Molecular fossils from phytoplankton reveal secular \( P_{\text{CO}_2} \) trend over the Phanerozoic

Caitlyn R. Witkowski\(^1\), Johan W. H. Weijers\(^2\), Brian Blais\(^3,4\), Stefan Schouten\(^1,5\), Jaap S. Sinninghe Damsté\(^1,5\)

Past changes in the atmospheric concentration of carbon dioxide (\( P_{\text{CO}_2} \