \right]$$

$$= E \left[ \prod_{\ell \in m} P[\eta_{\ell j} \leq \eta_{mj} + u_{mj} - u_{\ell j}] \bigg| \eta_{mj} \right]$$

$$= \int_\mathbb{R} \psi(t) \prod_{\ell \in m} \Psi(t + u_{mj} - u_{\ell j}) dt =: \tilde{\Psi} (\mathbf{u}_j; m).$$

where $\Psi$ is the CDF of $\psi$ as in the binary case. To this end, we define the likelihood potential $\Phi(U; y)$ as
(3.3)

\[ \Phi(U; y) = - \sum_{j \in Z'} \log \Psi(u_j; y(j)) = - \sum_{j \in Z'} \log \left( \int_{\mathbb{R}} \psi(t) \prod_{\ell \neq y(j)} \Psi(t + u_{y(j)} - u_{\ell}) dt \right), \]

which is in a similar form to (2.2).

3.3. Quadratic Regularization Via Graph Laplacians (Multi-Class Case).

Recall, the matrix \( C_\tau \) defined in (2.5) based on the graph Laplacian \( L \). In a similar way to the probit method we define a quadratic regularization term for matrices \( U \in \mathbb{R}^{M \times N} \) of the form

(3.4)

\[ \langle C_\tau^{-1}, U^T U \rangle_F = \sum_{j=1}^{N} \sum_{\ell=1}^{M} (C_\tau^{-1})_{j\ell} (U^T U)_{j\ell} = \sum_{m=1}^{M} \sum_{j=1}^{N} (C_\tau^{-1})_{j\ell} u_{m\ell} u_{mj}, \]

where \( \langle \cdot, \cdot \rangle_F \) is the Frobenius inner product. In the following we will use this quadratic term to regularize Problem 1.3 in the multi-class setting.

Remark 3.2. If we think of \( C_\tau^{-1} \) as a smoothing operator then the above choice for the regularization term promotes smoothness of the rows of \( U \) while the columns of \( U \) can be discontinuous. This means that each component of the function \( u : Z \to \mathbb{R}^M \) isomorphic to \( U \) is smooth amongst the vertices of \( G \) while the components themselves are allowed to be discontinuous at each node.

3.4. Properties Of The One-Hot Minimizer. Putting together the one-hot likelihood in (3.3) and the quadratic regularization term (3.4) we define the one-hot functional

(3.5)

\[ J(U) := \frac{1}{2} \langle C_\tau^{-1}, U^T U \rangle_F + \Phi(U; y), \quad U \in \mathbb{R}^{M \times N}. \]

We will see shortly that the one-hot functional has very similar properties to the probit functional \( J \) in binary classification. In particular, the regularization term (3.4) is strictly convex and provides stability and geometric information via the operator \( C_\tau \) and the one-hot likelihood \( \Phi \) is also convex and makes sure the minimizer of \( J \) is a good predictor of observed labels. We start by showing the convexity of the likelihood potential.

**Proposition 3.3 (Convexity of the one-hot likelihood).** Let \( \psi \) be a log-concave PDF on \( \mathbb{R} \). Then the function

\[ \tilde{\Psi}(v; m) = \int_{\mathbb{R}} \psi(t) \prod_{\ell \neq m} \Psi(t + v_m - v_\ell) dt, \quad v \in \mathbb{R}^M, \]

is log-concave on \( \mathbb{R}^M \) for all \( m \in \{1, \ldots, M\} \), and where \( \Psi \) is the CDF of \( \psi \).

**Proof.** By [1, Thm. 1] the functions \( \Psi \) are log-concave whenever \( \psi \) is log-concave. Furthermore, since log-concavity is preserved under affine transformations and finite products [29, Sec 3.1] we conclude that \( f(t, v) = \psi(t) \prod_{\ell \neq m} \Psi(t + v_m - v_\ell) \) is log-concave on \( \mathbb{R}^{M+1} \). The result now follows from the fact that the marginals of a log-concave function are also log-concave [26, Thm. 3] and \( \tilde{\Psi}(v; m) \) is precisely the marginal of \( f(t, v) \) over the \( t \) variable.

Putting this result together with the fact that the quadratic term in (3.5) is strictly convex whenever \( C_\tau^{-1} \) is strictly positive definite (which is true when \( \tau^2 > 0 \)) gives the following result.
Proposition 3.4. Let \( \psi \) be a continuous and log-concave PDF on \( \mathbb{R} \) and let \( C^{-1}_r \) be a strictly positive-definite matrix on \( \mathbb{R}^N \). Then the functional \( J \) defined in (3.5) with \( \Phi \) given by (3.3) is strictly convex.

We are now set to prove an analog of Proposition 2.4 for the one-hot functional.

Proposition 3.5 (Representer theorem for one-hot functional). Let \( G = \{X,W\} \) be a weighted graph and let \( \psi \) be a log-concave PDF. Suppose \( \Phi \) is given by (3.3) and the matrix \( C_r \) is given by (2.5) with parameters \( \sigma^2, \alpha > 0 \). Then,

(i) The one-hot functional \( J \) has a unique minimizer \( U^* \in \mathbb{R}^{M \times N} \).

(ii) The minimizer \( U^* \) satisfies the EL equations

\[
C_r^{-1}U^{*T} = \sum_{j \in Z'} e_j (f_j (u_j^*))^T, 
\]

where \( e_j \) is the \( j \)-th standard coordinate vector in \( \mathbb{R}^N \), the vector \( u_j^* \) denotes the \( j \)-th column of \( U^* \) and the functions \( f_j : \mathbb{R}^M \to \mathbb{R}^M \) are defined as

\[
f_j (v) = (f_{1,j} (v), \ldots, f_{M,j} (v))^T, \quad f_{m,j} (v) = \frac{1}{\Psi(v;y(j))} \frac{\partial \Psi(v;y(j))}{\partial v_m},
\]

for vectors \( v = (v_1, \ldots, v_M)^T \) and

\[
\frac{\partial \Psi(v;m)}{\partial v_i} = \begin{cases} 
- \int_\mathbb{R} \psi(t) \psi(t + v_m - v_i) \prod_{\ell \neq i,m} \Psi(t + v_m - v_i) dt & \text{if } i \neq m, \\
\sum_{k \neq m} \int_\mathbb{R} \psi(t) \psi(t + v_m - v_k) \prod_{\ell \neq k,m} \Psi(t + v_m - v_i) dt & \text{if } i = m.
\end{cases}
\]

(iii) The minimizer \( U^* \) can be represented using the expansion

\[
U^* = \sum_{j \in Z'} \tilde{a}_j c_j^T,
\]

where \( \tilde{a}_j \in \mathbb{R}^M \) and \( c_j = C_r e_j \in \mathbb{R}^N \).

(iv) The matrix \( U^* \) solves (3.6) if and only if the vectors \( \tilde{a}_j = (\tilde{a}_{1,j}, \ldots, \tilde{a}_{M,j})^T \in \mathbb{R}^M \) solve the nonlinear system of equations

\[
\tilde{a}_j = f_j \left( \sum_{k \in Z'} c_{jk} \tilde{a}_k \right), \quad \forall j \in Z',
\]

where \( c_{ij} \) denote the entries of \( C_r \).

Proof. The method of proof is very similar to Proposition 2.4. (i) Follows directly from Proposition 3.4. (ii) Observe that \( J(U) \) is continuously differentiable, and so (3.6) follows by directly computing the first order optimality conditions \( \nabla J(U^*) = 0 \). Proof of (iii) and (iv) is very similar to Proposition 2.4(iii) and (iv) and is essentially the result of solving the EL equations (3.6) directly.

Proposition 3.6 (One-hot dimension reduction). Suppose the conditions of Proposition 3.5 hold. Then

(i) The problem of finding the matrix \( U^* \in \mathbb{R}^{M \times N} \) the minimizer of the one-hot functional \( J \), is equivalent to the problem of finding the Matrix \( B^* \in \mathbb{R}^{M \times J} \) that solves

\[
(C_r')^{-1} B^{*T} = F'(B^*),
\]

where \( F' \) is given in Proposition 3.5.

(ii) The result of solving the EL equations (3.6) directly.

Proof. Observe that \( J(U) \) is continuously differentiable, and so (3.6) follows by directly computing the first order optimality conditions \( \nabla J(U^*) = 0 \). Proof of (iii) and (iv) is very similar to Proposition 2.4(iii) and (iv) and is essentially the result of solving the EL equations (3.6) directly.
where \( C'_r \) is as in (2.13) and, for matrices \( B \in \mathbb{R}^{M \times J} \) the map \( \mathcal{F}' : \mathbb{R}^{M \times J} \to \mathbb{R}^{J \times M} \) is defined by

\[
(\mathcal{F}'(B))_{im} := f_{\pi^{-1}(i)}(b_i) \quad \text{for} \quad (i, m) \in \{1, \ldots, J\} \times \{1, \ldots, M\},
\]

where the reordering map \( \pi \) is as in (2.12) and \( b_i \) denotes the \( i \)-th column of \( B \).

(ii) Moreover, the matrix \( B^* \) solves the optimization problem

\[
B^* = \arg \min_{B \in \mathbb{R}^{J \times M}} \mathcal{J}'(B),
\]

where

\[
\mathcal{J}'(B) := \frac{1}{2} \langle (C'_r)^{-1}, B^T B \rangle_F - \sum_{i=1}^{J} \log \bar{\Psi}(b_i; y(\pi^{-1}(i)))
\]

(iii) The matrices \( B^* \) and \( U^* \) satisfy the relationship

\[
U^* = \sum_{j \in \mathbb{Z}'^*} \tilde{b}_j^* c_j^T,
\]

where \( \tilde{b}_j^* \) denotes the \( \pi(j) \)-th column of \( B^*(C'_r)^{-T} \) and

\[
b_k^* = u_{\pi^{-1}(k)}^*, \quad k = \{1, \ldots, J\}.
\]

Proof. (i) Let \( A = (a_{mi}) \in \mathbb{R}^{M \times J} \) be the matrix with entries \( a_{mi} = \tilde{a}_{m \pi^{-1}(i)} \). That is, the columns of \( A \) are the \( \tilde{a}_j \) vectors. Then we can rewrite (3.8) as

\[
(3.10) \quad A = -\left( \mathcal{F}'(C'_r A^T) \right)^T,
\]

Let

\[
(3.11) \quad B^* = C'_r A^T \in \mathbb{R}^{J \times M}
\]

then we can rewrite (3.10) as

\[
(C'_r)^{-1} B^* = \mathcal{F}'(B^*).
\]

(ii) Denote by \( b_{mi}^* \) the entries of \( B^* \). Then we can directly verify that

\[
(\mathcal{F}'(B^*))_{im} = -\frac{\partial}{\partial b_{mi}^*} \sum_{i=1}^{J} \log \bar{\Psi}(b_i^*; y(\pi^{-1}(i))),
\]

from which we infer that the matrix \( B^* \) indeed solves the following optimization problem

\[
B^* = \arg \min_{B \in \mathbb{R}^{J \times M}} \frac{1}{2} \langle (C'_r)^{-1}, B^T B \rangle_F - \sum_{i=1}^{J} \log \bar{\Psi}(b_i; y(\pi^{-1}(i)))
\]

(iii) Following (3.11) \( A = B^*(C'_r)^{-T} \). Let \( a_i \) denote the columns of \( A \). Then by Proposition 3.5(iii),

\[
U^* = \sum_{j \in \mathbb{Z}'} \tilde{a}_j^* c_j^T = \sum_{i=1}^{J} \tilde{a}_{\pi^{-1}(i)}^* c_{\pi^{-1}(i)} = \sum_{i=1}^{J} a_i c_{\pi^{-1}(i)} = \sum_{j \in \mathbb{Z}'} \tilde{b}_j^* c_j^T.
\]
On the other hand, using \( B^* = A(C^j)^T \) and Proposition 3.5(iii) we can write
\[
b^*_{mk} = \sum_{i=1}^{j} a_{m \pi^{-1}(i)} c_{\pi^{-1}(i), \pi^{-1}(k)} = u_{m \pi^{-1}(k)},
\]
which gives the desired identity connecting \( b^*_k \) and \( u^*_{\pi^{-1}(k)} \).

3.5. Consistency Of The One-Hot Method. In analogy with binary classification we now discuss consistency of multi-class classification using the one-hot method. Our results here make use of the perturbation theory developed in subsection 2.5. As in subsection 2.6 we consider a graph \( G_0 = \{X, W_0\} \) consisting of \( K \) connected clusters \( \tilde{Z}_1, \ldots, \tilde{Z}_K \) and let \( G_\epsilon = \{X, W_\epsilon\} \) be a family of graphs parameterized by \( \epsilon > 0 \) that are perturbations of \( G_0 \). We denote by \( C_{\tau, \epsilon} \) the covariance matrix corresponding to the graph \( G_\epsilon \) as defined in (2.26). Further, we assume the data \( y \) is generated by a ground truth function \( U^\dagger \in \mathbb{R}^{M \times N} \) that is
\[
y(j) = S(u^j \dagger + \eta_j), \quad j \in \mathbb{Z}',
\]
where \( S \) is defined in (3.1) and we define the noise \( \eta_{mj} \) through a reference random variable analogous to (2.28):
\[
\eta_{mj} = \gamma \bar{\eta}_{mj}, \quad \bar{\eta}_{mj} \overset{	ext{iid}}{\sim} \psi,
\]
where \( \psi \) is a mean zero PDF with unit standard deviation. In the same spirit as subsection 2.6, our first task is to estimate the probability of the event where the observed labels \( y(j) \) are exact, i.e., \( y(j) \) coincides with the index of the maximal element in the \( j \)-th column of \( U^\dagger \).

**Lemma 3.7.** Suppose \( \psi \) is log-concave then there exist constants \( \omega_1, \omega_2 > 0 \) so that
\[
\mathbb{P}(y(j) = S(u^j \dagger), \forall j \in \mathbb{Z}') \\
\geq \int_{\mathbb{R}} \psi(t) \prod_{j \in \mathbb{Z}'} \left[ 1 - \omega_2 \exp \left( -\frac{\omega_1}{\gamma} \left( t + \min_{k \neq y(j)} \{ u^j_{y(j)k} - u^j_{yk} \} \right) \right) \right] M^{-1} dt.
\]
That is, if \( \gamma \) is small the data \( y \) is exact with high probability.

**Proof.** Observe that \( y(j) = S(u^j \dagger) \) whenever \( u^j_{y(j)j} + \eta_{y(j)j} \geq u^j_{m \pi^{-1}(y(j))} + \eta_{m \pi^{-1}(y(j))} \) for all \( m \neq y(j) \). Therefore,
\[
\mathbb{P}(y(j) = S(u^j \dagger) \forall j \in \mathbb{Z}') = \mathbb{P}\left( \{ \eta_{mj} \leq \eta_{y(j)j} + u^j_{y(j)j} - u^j_{m \pi^{-1}(y(j))} : j \in \mathbb{Z}', m \neq y(j) \} \right)
\geq \mathbb{E} \mathbb{P}\left( \{ \eta_{mj} \leq \eta_{y(j)j} + u^j_{y(j)j} - u^j_{m \pi^{-1}(y(j))} : j \in \mathbb{Z}', m \neq y(j) \} | \eta_{y(j)j} \right).
\]
Now by Lemma 2.10 and Markov’s inequality (see proof of Lemma 2.11) along with independence of the \( \eta_{mj} \) we conclude there exist constants \( \omega_1, \omega_2 > 0 \) so that for fixed \( j \in \mathbb{Z}' \),
\[
\mathbb{P}\left( \{ \eta_{mj} \leq \eta_{y(j)j} + u^j_{y(j)j} - u^j_{m \pi^{-1}(y(j))} : m \neq y(j) \} | \eta_{y(j)j} \right)
\geq \mathbb{P}\left( \{ \eta_{mj} \leq \eta_{y(j)j} + \min_{k \neq y(j)} \{ u^j_{y(j)k} - u^j_{yk} \} : m \neq y(j) \} | \eta_{y(j)j} \right)
\geq \prod_{m \neq y(j)} \left[ 1 - \omega_2 \exp \left( -\frac{\omega_1}{\gamma} \left( \eta_{y(j)j} + \min_{k \neq y(j)} \{ u^j_{y(j)k} - u^j_{yk} \} \right) \right) \right]
\geq \left[ 1 - \omega_2 \exp \left( -\frac{\omega_1}{\gamma} \left( \eta_{y(j)j} + \min_{k \neq y(j)} \{ u^j_{y(j)k} - u^j_{yk} \} \right) \right) \right] M^{-1}.
\]
Therefore,
\[
\mathbb{P}\left(\{\eta_{mj} \leq \eta_{y(j)} + u_{y(j)}^j - u_{mj}^j; j \in Z', m \neq y(j)\}\right) \geq \prod_{j \in Z'} \left[1 - \omega_2 \exp\left(-\frac{\omega_1}{\gamma} \left(\eta_{y(j)} + \min_{k \neq j} \{u_{y(j)}^k - u_{mj}^k\}\right)\right)\right]^{M-1}.
\]
Integrating the above bound over \(\eta_{y(j)}\) gives the desired result. \(\square\)

The following lemma is the analog of Lemma 2.12 for the one-hot model (3.12). The method of proof is identical to that lemma and is therefore omitted.

**Lemma 3.8.** Suppose (3.12) and (3.13) hold, \(\psi\) is log-concave and
\[
\min_{m,k \in \{1,\ldots,M\}, m \neq k} \{u_{mj} - u_{kj}\} > 0 \quad \forall j \in Z'.
\]
Then for any sequence \(\gamma \downarrow 0\), \(y(j) \xrightarrow{a.s.} S(u_j^\gamma)\) with respect to \(\prod_{(m,j) \in \{1,\ldots,M\} \times Z'} \psi(t_{mj})\) the law of the i.i.d. sequence \(\{\eta_{mj}\}_{(m,j) \in \{1,\ldots,M\} \times Z'}\).

With the above lemmata at hand we are now in a position to study consistency of minimizers of the one-hot functional
\[
J_{\tau,\epsilon,\gamma}(U) := \frac{1}{2} \{C_{\tau,\epsilon}^{-1}U^TU\}_{\cdot} + \Phi_{\gamma}(U; y), \quad U \in \mathbb{R}^{M \times N},
\]
where
\[
\Phi_{\gamma}(U; y) := -\sum_{j \in Z'} \log \Psi_{\gamma}(u_j; y(j)), \quad \Psi_{\gamma}(v; m) := \int_{\mathbb{R}} \psi_{\gamma}(t) \prod_{\ell \in m} \psi_{\gamma}(t + v_\ell - v_\ell) dt
\]
and \(\Psi_{\gamma}\) is the CDF of \(\psi_{\gamma}(\cdot) := \frac{1}{\gamma} \psi(\cdot / \gamma)\) as before.

**3.5.1. One-Hot Consistency With A Single Observed Label.** Once again we start with the case of a single observed label with \(Z' = \{1\}\) belonging to the first cluster \(Z_1\) and without loss of generality we assume \(u_{11}^\gamma > u_{m1}^\gamma\) for all \(m \neq 1\) so that the correct label of the observed node is 1.

**Proposition 3.9.** Consider the single observation setting above and suppose Assumptions 1 and 2 are satisfied by \(G_0\) and \(G_\epsilon\). Let \(U^*\) be the minimizer of \(J_{\tau,\epsilon,\gamma}\) and let \(\gamma > 0\).
(a) If \(\epsilon = o(\tau^2)\) as \(\tau \to 0\) then \(\exists \tau_0 > 0\) so that \(\forall (\tau, \gamma) \in (0, \tau_0) \times (0, \infty)\) and \(\forall j \in \hat{Z}_1\)
\[
\mathbb{P}\{S(u_j^\gamma) = 1\} \geq \int_{\mathbb{R}} \psi_{\gamma}(t) \left[1 - \omega_2 \exp\left(-\frac{\omega_1}{\gamma} \left(t + \min_{m \neq 1} \{u_{11}^\gamma - u_{m1}^\gamma\}\right)\right)\right] dt,
\]
where \(\omega_1, \omega_2 > 0\) are uniform constants depending only on \(\psi\).
(b) If \(\epsilon = \Theta(\tau^2)\) then the above statement holds for all \(j \in Z\).

**Proof.** (a) The method of proof is very similar to that of Proposition 2.13. The dimension reduced system (3.9) takes the simpler form
\[
b_{\gamma}^* = (C_{\tau,\epsilon})_{11}^{11} f_1(b_{\gamma}^*).
\]
As before, if \(\epsilon = o(\tau^2)\) by Proposition 2.9(a) there exists \(\tau_0 > 0\) so that \(\forall \tau \in (0, \tau_0)\) (2.35) holds and so, up to leading order (3.17) is equivalent to
\[
b_{\gamma}^* = |(\hat{X}_1)_{11}^{11} f_1(b_{\gamma}^*)|.
\]
Now consider the event where \( y(1) = S(\mathbf{u}_1^j) = 1 \), i.e., the data is exact. Then, we immediately see from (3.7) and the fact that \( \psi \gamma \) and \( \Psi \gamma \) are positive that, the only entry of \( \mathbf{f}_1(\mathbf{b}_j^*) \) that is not negative is the first entry and so \( b_{11}^* > 0 \) while \( b_{m1}^* < 0 \) for all \( m \geq 1 \). Finally, by Proposition 3.6(iii) we can write

\[
\mathbf{U}^* = \mathbf{c}_1, \epsilon \cdot \mathbf{f}_1(\mathbf{b}_j^*)^T = (\mathbf{x}_1)_1 \cdot \epsilon \cdot \mathbf{f}_1(\mathbf{b}_j^*)^T = \mathcal{O}(\epsilon/\tau^2 + \tau^{2\alpha} + \epsilon).
\]

It is then straightforward to see that when \( \tau \) is sufficiently small then for all \( j \in \tilde{Z}_1 \) we have \( S(\mathbf{u}_1^j) = y(1) = \tilde{S}(\mathbf{u}_1^j) = 1 \) and the claim follows by bounding the probability of the event where \( y(1) = 1 \) using Lemma 3.7. Part (b) follows by a very similar argument to proof of Proposition 2.13(b).

The following corollary is the analogue of Corollary 2.14 for the one-hot method. The proof follows from the proof of Proposition 3.9 and Lemma 3.8.

**Corollary 3.10.** Suppose Proposition 3.9 and condition (3.14) are satisfied. Then the following holds with a.s. convergence in the sense of Lemma 3.8:

(a) For any sequence \( \gamma, \tau, \epsilon \downarrow 0 \) along which \( \epsilon = o(\tau^2) \) it holds that

\[
S(\mathbf{u}_1^j) \xrightarrow{a.s.} S(\mathbf{u}_1^j), \quad \forall j \in \tilde{Z}_1.
\]

(b) For any sequence \( \gamma, \tau, \epsilon \downarrow 0 \) along which \( \epsilon = \Theta(\tau^2) \) the above statement holds true for all \( j \in \mathbb{Z} \).

3.5.2. One-Hot Consistency With Multiple Observed Labels. We finally consider the general setting where multiple labels are observed and \( |Z'| = J \geq 2 \). We need the analog of Assumption 3 in multi-class classification:

**Assumption 4.** Let \( \tilde{Z}_k \) be a cluster within which a label has been observed, i.e., \( \tilde{Z}_k \cap Z' \neq \emptyset \). Then \( S(\mathbf{u}_1^j) \) is constant for all \( j \in \tilde{Z}_k \).

**Proposition 3.11.** Consider the multiple observation setting above and suppose Assumptions 1, 2 and 4 are satisfied by \( G_0, G_\epsilon \) and \( U^\dagger \). Let \( \mathbf{U}^* \) be the minimizer of \( \mathcal{J}_{\tau, \epsilon, \gamma} \) and \( \mathbb{Z}'' \) be as in (2.36) the set of nodes in clusters for which labels have been observed. If \( \epsilon = o(\tau^2) \) as \( \tau \to 0 \) then \( \exists \tau_0 > 0 \) so that \( \forall (\tau, \gamma) \in (0, \tau_0) \times (0, \infty) \) and \( \forall j \in \mathbb{Z}'' \)

\[
\mathbb{P}\left( S(\mathbf{u}_1^j) = S(\mathbf{u}_1^j) \right) \geq \int_{\mathbb{R}} \psi_\gamma(t) \prod_{j \in Z''} \left[ 1 - \omega_1 \exp\left( -\frac{\omega_1}{\gamma}\left( t + \min_{m \neq y(j)} \left\{ u_{y(j)}^f - u_{m(j)}^f \right\} \right) \right) \right]^{M-1} dt,
\]

where \( \omega_1, \omega_2 > 0 \) are uniform constants depending only on \( \psi \).

**Proof.** The proof follows similar steps to the binary result in Proposition 2.15 and we use the same notation as in the proof of that result. Here the dimension reduced system (3.9) takes the form

\[
(C_{\tau, \epsilon})^{-1} B^* = \mathcal{F}'(B^*).
\]

Then, Proposition A.10 implies that \( C_{\tau, \epsilon}' \) is nearly block diagonal and (2.38) holds. Then, up to leading order (3.18) takes the form

\[
(\mathbf{x}_k)_j^{-1} b_{\tau(j)}^* = \sum_{i \in \tilde{Z}_k} (\mathbf{x}_k)_i \cdot \mathbf{f}_i(\mathbf{b}_i^*) / \mathbb{Z}_k, \quad \text{for } j \in \tilde{Z}_k \text{ and } k \in \{1, \ldots, K\},
\]

where we used the same notation as in (3.7) and made use of the approximation (2.38) for the elements of \( C_{\tau, \epsilon}' \). Once again the right hand side of the above expression is
independent of \(j\) and so the \((\tilde{x}_k)^{-1} b_{\pi(j)}^*\) vectors are constant for all \(j \in \tilde{Z}'_k\). We then have
\[
b_{\pi(j)}^* = (\tilde{x}_k)_j \sum_{i \in \tilde{Z}'_k} (\tilde{x}_k)_i f_i \left( \frac{(\tilde{x}_k)_j}{(\tilde{x}_k)_j} b_{\pi(j)}^* \right), \quad \text{for } j \in \tilde{Z}'_k \text{ and } k \in \{1, \ldots, K\}.
\]

Now consider the event where the data \(y\) is exact which happens with high probability following Lemma 3.7. Since \(U^1\) satisfies Assumption 4 then \(y(j)\) is constant for all \(j \in \tilde{Z}'_k\). Using the definition of \(f_j\) given in (3.7), we directly verify that the only positive coordinate of \(f_i \left( \frac{(\tilde{x}_k)_j}{(\tilde{x}_k)_j} b_{\pi(j)}^* \right)\) is the \(y(j)\)-th coordinate while all other coordinates are negative. Since \((\tilde{x}_k)_i\) and \((\tilde{x}_k)_j\) are both strictly positive in the above, we conclude \(S(b_{\pi(j)}^*) = y(j) = S(u_j^1)\). The desired result now follows by Proposition 3.6(iii). \(\square\)

**Corollary 3.12.** Suppose Theorem 3.11 and condition (3.14) are satisfied. Then for any sequence \(\gamma, \tau, \epsilon \downarrow 0\) along which \(\epsilon = o(\tau^2)\) it holds that
\[
S(u_j^1) \xrightarrow{a.s.} S(u_j^1), \quad \forall j \in \tilde{Z}'',
\]
with a.s. convergence in the sense of Lemma 3.8.

**4. Numerical Experiments.** In this section we turn our attention to numerical experiments that are designed to confirm our theoretical findings, and to expand upon the behavior of the probit and one-hot methods beyond our theory. In subsection 4.1 we study the spectrum of graph Laplacians on a graph consisting of three clusters that are weakly connected reaffirming the analysis of appendix A. Subsection 4.2 is dedicated to the consistency of the probit method. Here we demonstrate a curve in the \((\epsilon/\tau^2, \alpha)\) plane across which probit transitions from being consistent to propagating the majority label. Finally, we repeat similar experiments for the one-hot method in subsection 4.3 demonstrating a similar phase transition curve in the \((\epsilon/\tau^2, \alpha)\) plane and showing that the curve is sensitive to the number of observed labels in different clusters.

**4.1. Spectrum Of Covariance Operators.** We begin with a numerical demonstration of the perturbation theory of appendix A and in particular the result of Proposition A.6. At the same time we will introduce a synthetic experiment which is used throughout this section for illustration.

We consider a random dataset using points drawn from a mixture of three Gaussian distributions centered at \((1,0,0)\), \((0,1,0)\) and \((0,0,1)\) with variance 0.1. We draw \(N = 150\) points in total and the dataset has three clusters with 50 points in each one. In order to construct a weighted graph on this dataset we choose the kernel function
\[
\kappa(t) = 1_{\{t \leq 0.25\}}(t),
\]
and set \(w_{ij}^{(0)} = \kappa(|x_i - x_j|)\) where \(|\cdot|\) denotes the Euclidean norm in \(\mathbb{R}^3\). Figure 4.1(a) shows the data points as well as the connected components of the resulting weighted graph in this example. With the weight matrix \(W_0\) at hand we define the graph Laplacian operator \(L_0 = D_0 - W_0\) and let \(C^{-1}_{\tau,0} = \tau^{-2\alpha}(L_0 + \tau^2 I)^{-\alpha}\). In other words,
we fix $p = 0$ and so the functions $\{\hat{X}_k\}_{k=1}^K$ simplify to the indicator functions on the clusters $\hat{Z}_1, \ldots, \hat{Z}_K$. We further define a perturbation of this matrix by replacing $W_0$ with $W_\epsilon$ with entries $w_{ij}^{(\epsilon)} = \kappa_\epsilon(|x_i - x_j|)$ where the perturbed kernel has the form

(4.1) \[
\kappa_\epsilon(t) = \kappa(t) + \epsilon \exp\left(-\frac{t^2}{(0.25 + \epsilon)^2}\right).
\]

Clearly, the resulting weighted graph for any positive value of $\epsilon$ is fully connected but the weight of edges connecting the three clusters are at most of order $\epsilon$. We consider the perturbed covariance matrix $C_{\tau, \epsilon}^{-1} = \tau^{-2\alpha}(L_\epsilon + \tau^2 I)^{\alpha}$ and study its low-lying spectrum. In the notation of appendix A we use $\lambda_{2, \epsilon}$ and $\lambda_{3, \epsilon}$ to denote the first two non-trivial eigenvalues of $C_{\tau, \epsilon}$. Figure 4.1(b) shows that as $\epsilon / \tau^2$ becomes small $\lambda_{j, \epsilon}^2 - 1$ vanishes linearly in $\epsilon / \tau^2$ for $j = 2, 3$ which is in perfect agreement with Proposition A.6(ii). We also observe that $\lambda_{1, \epsilon}$ blows up with $\tau^{-2}$ as predicted in Proposition A.7. On the other hand, Figure 4.1(c) shows the $\ell^2$ distance between the second and third eigenvectors of $C_{\tau, \epsilon}$ with their projection onto the span of the set functions $\{\hat{X}_k\}_{k=1}^K$. We displayed the case $\alpha = 1$, the behavior for other choices of $\alpha$ is similar. Here $P_0$ denotes the projection onto the span of $\{\hat{X}_k\}_{k=1}^K$ following the notation of appendix A. We observed that $\|(I - P_0)\phi_{j, \epsilon}\|_2$ goes to zero linearly in $\epsilon$ for $j = 2, 3$, which is precisely the rate predicted in Proposition A.6(iii) suggesting that the bound is sharp.

4.2. Binary Classification With Probit. We now consider a binary classification problem on the synthetic dataset of subsection 4.1. Figure 4.2(a) shows the true label of the 150 points in the dataset. Blue points have label $+1$ while red points have label $-1$. For the SSL problem we assume one label is observed within each cluster and that the observed labels are correct, i.e., $y = (+1, +1, -1)^T$. We take the observation noise $\eta_j$ to be i.i.d. logistic random variables with mean zero. More precisely,

$$\psi_\gamma(t) = \frac{\exp(-t/\gamma)}{\gamma(1 + \exp(-t/\gamma))}, \quad \Psi_\gamma(t) = (1 + \exp(-t/\gamma))^{-1}.$$ 

We use the $\kappa_\epsilon$ kernel of (4.1) and construct the graph Laplacian $L_\epsilon$ and the covariance operator $C_{\tau, \epsilon}$ as in subsection 4.1 above. Since the matrix $C_{\tau, \epsilon}^{-1}$ is ill-conditioned for small $\tau$ and large values of $\alpha$ we found it crucial to use a low-rank approximation to $C_{\tau, \epsilon}$ in order to solve the EL equations (2.8) in a stable manner. Following the expansion (2.17) and the fact that there exists a uniform spectral gap between $\lambda_{3, \epsilon}$ and $\lambda_{4, \epsilon}$ (recall Figure 4.1(b)) we consider the truncated expansion

(4.2) \[
\hat{C}_{\tau, \epsilon} = \sum_{k=1}^n \frac{1}{\lambda_{k, \epsilon}} \phi_{k, \epsilon} \phi_{k, \epsilon}^T,
\]

where a suitable truncation $n < N$ will be chosen later, and solve the approximate EL equations

$$u^* = \sum_{j \in 2^T} \hat{C}_{\tau, \epsilon} F_j(u_j^*) e_j.$$ 

We used MATLAB’s `fsolve` function for this task. For our first set of experiments we fix the noise parameter $\gamma = 0.5$ and used $n = 10$ terms in the approximation of $\hat{C}_{\tau, \epsilon}$. We then vary $\epsilon$, $\tau$ and $\alpha$. We considered $\tau \in (0.01, 1)$, $\epsilon / \tau^2 \in (0.01, 0.5)$, and $\alpha \in (0.25, 10)$,
Fig. 4.1: (a) The disconnected graph $G_0$ constructed by random draws from a mixture of three Gaussians. (b) The first three eigenvalues of the perturbed inverse covariance operator $C^{-1}$ with $\alpha = 1$ for different choices of $\epsilon$ and $\tau^2$. The fourth eigenvector $\lambda_4,\epsilon$ blows up with $\tau^{-2}$ as predicted while $\lambda_2,\epsilon$ and $\lambda_3,\epsilon$ converge to 1 linearly in $\epsilon/\tau^2$. (c) The distance between $\phi_{2,\epsilon}$ and $\phi_{3,\epsilon}$ and their projections onto the span of the set functions $\{\chi_j\}_{j=1}^3$. The distance vanishes linearly in $\epsilon$.

i.e., for each value of $\alpha$ we pick two sequences of $\tau$ and $\epsilon/\tau^2$ values and set $\epsilon = \tau^2 \times \epsilon/\tau^2$. Figure 4.2(b) shows the percentage of mislabelled points when $\text{sgn}(u^*)$ is used as the label predictor. The maximum error of 33% corresponds to all red points being labelled as blue. Our results suggest that when $\epsilon/\tau^2$ is large the Probit classifier $u^*$ tends to assign the majority labels to all points in the dataset. Furthermore, we observe a sharp transition between perfect label recovery and assignment of majority labels. This effect is amplified for larger values of $\alpha$ in that the transition seems to happen for a smaller value of $\epsilon/\tau^2$.

We also consider the distance between the span of the set functions $\chi_j$ and the minimizer $u^*$. Figure 4.2(c) shows $\| (I - P_0) u^* \|_2$ as a function of $\tau^2$ and for different values of $\alpha$. We see that for smaller values of $\alpha$ the projection error is $O(\tau^{-2\alpha})$ which is in line with the predicted error between $c_{j,\epsilon}$ and the span of $\chi_j$ in Proposition 2.9(a).
since for smaller values of $\alpha$ the leading order error term is $O(\tau^2\alpha)$. When $\alpha$ is large the projection error is controlled by the $O(\epsilon/\tau^2 + \epsilon)$ terms in the error bound of Proposition 2.9(a) and no longer depends on $\alpha$.

We noticed that the labelling accuracy is more or less independent of $\gamma$ so long as the data $y$ is correct as demonstrated in Figure 4.3. We also note that, for the most part, the labelling accuracy is independent of $n$ as well. As shown in Figure 4.3 the labelling accuracy increases slightly only for small values of $\alpha$ and larger values of $\epsilon/\tau^2$.

![Fig. 4.2: (a) The true binary labels in the synthetic dataset of subsection 4.2. Blue points have label $+1$ and red points have label $-1$. (b) Heat map of the percentage of mislabelled points using the probit classifier. The 33% error mark corresponds to assigning label $+1$ to all red points which constitute a third of the dataset. For fixed values of $\alpha$ we observe a sharp transition as $\epsilon/\tau^2$ increases where we go from labelling all of the points correctly to labelling the red points as blue. (c) The distance between $u^*$ and the span of $\{X_j\}_{j=1}^3$. This distance is $O(\tau^{2\alpha})$ when $\alpha$ is small and does not depend on $\alpha$ when it is large indicating that the distance is controlled by $O(\epsilon/\tau^2 + \epsilon)$.](image)

For our final set of experiments we consider noisy data. First, we fix $\tau = 0.5$, $\epsilon/\tau^2 = 0.1$, $n = 10$, and take $\alpha \in (0.25, 10)$ and $\gamma \in (0, 1)$. For each value of $\alpha$ and $\gamma$ we perform 100 experiments where we randomly perturb the data $y$ by drawing
independent measurement noise $\eta_j$ using the model (2.27) and consider the labelling accuracy of the probit model. If all labels are recovered correctly by $\text{sgn}(u^*)$ we consider the experiment a success and otherwise a failure.

In Figure 4.4(a), we plot the probability of success of predicting the correct label of all points as a function of $\gamma$ and $\epsilon/\tau^2$ for fixed $\alpha = 2$. We chose $\tau = 0.5$, $\epsilon/\tau^2 \in (0.1,0.6)$ and $\gamma \in (0.1,1)$. Here we see a clear transition in the success probability as a function of $\epsilon/\tau^2$. When $\epsilon/\tau^2$ is small the success probability is almost independent of $\epsilon/\tau^2$ and depends only on $\gamma$ but for larger values of $\epsilon/\tau^2$ the success probability suddenly drops to zero meaning that some points are always mislabelled. This behavior is in line with Figure 4.3 where we observed a sharp increase in the prediction error when $\epsilon/\tau^2$ is too large. We emphasize that this behavior is also in line with Proposition 2.15 stating that the probability of success is controlled only by $\gamma$ provided that $\epsilon/\tau^2$ and $\epsilon$ are sufficiently small.

Next, we fixed $\epsilon/\tau^2 = 0.1$ and modified $\alpha$, see Figure 4.4(b). We do not observe any dependence of the success probability on $\alpha$. This is in line with Proposition 2.15, which states that if $\epsilon$ and $\epsilon/\tau^2$ are sufficiently small then the success probability is essentially controlled by the probability of the event where the data is correct which depends only on $\gamma$.

4.3. Multi-Class Classification Using One-Hot. For the next set of numerical experiments we consider multi-class classification with the One-hot method. Once again we use the synthetic dataset of subsection 4.1 but now we assume there exist three classes within the graph as depicted in Figure 4.5. Similar to previous sections we take $\psi_\gamma$ to be the logistic distribution but this time use the model (3.2) for the
Fig. 4.4: Heat map of the probability of success of probit in predicting the correct label of all the points in the dataset. (a) We plot the success probability of probit as a function of $\epsilon/\tau^2$ and $\gamma$ for fixed value of $\alpha = 2$. When $\epsilon/\tau^2$ is small the success probability appears to only depend on $\gamma$ but as $\epsilon/\tau^2$ increases we see a sharp transition where the success probability drops to zero indicating that some points are always mislabelled in this regime. (b) The success probability for different values of $\alpha$ and $\gamma$ for fixed value of $\epsilon/\tau^2 = 0.1$. We do not observe any strong dependence on $\alpha$ and the success probability appears to depend on $\gamma$ only.

observed labels. We are assuming that we are given one label in each cluster, i.e. $J = 3$. In the perfect measurement case $y = (1, 2, 3)^T$. The main modification in this case, as compared to binary classification is that now we need to minimize the one-hot functional which has a more complicated misfit function as in (3.3). Furthermore, the minimizer is now a matrix $U^* \in \mathbb{R}^{M \times N}$ where $M = 3$ and $N = 150$. In this case (3.6) is a nonlinear system of equations in $3 \times 150$ dimensions which is slow to solve. Instead, we solve the dimension reduced system (3.9) and identify $U^*$ via $B^*$. We noticed that this approach offers significant speedup in our calculations. The dimension reduced system (3.9) is small enough that MATLAB’s `fsolve` can still be very effective. We highlight that we approximate the matrix $C_{\epsilon,\tau}'$ by finding $\hat{C}_{\epsilon,\tau}$ as in (4.2) and then keep only the rows and columns of $\hat{C}_{\epsilon,\tau}$ that correspond to the observation vertices in $Z'$.

Overall we find that the one-hot method behaves similarly to probit as expected following our analysis. In Figures 4.6 we show the accuracy of the one-hot method in predicting the correct label of the points using perfect observed labels $y$. Similarly to the probit case we see little sensitivity to $n$ and $\gamma$ but a clear phase transition in the prediction error as $\epsilon/\tau^2$ increases for each value of $\alpha$. We see that the prediction error is either very small or close to 66%. The latter value is a result of all three clusters being labelled as the same class. Overall, it seems that the prediction error is smaller and less sensitive to $\epsilon/\tau^2$ when $\alpha$ is small.

Similarly to the probit case we also study the success probability of one-hot for different values of $\alpha$, $\epsilon/\tau^2$ and $\gamma$. Here we say that the one-hot classification is successful if all labels within the dataset are predicted correctly. As before we vary the value of $\gamma$ between 0 and 1 and estimate the success probability of one-hot by averaging over 100 trial runs with randomly perturbed observed labels $y$. Figure 4.7(a)
and (b) show a heat-map of success probability of one-hot for different values of $\epsilon/\tau^2$ and $\gamma$. Here we observe some dependence between the success probability and $\epsilon/\tau^2$. In fact, for fixed value of $\gamma$ we see a small increase in success probability as $\epsilon/\tau^2$ increases. However, as depicted in Figure 4.7(b) increasing $\epsilon/\tau^2$ eventually leads to a sudden drop in probability of success. This behavior is again in line with the phase transition observed in Figure 4.6. On the other hand, we observe in Figure 4.7(c) that for fixed values of $\epsilon/\tau^2$ the success probability is effectively independent of $\alpha$ and only controlled by $\gamma$. This is in line with our numerical results in the binary case, see Figure 4.4(a).

![Fig. 4.5: Visualization of the three classes within the three cluster dataset for multi-class classification using one-hot. We observe a single label in each cluster.](image)

**4.3.1. Effect Of Number Of Observations In Each Cluster.** For our final set of observations we consider varying the number of observations in each cluster. We use the same dataset as above with $N = 150$ in three distinct clusters but this time we vary the number of observed labels in each cluster. In Figure 4.8 (a) and (b) we compare the accuracy of one-hot with a single observation in all clusters and with three observations in all clusters respectively. We only consider noiseless observations in this case. We see a small perturbation in the error phase transition for larger number of observations but overall the accuracy appears to depend weakly on the number of observations so long as we have the same number of observations in all clusters. Figure 4.8(c) shows the same experiment as above except that here we took two observations in one of the clusters and a single observation in the other two. Figure 4.9(d) shows a similar calculation with three observations in one cluster and a single observation in the rest. In comparison to Figure 4.8(a) and (b) we now see a major change in the accuracy of one-hot, namely that the jump in error now occurs for smaller values of $\epsilon/\tau^2$ indicating that the majority label of one of the clusters is propagated to the rest of the dataset when we have an unbalanced number of observations within the clusters.

In Figure 4.9 we show the success probability of one-hot when an unbalanced number of labels are observed in the clusters: three labels are observed in one cluster and single labels are seen in the rest. As in previous success probability calculations we randomly perturbed the observed labels in 100 trials and approximated the success probability of one-hot as a function of $\epsilon/\tau^2$ and $\gamma$. As before, we see a sharp transition in the success probability as $\epsilon/\tau^2$ grows but below a certain critical value of $\epsilon/\tau^2$ the
success probability appears to only depend on $\gamma$. We also note that this critical value of $\epsilon/\tau^2$ appears to shift towards smaller values for larger $\alpha$.

These experiments reveal an interesting and complicated feature of the probit and one-hot minimizers in connection to the balancing of labelled points in clusters that warrant future analysis. It appears that having a balanced number of labels in different clusters allows for a larger range of acceptable $\epsilon, \tau^2$ parameters; note that the blue regions are larger in Figure 4.8(a, b) when all clusters have the same number of labelled points compared to Figure 4.8(c, d) where one cluster has more labelled points. This suggests that balancing of labelled points in practical applications might lead to better accuracy albeit at a high computational cost. The sensitivity to the balancing of labelled points further highlights the importance hierarchical Bayesian methods can tune the $\tau, \alpha$ parameters automatically.

5. Conclusions. We have studied the consistency of the probit and one-hot methods for SSL, demonstrating that the combination of ideas from unsupervised learning and supervised learning can lead to consistent labelling of large data sets, given only a few labels. Our theory and numerical results demonstrate that with careful choice of the function of the graph Laplacian appearing in the quadratic penalty, namely the parameters $\alpha, \tau$ and $\epsilon$, correct labelling of the dataset can be achieved asymptotically.

However, our theory and numerics also indicate that the choice of these parameters is crucial and can lead to failure of the methods. For example, we observed that when $\epsilon/\tau^2$ is too large then the methods have a tendency to propagate the majority label rather than matching the observed labels. This sensitivity strongly suggests the importance of hierarchical Bayesian techniques which can determine such choices in
Fig. 4.7: Heat map of success probability of one-hot as a function of $\gamma$, $\alpha$ and $\epsilon/\tau^2$. (a) and (b) show the success probability as a function of $\epsilon/\tau^2$ for $\alpha = 2$ and $\alpha = 6$. In the latter case we see a sudden drop in the success probability as $\epsilon/\tau^2$ increases, even for very small values of $\gamma$. (c) shows the success probability as a function of $\alpha$ and $\gamma$ for fixed $\epsilon/\tau^2 = 0.1$. Here the success probability is mostly controlled by $\gamma$ and does not appear to depend on $\alpha$.

a data-driven fashion. Proving that hierarchical methods can learn the scaling of $\tau$ in terms of $\epsilon$ that emerges from our analysis would be of interest.

There are a number of directions in which this work can be taken, including the study of Bayesian posterior consistency, which we undertake in [7] for the harmonic-function based approach to graph-based SSL, and the study of the limit of large unlabelled data sets in [20, 21]. Another interesting question is a detailed analysis of the majority label propagation phenomenon that is observed when $\epsilon/\tau^2$ is too large. Furthermore, throughout this paper we mainly focused on the setting where the ground truth function $u^*$ is consistent with the clustering and assigns the same label to all points within the same cluster. Then the question arises, how do probit and one-hot behave when mislabelled points are present in the data or $u^*$ assigns more than one class to a cluster. It would also be interesting to study different clustering assumptions, such as those arising from stochastic block models [23].

the spectrum of the covariance operators $C_G$ ensures that some preliminary results regarding the spectrum of $C_G$. Throughout this section we use the notation of subsection 2.5. We start with $L_0$ and let functions on $\tilde{L}_0$ has a one-dimensional null-space consisting of constant functions on $\tilde{G}_k$.

**Lemma A.1.** Suppose $G_0 = \{X,W\}$ is a proximity graph satisfying Assumption 1, and let $L_0$ be a graph Laplacian operator on $G_0$ as in (2.3) with $p = q$. Then $L_0$ is positive semi-definite for any choice of $p \in \mathbb{R}$ and the matrix $C^{-1}_{G_0}$ as in (2.23) is symmetric and strictly positive definite for any values of $\tau^2 > 0$ and $\alpha > 0$.

**Proof.** Assume $Z = \{\tilde{Z}_1, \tilde{Z}_2, \ldots, \tilde{Z}_K\}$ where $\tilde{Z}_k$ are the collection of nodes in the

**Appendix A. Spectral Analysis Of Covariance Operators.** Here we study the spectrum of the covariance operators $C_{\tau,0}$ and $C_{\tau,\epsilon}$ and prove Propositions 2.8 and 2.9. Throughout this section we use the notation of subsection 2.5. We start with some preliminary results regarding the spectrum of $C_{\tau,0}$. Recall that Assumption 1 ensures that $G_0$ consists of $K < N$ disconnected components $\tilde{G}_k$ and that the graph Laplacian restricted to each $\tilde{G}_k$ has a one-dimensional null-space consisting of constant functions on $\tilde{G}_k$.

**Lemma A.1.** Suppose $G_0 = \{X,W\}$ is a proximity graph satisfying Assumption 1, and let $L_0$ be a graph Laplacian operator on $G_0$ as in (2.3) with $p = q$. Then $L_0$ is positive semi-definite for any choice of $p \in \mathbb{R}$ and the matrix $C^{-1}_{G_0}$ as in (2.23) is symmetric and strictly positive definite for any values of $\tau^2 > 0$ and $\alpha > 0$.

**Proof.** Assume $Z = \{\tilde{Z}_1, \tilde{Z}_2, \ldots, \tilde{Z}_K\}$ where $\tilde{Z}_k$ are the collection of nodes in the
The $k^{th}$ component $\tilde{G}_k$ of $G_0$ and let $\tilde{L}_k$ denote the graph Laplacian operator on $\tilde{G}_k$ constructed as in (2.3) by replacing $D_0$ and $W_0$ with $\tilde{D}_k$ and $\tilde{W}_k$ the submatrices corresponding to $\tilde{G}_k$.

Then by [13, Lem. 1.7] the matrices $\tilde{L}_k$ are positive semi-definite with eigenvalues $0 = \tilde{\sigma}_1,k < \tilde{\sigma}_2,k \leq \tilde{\sigma}_3,k \leq \ldots \leq \tilde{\sigma}_{N_k,k}$ where $N_k = |\tilde{Z}_k|$. It follows that $L_0 = \text{diag}(\hat{L}_1, \hat{L}_2, \ldots, \hat{L}_K)$ and so $L_0$ is also positive semi-definite with eigenvalues $0 = \sigma_{1,0} = \sigma_{2,0} = \ldots = \sigma_{K,0} < \sigma_{K+1,0} \leq \sigma_{K+2,0} \leq \ldots \leq \sigma_{N,0}$.

Now suppose $\alpha = 1$. Then it is straightforward to check that $C_{\tau,0}^{-1}$ has eigenvalues $\lambda_{k,0} = (\tau^{-2}\sigma_{k,0} + 1)$, so that $1 = \lambda_{1,0} = \lambda_{2,0} = \lambda_{K,0} < \lambda_{K+1,0} \leq \lambda_{K+2,0} \leq \ldots \leq \lambda_{N,0}$ and so it is strictly positive definite. The case with $\alpha > 0$ then follows since the eigenvalues are simply $\lambda_{k,0} = (\tau^{-2}\sigma_{k,0} + 1)^\alpha$.

**Lemma A.2.** Suppose $\tau^2, \alpha > 0$ and let $\{\lambda_{k,0}\}_{k=1}^N$ and $\{\phi_{k,0}\}_{k=1}^N$ be the eigenvalues and eigenvectors of $C_{\tau,0}^{-1}$ respectively. Then

$$c_{j,0} = \sum_{k=1}^N \frac{1}{\lambda_{k,0}} (\phi_{k,0}, \phi_{k,0}).$$

**Proof.** Since $C_{\tau,0}^{-1}$ is self-adjoint and positive it has an eigendecomposition

$$C_{\tau,0}^{-1} = QAQ^{-1},$$

where $A$ is a diagonal matrix with diagonal elements $\lambda_{k,0}$ and $Q = [\phi_{1,0}, \ldots, \phi_{N,0}]$ is a unitary matrix with columns $\phi_{k,0}$. Substituting this expression in the identity $c_{j,0} = C_{\tau,0}e_j$ and noting that $Q^{-1} = Q^T$ then gives

$$c_{j,0} = QA^{-1}Q^T e_j = \left[ \frac{1}{\lambda_{1,0}} \phi_{1,0}, \frac{1}{\lambda_{2,0}} \phi_{2,0}, \ldots, \frac{1}{\lambda_{N,0}} \phi_{N,0} \right] \left[ \begin{array}{c} (\phi_{1,0})_j \\ (\phi_{2,0})_j \\ \vdots \\ (\phi_{N,0})_j \end{array} \right],$$

which concludes the proof.

**A.1. Proof of Proposition 2.8: Disconnected clusters.**

**Proposition A.3** (Disconnected clusters). Let $G_0$ satisfy Assumption 1 with $K < N$ components $\tilde{G}_k$. Let $\tilde{X}_k$ be as in (2.21). Then for $k = 1, \ldots, K$

$$\lambda_{k,0} = 1 \quad \text{and} \quad \phi_{k,0} \in \text{span}\{\tilde{X}_j\}_{j=1}^K,$$

and $\lambda_{K+1,0} > 1$.

**Proof.** The statement involving the eigenvalues $\{\lambda_{k,0}\}_{k=1}^{K+1}$ follows from the proof of Lemma A.1 and so we only prove the result regarding the eigenfunctions. Observe that since $G_0$ consists of $K$ disconnected components then $L_0 = \text{diag}(\hat{L}_1, \ldots, \hat{L}_K)$ and each block matrix $\hat{L}_k$ is itself a graph Laplacian. Writing the inner product $\langle x, Lx \rangle$ in symmetric form as in (2.4), it is easy to see that the first eigenvector of any graph Laplacian operator $L$ of the form (2.3) is $D_0^p \mathbf{1}$ for $p = q$ with corresponding zero eigenvalue. Using this fact for the submatrices $\hat{L}_k$, we infer that $L_0 \tilde{X}_k = 0$ for $k = 1, \ldots, K$. We now conclude the proof by noting that $C_{\tau,0}^{-1}$ and $L_0$ have the same eigenvectors.

**Proposition A.4.** Suppose $G_0$ satisfies Assumption 1. Then

$$c_{j,0} = (\tilde{X}_k)_j \tilde{X}_k + O(\tau^{2\alpha}) \quad \forall j \in \tilde{Z}_k.$$
Proof. Follows directly from the expansion (A.1) and the observation that $\lambda_{1,0} = \cdots = \lambda_{K,0} = 1$ while $\lambda_{K+1,0}^{-1} = O(\tau^{-2\alpha})$. Finally, note that

$$\sum_{t=1}^{K}(\tilde{x}_t)_j\tilde{x}_t = (\tilde{x}_K)_j\tilde{x}_K \quad \forall j \in \tilde{Z}_k.$$ 

\[ \square \]

A.2. Proof of Proposition 2.9: Weakly connected clusters. We now analyze the spectrum of the $C_{\tau,\epsilon}$ operators beginning with auxiliary results regarding the matrices $W_\epsilon$ and $L_\epsilon$.

Lemma A.5. Let $W_\epsilon$ be as in (2.24) and suppose Assumptions 1 and 2 are satisfied. Let $L_\epsilon$ be as in (2.26). Then there exists $\epsilon_0 > 0$ so that for all $\epsilon \in (0, \epsilon_0)$ the matrix $W_\epsilon$ has non-negative weights and the graph Laplacian operator $L_\epsilon$ satisfies an expansion of the form

(A.2) \[ L_\epsilon = L_0 + \sum_{h=1}^{\infty} \epsilon^h L^{(h)} \]

with $\|L^{(h)}\|_{2} \in \ell^\infty$.

Note that in the above, the perturbations $L^{(h)}$ are not necessarily of graph Laplacian form.

Proof. First, we prove that for sufficiently small $\epsilon$ the $W_\epsilon$ matrix has non-negative weights and is therefore a well-defined weight matrix for the graph $G_\epsilon$. By (2.25), we only need to consider indices $i,j$ for which $w^{(0)}_{ij} > 0$ since $w^{(h)}_{ij}$ may be negative for such indices, i.e., by Assumption 2 these are only the edge weights within clusters since perturbed edge weights between different clusters are constrained to be positive. Since $\|W^{(h)}\|_{2}$ is uniformly bounded we can use the equivalence of the $\ell_2$ and $\ell_\infty$ norms to infer that all entries of $W^{(h)}$ are also uniformly bounded. Then for $i,j \in \tilde{Z}_k$ we have

$$w^{(\epsilon)}_{ij} = w^{(0)}_{ij} + \sum_{h=1}^{\infty} \epsilon^h w^{(h)}_{ij} \geq w^{(0)}_{ij} - \sup_{h} |w^{(h)}_{ij}| \left( \frac{\epsilon}{1 - \epsilon} \right),$$

which is positive for all $i,j \in \tilde{Z}_k$ for sufficiently small $\epsilon \leq \epsilon_k$. Taking the infimum of $\epsilon_k$ we get the uniform constant $c_0$.

It is straightforward to check that $D_\epsilon = D_0 + \sum_{h=1}^{\infty} \epsilon^h D^{(h)}$ where the $D^{(h)} := \text{diag}(W^{(h)}1)$ are the degree matrices of the $W^{(h)}$. Let $d^{(0)}_i, d^{(\epsilon)}_i$ and $d^{(h)}_i$ denote the diagonal entries of $D_0, D_\epsilon$ and $D^{(h)}$ respectively. Then for $i = 1,\ldots,N$,

$$d^{(\epsilon)}_i = d^{(0)}_i \left( 1 + \sum_{h=1}^{\infty} \epsilon^h d^{(h)}_i \right).$$

It follows from Assumption 1(b) that the entries $d^{(0)}_i$ of the degree matrix $D_0$ are strictly positive (i.e., the components $\tilde{G}_k$ are pathwise connected) and so the ratio inside the inner sum is bounded. Thus, we can further write

$$d^{(\epsilon)}_i = d^{(0)}_i \left( 1 + \epsilon \sum_{h=1}^{\infty} \epsilon^h d^{(h+1)}_i \frac{d^{(h)}_i}{d^{(0)}_i} \right) = d^{(0)}_i \left( 1 + \epsilon d_i \right).$$
where the entries $\hat{d}_i$ are well-defined since the sum inside the bracket converges for $\epsilon < 1$. Assuming $\epsilon$ is sufficiently small so that $\epsilon \hat{d}_i < 1$ we can use the generalized binomial expansion to write for any $\beta \in \mathbb{R}$

$$
\left( d_i^{(e)} \right)^{\beta} = \left( d_i^{(0)} \right)^{\beta} \left( 1 + \epsilon \hat{d}_i \right)^{\beta} = \left( d_i^{(0)} \right)^{\beta} \left( 1 + \sum_{h=1}^{\infty} \beta \binom{\beta}{h} \epsilon^h \left( \hat{d}_i \right)^h \right).
$$

Thus, for any $p \in \mathbb{R}$ there exists a diagonal matrix $\hat{D}^{(p)}$ so that

$$
D_\epsilon^{-p} = D_0^{-p} + \epsilon \hat{D}^{(p)},
$$

and the entries of $\hat{D}^{(p)}$ are uniformly bounded for sufficiently small $\epsilon$. Therefore, we can write

$$
L_\epsilon = D_\epsilon^{-p} (D_\epsilon - W_\epsilon) D_\epsilon^{-p}
$$

$$
= D_\epsilon^{-p} (D_0 + \sum_{h=1}^{\infty} \epsilon^h D^{(h)} - W_0 - \sum_{h=1}^{\infty} \epsilon^h W^{(h)}) D_\epsilon^{-p}
$$

$$
= D_\epsilon^{-p} (D_0 - W_0 + \sum_{h=1}^{\infty} \epsilon^h (D^{(h)} - W^{(h)})) D_\epsilon^{-p}
$$

$$
= D_\epsilon^{-p} (D_0 - W_0) D_\epsilon^{-p} + \sum_{h=1}^{\infty} \epsilon^h D_\epsilon^{-p} (D^{(h)} - W^{(h)}) D_\epsilon^{-p}
$$

$$
= L_0 + \sum_{h=1}^{\infty} \epsilon^h L^{(h)},
$$

where the $L^{(h)}$ matrices are obtained by gathering the $O(\epsilon^h)$ terms. Note that since the entries of $W^{(h)}$ and $\hat{D}^{(p)}$ are uniformly bounded then all entries of the $L^{(h)}$ are bounded uniformly from which it follows that $\|L^{(h)}\|_2 \in \ell^\infty$.

We now characterize the low-lying eigenvalues and eigenvectors of $C^{-1}_{\epsilon,\tau}$.

**Proposition A.6 (The spectrum of $C^{-1}_{\epsilon,\tau}$).** Suppose Assumptions 1 and 2 are satisfied and let $\{\lambda_{j,\epsilon}, \phi_{j,\epsilon}\}$ denote the orthonormal eigenpairs of $C^{-1}_{\epsilon,\tau}$. Then there exists $\epsilon_0 > 0$ so that

(i) $\lambda_{1,\epsilon} = 1$ and $\phi_{1,\epsilon} = \tilde{X}$, as in (2.22).

(ii) For any $\epsilon \in (0, \epsilon_0)$, there exists constants $\Xi_1 = \Xi_1(K, \|L^{(1)}\|_2) > 0$ and $\Xi_2 = \Xi_2(K, \sup_{h \geq 2} \|L^{(h)}\|_2, \epsilon_0) > 0$ independent of $\epsilon$ so that

$$
\lambda_{k,\epsilon} \leq \left( 1 + \Xi_1 \epsilon \tau^{-2} + \Xi_2 \epsilon^2 \tau^{-2} \right)^{\alpha}, \quad \forall k \in \{2, \ldots, K\}.
$$

(iii) If there exists a uniform constant $\vartheta > 0$ so that $\lambda_{K+1,\epsilon} - 1 \geq \vartheta$ then there exists a constant $\Xi_3 = \Xi_3(K, \|L^{(1)}\|_2, \vartheta) > 0$ independent of $\epsilon \in (0, \epsilon_0)$ so that

$$
\left| 1 - \sum_{j=1}^{K} \langle \phi_{j,\epsilon}, \tilde{X}_k \rangle \right|^2 \leq \Xi_3 \epsilon^2 + O(\epsilon^3), \quad \forall j \in \{1, \ldots, K\},
$$

with $\tilde{X}_k$ as in (2.21).

**Proof.** (i) Follows from the fact that $L_\epsilon$ is a graph Laplacian operator with first eigenvalue $\sigma_{1,\epsilon} = 0$ and first eigenvector $\phi_{1,\epsilon} = D_\epsilon^{-1} 1/\|D_\epsilon^{-1} 1\|_2$. 

41
(ii) Let $\sigma_{j,\epsilon}$ for $j = 1, \ldots, N$ denote the eigenvalues of $L_\epsilon$. By the min-max principle (see for example [19, Thm. 8.1.2], also known as Courant–Fisher theorem)

\begin{equation}
(\text{A.5}) \quad \sigma_{k,\epsilon} = \min_{U \in \mathbb{V}_k} \max_{\|x\|=1} \langle x, L_\epsilon x \rangle,
\end{equation}

where $\mathbb{V}_k$ is the set of all $k$-dimensional subsets in $\mathbb{R}^N$. Now for $k \leq K$ take $U = \text{span}\{\bar{\chi}_j\}_{j=1}^k$. Since the vectors $\bar{\chi}_j$ are by definition orthonormal then $U$ is a $k$-dimensional subspace of $\mathbb{R}^N$. These vectors are also in the null space of $L_0$ and so we have for $i, j \in \{1, \ldots, K\}$

\begin{equation}
(\text{A.6}) \quad \langle \bar{\chi}_i, L_\epsilon \bar{\chi}_j \rangle = \sum_{h=1}^{\infty} e^h \langle \bar{\chi}_i, L^{(h)} \bar{\chi}_j \rangle \leq \sum_{h=1}^{\infty} e^h \|L^{(h)}\|_2 = e \|L^{(1)}\|_2 + e^2 \left( \sup_{h=2,3,\ldots} \|L^{(h)}\|_2 \right) \varepsilon/(1-\varepsilon).
\end{equation}

We can now generalize this bound to all unit vectors $x \in U$ to get

\begin{equation*}
\langle x, L_\epsilon x \rangle \leq \Xi_1 \varepsilon + \Xi_2 \epsilon^2
\end{equation*}

where

\begin{equation*}
\Xi_1 := K^2 \|L^{(1)}\|_2, \quad \Xi_2 := \frac{K^2}{(1-\varepsilon)^2} \left( \sup_{h=2,3,\ldots} \|L^{(h)}\|_2 \right).
\end{equation*}

From (A.5) we now infer that

\begin{equation}
(\text{A.7}) \quad \sigma_{k,\epsilon} \leq \Xi_1 \varepsilon + \Xi_2 \epsilon^2, \quad \forall k \in \{2, \ldots, K\}.
\end{equation}

Then (A.3) follows by noting that $\lambda_{k,\epsilon} = \varepsilon^{-2\alpha}(\sigma_{k,\epsilon} + \epsilon^2)^\alpha$.

(iii) Using the fact that $L_0 \bar{\chi}_k = 0$ for $k = 1, \ldots, K$ we can write

\begin{equation*}
\|L_\epsilon \bar{\chi}_k\|^2 = \langle L_\epsilon \bar{\chi}_k, L_\epsilon \bar{\chi}_k \rangle = \sum_{h=1}^{\infty} \sum_{\ell=1}^{\infty} e^h \epsilon^2 \langle L^{(h)} \bar{\chi}_k, L^{(\ell)} \bar{\chi}_k \rangle \\
\leq \epsilon^2 \|L^{(1)}\|_2^2 + \left( \sup_{\ell=2,3,\ldots} \|L^{(\ell)}\|_2^2 \right) \left( \epsilon^2/(1-\varepsilon) \right)^2.
\end{equation*}

Now let $\bar{\chi}_k = \sum_{j=1}^{N} q_k \phi_{j,\epsilon}$ and assume $\sigma_{K+1,\epsilon} \geq \vartheta$. Note that $q_{kj} \leq 1$ for all $k \in \{1, \ldots, K\}$ and $j \in Z$ since $\bar{\chi}_k$ is normalized. Then the above calculation yields

\begin{equation*}
\langle L_\epsilon \bar{\chi}_k, L_\epsilon \bar{\chi}_k \rangle = \sum_{j=1}^{N} q_{kj}^2 \sigma_{j,\epsilon}^2 \leq \epsilon^2 \|L^{(1)}\|_2^2 + \mathcal{O}(\epsilon^4).
\end{equation*}

From this it follows that

\begin{equation*}
\vartheta^2 \left( 1 - \sum_{j=1}^{K} q_{kj}^2 \right) = \vartheta^2 \sum_{j=K+1}^{N} q_{kj}^2 \leq \sum_{j=K+1}^{N} q_{kj}^2 \sigma_{j,\epsilon}^2 \\
\leq \epsilon^2 \|L^{(1)}\|_2^2 - \sum_{j=1}^{K} q_{kj}^2 \sigma_{j,\epsilon}^2 + \mathcal{O}(\epsilon^4).
\end{equation*}
Now using (A.7) we obtain
\[
\left| 1 - \sum_{j=1}^{K} (\phi_{j,\epsilon} \cdot \tilde{x}_j)^2 \right| = \left| 1 - \sum_{j=1}^{K} g_{kj}^2 \right| \leq \frac{1}{q^2} \left( \epsilon^2 \| L^{(1)} \|_2^2 + \sum_{j=1}^{K} \sigma_{j,\epsilon}^2 + O(\epsilon^4) \right) \leq 3\epsilon^2 + O(\epsilon^3).
\]

The desired result follows since $C_{\epsilon,\tau}^{-1}$ has the same eigenfunctions as $L_{\epsilon}$. \(\square\)

The result in part (iii) of Proposition A.6 is central to the rest of our arguments as it states that the eigenvectors $\{\phi_{j,\epsilon}\}_{j=1}^{K}$ and the functions $\{\tilde{x}_j\}_{j=1}^{K}$ have nearly the same span for small $\epsilon$ provided that $L_{\epsilon}$ has a uniform spectral gap between $\sigma_{K,\epsilon}$ and $\sigma_{K+1,\epsilon}$. We now show that this condition is satisfied under very general conditions.

**Proposition A.7 (Existence of spectral gaps).** Suppose Assumptions 1 and 2 are satisfied. Then
\[
\sigma_{K+1,\epsilon} \geq \theta - \sum_{h=1}^{\infty} \epsilon^h \| L^{(h)} \|_2 \quad \text{and} \quad \lambda_{K+1,\epsilon} \geq \tau^{-2\alpha} \left( \tau^2 + \theta - \sum_{h=1}^{\infty} \epsilon^h \| L^{(h)} \|_2 \right)^\alpha,
\]
where $\theta > 0$ is the constant appearing in Assumption 1(b).

**Proof.** By the max-min principle
\[
\sigma_{k+1,\epsilon} = \max_{U \in \mathcal{V}_k} \min_{\|x\|_1 = 1} \langle x, L_{\epsilon} x \rangle.
\]
where $\mathcal{V}_k$ denotes the set of $k$-dimensional subspaces of $\mathbb{R}^N$ and $x^\perp U$ means the vector $x$ belongs to the orthogonal complement of $U$.

Now take $U = \text{span} \{\tilde{x}_j\}_{j=1}^{K}$. Let $x_0 \in \mathbb{R}^{N_k}$ denote the restriction of $x$ to the subset of indices $\tilde{Z}_k$. Then $x_0^T \tilde{D}_k (\tilde{D}^T_0 \mathbf{1}) = 0$, where we recall $\tilde{D}_k$ is the degree matrix of the $k$-th cluster $\tilde{G}_k$. Now we can write for all $k \in \{1, \ldots, K\}$,
\[
\langle x, L_{\epsilon} x \rangle = \langle x, L_0 x \rangle + \sum_{h=1}^{\infty} \epsilon^h \langle x, L^{(h)} x \rangle = \sum_{k=1}^{K} \langle x_k, L_k x_k \rangle + \sum_{h=1}^{\infty} \epsilon^h \langle x, L^{(h)} x \rangle \geq \theta \sum_{k=1}^{K} \langle x_k, x_k \rangle + \sum_{h=1}^{\infty} \epsilon^h \langle x, L^{(h)} x \rangle \geq \theta \|x\|^2 - \sum_{h=1}^{\infty} \epsilon^h \| L^{(h)} \|_2 \|x\|^2 = \left( \theta - \sum_{h=1}^{\infty} \epsilon^h \| L^{(h)} \|_2 \right) \|x\|^2.
\]

The lower bound on $\sigma_{K+1,\epsilon}$ now follows from (A.8) while the lower bound on $\lambda_{K+1,\epsilon}$ follows from the observation that $\lambda_{j,\epsilon} = \tau^{-2\alpha} (\sigma_{j,\epsilon} + \tau^2)^\alpha$ from the definition of $C_{\epsilon,\tau}^{-1}$. \(\square\)

**Example A.8 (Perturbed kernels).** Consider a proximity graph $G$ where the weight matrix $W_0$ is given by
\[
w_{ij}^{(0)} = \kappa(x_i - x_j), \quad i, j \in \mathbb{Z},
\]
where $\kappa : \mathbb{R}^N \to \mathbb{R}$ is a positive, uniformly bounded, radially symmetric and non-increasing kernel with full support and $\int_{\mathbb{R}^N} \kappa(x)^2 \, dx < +\infty$. Now let $\tilde{\kappa} : \mathbb{R}^N \to \mathbb{R}$ be another radially symmetric, positive and uniformly bounded function and define the perturbed weight matrix $W_\epsilon$ by

$$w_{ij}^{(\epsilon)} = w_{ij}^{(0)} + \epsilon \tilde{\kappa}(x_i - x_j).$$

Then the resulting perturbed graph Laplacian $L_\epsilon$ satisfies the conditions of Propositions A.6 and A.7. As a concrete example take $\kappa(x) = \exp(-\|x\|)$ and take $\tilde{\kappa}(x) = 1$. For more details on applications using this type of weight matrix, see [48].

Example A.9 (Adding a few edges). As another example consider a weight matrix $W_0$ of block diagonal form consisting of two matrices $W_+$ and $W_-$ corresponding to two disjoint and connected subgraphs, i.e,

$$W_0 = \text{diag}(W_+, W_-)$$

and any pair of nodes, both in $W_+$ (resp. $W_-$) are connected by a sequence of edges with strictly positive weights. Since each subgraph is assumed to be connected then the graph $G_0$ satisfies Assumption 1. Let $Z$ denote the collection of all nodes in the graph and select a subset $\tilde{Z} \subset Z$ such that $2 \leq |\tilde{Z}| \leq |Z|$ and $\tilde{Z}$ contains at least one point in each of the two disjoint components. Define the matrix

$$w_{ij}^{(1)} = \begin{cases} 1, & i, j \in \tilde{Z}, i \neq j, \\ 0, & \text{otherwise}, \end{cases}$$

and consider the perturbation

$$W_\epsilon = W_0 + \epsilon W^{(1)}.$$

This perturbation corresponds to weak coupling of two disjoint subgraphs by adding edges between subgraphs. Once again, we can directly verify that the resulting perturbed graph Laplacian $L_\epsilon$ satisfies the conditions of Propositions A.6 and A.7.

At the end of this section we use our results on the closeness of the eigenvectors $\{\tilde{\phi}_\ell, \tilde{\chi}_k\}$ to identify the geometry of the $c_{\ell,k}$, the columns of $C_{\tau, \epsilon}$.

**Proposition A.10.** Suppose Assumptions 1 and 2 are satisfied. Then

(a) If $\epsilon = o(\tau^2)$ there exists a constant $\Xi_4 > 0$ independent of $\epsilon$ and $\tau$ so that

$$\|c_{\ell,k} - (\tilde{\chi}_k)c_{\ell,k}\|_2^2 \leq \Xi_4 \left( \frac{\epsilon^2}{\tau^4} + \tau^{4\alpha} + \epsilon^2 \right), \quad \forall \ell \in \tilde{Z}_k.$$

That is, the columns of $C_{\tau, \epsilon}$ have the same geometry as the weighted set functions $\tilde{\chi}_k$ when $\epsilon, \tau$ and $\epsilon/\tau^2$ are small.

(b) If $\epsilon/\tau^2 = \beta$ is constant, there exists a constant $\Xi_5 > 0$ independent of $\epsilon$ and $\tau$ so that

$$\|c_{\ell,\epsilon} - [(1 - \tilde{\beta})\tilde{\chi}_k c_{\ell,k} + \tilde{\beta}(\tilde{\chi}_k)c_{\ell,\tilde{k}}]\|_2^2 \leq \Xi_5 \left( \epsilon^2 + \tau^{4\alpha} \right), \quad \forall \ell \in \tilde{Z}_k,$$

where $\tilde{\beta} = (1 + \Xi_1 \beta)^{-\alpha}$ and $\Xi_1$ is the constant in (A.3).
Proof. Let $P_\epsilon \in \mathbb{R}^{N \times N}$ denote the projection matrix onto $\text{span}\{\phi_{j,\epsilon}\}_{j=1}^K$ and $P_0 \in \mathbb{R}^{N \times N}$ denote the projection onto $\text{span}\{\bar{X}_k\}_{k=1}^K$. Define the residuals

$$ \mathbf{r}_k := (I - P_\epsilon) \bar{X}_k = \bar{X}_k - \sum_{j=1}^K (\phi_{j,\epsilon}, \bar{X}_k) \phi_{j,\epsilon}, $$

$$ \mathbf{s}_j := (I - P_0) \phi_{j,\epsilon} = \phi_{j,\epsilon} - \sum_{k=1}^K (\phi_{j,\epsilon}, \bar{X}_k) \bar{X}_k. $$

By Proposition A.6(iii) there exists a uniform constant $\Xi_0 > 0$ so that

$$ \sum_{k=1}^K \|\mathbf{r}_k\|^2 = \sum_{j=1}^K \|\mathbf{s}_j\|^2 = K - \sum_{k=1}^K \sum_{j=1}^K (\phi_{j,\epsilon}, \bar{X}_k)^2 \leq K \Xi_0 \epsilon^2. \tag{A.9} $$

Writing $\phi_{j,\epsilon} = P_0 \phi_{j,\epsilon} + \mathbf{s}_j$ for any $j \in \{1, ..., N\}$ and using the fact that the $\{\phi_{j,\epsilon}\}_{j=1}^K$ are unit vectors, we can estimate

$$ \left\| \sum_{j=1}^K (\phi_{j,\epsilon})_\ell \phi_{j,\epsilon} - \sum_{k=1}^K (\bar{X}_k)_\ell \bar{X}_k \right\|^2 \leq 2 \sum_{j=1}^K (\phi_{j,\epsilon})_\ell P_0 \phi_{j,\epsilon} - \sum_{k=1}^K (\bar{X}_k)_\ell \bar{X}_k + 2 \sum_{k=1}^K (\phi_{j,\epsilon})_\ell \mathbf{s}_j \right\|^2$$

$$ = 2 \left\| \sum_{k=1}^K \left[ \left( \sum_{j=1}^K (\phi_{j,\epsilon})_\ell \phi_{j,\epsilon} \right) - (\bar{X}_k)_\ell \bar{X}_k \right] \right\|^2 + 2 \sum_{j=1}^K \|\mathbf{s}_j\|^2$$

$$ = 2 \left\| \sum_{k=1}^K ((P_\epsilon I) \bar{X}_k)_\ell \bar{X}_k \right\|^2 + 2 \sum_{j=1}^K \|\mathbf{s}_j\|^2$$

$$ \leq 2K \sum_{k=1}^K \|((P_\epsilon I) \bar{X}_k)^2 + 2 \sum_{j=1}^K \|\mathbf{s}_j\|^2$$

$$ \leq 2K \sum_{k=1}^K \|\mathbf{r}_k\|^2 + 2 \sum_{j=1}^K \|\mathbf{s}_j\|^2 \leq 4K^2 \Xi_0 \epsilon^2, \tag{A.10} $$

where the last inequality follows from (A.9).

Now recall the expansion (2.17) for columns of $C_{\epsilon,\tau}$,

$$ \mathbf{c}_{\ell,\epsilon} = \sum_{j=1}^N \frac{1}{\lambda_{j,\epsilon}} (\phi_{j,\epsilon})_\ell \phi_{j,\epsilon}. $$

For (a), we want to estimate

$$ \left\| \mathbf{c}_{\ell,\epsilon} - \sum_{k=1}^K (\bar{X}_k)_\ell \bar{X}_k \right\|^2 \leq 3 \left\| \sum_{j=K+1}^N \frac{1}{\lambda_{j,\epsilon}} (\phi_{j,\epsilon})_\ell \phi_{j,\epsilon} \right\|^2 + 3 \left\| \sum_{j=1}^K \left( \frac{1}{\lambda_{j,\epsilon}} - 1 \right) (\phi_{j,\epsilon})_\ell \phi_{j,\epsilon} \right\|^2 + 3 \left\| \sum_{j=1}^K (\phi_{j,\epsilon})_\ell \phi_{j,\epsilon} - \sum_{k=1}^K (\bar{X}_k)_\ell \bar{X}_k \right\|^2 \tag{A.11}$$

The last term is of order $\epsilon^2$ by (A.10). The first term can be controlled using Propo-
Then instead of (A.12), we use the bound in Proposition A.6(ii) to estimate
\[
\left\| \sum_{j=K+1}^{N} \frac{1}{\lambda_{j,\epsilon}} (\phi_{j,\epsilon})_\ell \phi_{j,\epsilon} \right\|^2 \leq \left( \frac{N-K}{\lambda_{K+1,\epsilon}} \right)^2 \\
\leq (N-K)^2 \sigma^2 \left( \tau^2 + \theta - \epsilon \right) + \epsilon^2 \left( \sup_{h \in \mathbb{Z}} \|L^{(h)}\|_2 \right)^2 \\
\leq (N-K)^2 \sigma^2 \tau^{4\alpha} + O \left( \tau^{4\alpha} \left( \tau^2 + \epsilon \right) \right),
\]
where \( \theta > 0 \) is the constant appearing in Assumption 1(b). Next, when \( \epsilon/\tau^2 \) is small, we can estimate the second term in the right-hand side of (A.11) using Proposition A.7 together with the same bound as in (A.6),
\[
\left\| \sum_{j=1}^{K} \left( \frac{1}{\lambda_{j,\epsilon}} - 1 \right) (\phi_{j,\epsilon})_\ell \phi_{j,\epsilon} \right\|^2 \leq K \sum_{j=1}^{K} \left| \frac{1}{\lambda_{j,\epsilon}} - 1 \right|^2 \left\| (\phi_{j,\epsilon})_\ell \right\|^2 \\
\leq \alpha^2 K^2 \Xi^2_2 \left( \frac{\epsilon}{\tau^2} \right)^2 + O \left( \epsilon^3 \tau^{-6} \right).
\]
Putting the above estimates together, we can find a constant \( \Xi_\tau = \Xi_\tau(N, K, \theta, \alpha, \epsilon_0) > 0 \) independent of \( \epsilon \) and \( \tau \) such that for all \( \ell \in \mathbb{Z} \),
\[
\left\| c_{\ell,\epsilon} - \sum_{k=1}^{K} (\tilde{x}_k)_\ell \tilde{x}_k \right\|^2 \leq \Xi_\tau \left( \tau^{4\alpha} + \left( \frac{\epsilon}{\tau^2} \right)^2 + \epsilon^2 \right) + O \left( \tau^{4\alpha} \left( \tau^2 + \epsilon \right) \right) + O \left( \left( \frac{\epsilon}{\tau^2} \right)^3 \right).
\]
Finally, note that for each \( \ell \in \mathbb{Z} \), there exists a unique \( k_0 \in \{1, ..., K\} \) such that \( \ell \in \tilde{z}_{k_0} \).

Then
\[
\sum_{k=1}^{K} (\tilde{x}_k)_\ell \tilde{x}_k = (\tilde{x}_{k_0})_\ell \tilde{x}_{k_0},
\]
which concludes the proof of statement (a).

To prove (b), the argument is similar. For \( \beta := \epsilon/\tau^2 \), we have
\[
\tilde{\beta} = (1 + \beta \Xi_1)^{-\alpha} > 0.
\]
Then, instead of (A.12), we use the bound in Proposition A.6(ii) to estimate
\[
\left| \frac{1}{\lambda_{j,\epsilon}} - \tilde{\beta} \right| = \left| \frac{1 - \beta \lambda_{j,\epsilon}}{\lambda_{j,\epsilon}} \right| \leq \left| 1 - \beta \lambda_{j,\epsilon} \right| = \tilde{\beta} \left| \lambda_{j,\epsilon} - \frac{1}{\beta} \right| \\
\leq \tilde{\beta} \left( (\beta^{-1/\alpha} + \epsilon \beta \Xi_2) \alpha - \beta^{-1} \right) = \frac{\alpha \beta \Xi_2}{(1 + \beta \Xi_1)} \epsilon + O(\epsilon^2) \quad \text{for } j \in \{2, ..., K\}.
\]
Therefore, our goal is to control
(A.13)
\[
\left\| c_{\ell, \epsilon} - (1 - \tilde{\beta}) (\phi_{1, \epsilon})_{\ell} \phi_{1, \epsilon} - \tilde{\beta} \sum_{k=1}^{K} (\bar{X}_k)_{\ell} \bar{X}_k \right\|^2
\]
\[
\leq 3 \left\| \sum_{j=K+1}^{N} \frac{1}{\lambda_{j, \epsilon}} (\phi_{j, \epsilon})_{\ell} \phi_{j, \epsilon} \right\|^2
\]
\[
+ 3 \left\| \sum_{j=1}^{K} \frac{1}{\lambda_{j, \epsilon}} (\phi_{j, \epsilon})_{\ell} \phi_{j, \epsilon} - (1 - \tilde{\beta}) (\phi_{1, \epsilon})_{\ell} \phi_{1, \epsilon} - \tilde{\beta} \left( \sum_{j=1}^{K} (\phi_{j, \epsilon})_{\ell} \phi_{j, \epsilon} \right) \right\|^2
\]
\[
+ 3 \left\| \beta \left( \sum_{j=1}^{K} (\phi_{j, \epsilon})_{\ell} \phi_{j, \epsilon} - \sum_{k=1}^{K} (\bar{X}_k)_{\ell} \bar{X}_k \right) \right\|^2
\]
\[
= 3 \left\| \sum_{j=K+1}^{N} \frac{1}{\lambda_{j, \epsilon}} (\phi_{j, \epsilon})_{\ell} \phi_{j, \epsilon} \right\|^2
\]
\[
+ 3 \sum_{j=1}^{K} \left( \frac{1}{\lambda_{j, \epsilon}} - \tilde{\beta} \right) (\phi_{j, \epsilon})_{\ell} \phi_{j, \epsilon} \right\|^2
\]
\[
+ 3\tilde{\beta}^2 \left\| \sum_{j=1}^{K} (\phi_{j, \epsilon})_{\ell} \phi_{j, \epsilon} - \sum_{k=1}^{K} (\bar{X}_k)_{\ell} \bar{X}_k \right\|^2 .
\]

Thanks to the previous estimate, the second term can be bounded by
\[
\left\| \sum_{j=2}^{K} \left( \frac{1}{\lambda_{j, \epsilon}} - \tilde{\beta} \right) (\phi_{j, \epsilon})_{\ell} \phi_{j, \epsilon} \right\|^2 \leq (K - 1)^2 \left( \frac{\alpha \beta \Xi_2}{(1 + \beta \Xi_1)} \right)^2 \epsilon^2 + \mathcal{O}(\epsilon^3).
\]

The first and last terms in (A.13) can be estimated as for part (a), and so we can find a constant \( \Xi_8 = \Xi_8(N, K, \theta, \alpha, \epsilon_0) > 0 \) independent of \( \epsilon \) and \( \tau \) such that for all \( \ell \in Z \),
\[
\left\| c_{\ell, \epsilon} - (1 - \tilde{\beta}) (\phi_{1, \epsilon})_{\ell} \phi_{1, \epsilon} - \tilde{\beta} \sum_{k=1}^{K} (\bar{X}_k)_{\ell} \bar{X}_k \right\|^2
\]
\[
\leq \Xi_8 \left( \tau^{4\alpha} + \epsilon^2 \right) + \mathcal{O} \left( \tau^{4\alpha} (\tau^2 + \epsilon) \right) + \mathcal{O}(\epsilon^3).
\]

From Proposition A.6(i), we know that \( \phi_{1, \epsilon = D_p \| D_p \| 1} \). Further, using the expansion \( D_p = D_p + \epsilon D_p(p) \) derived in the proof of Lemma A.5, we can simplify the middle term in the expression on the left-hand side above,
\[
(1 - \tilde{\beta}) (\phi_{1, \epsilon})_{\ell} \phi_{1, \epsilon} = (1 - \tilde{\beta})(\bar{X})_{\ell} \bar{X} + \mathcal{O}(\epsilon).
\]

This concludes the proof of Proposition A.10. \( \Box \)
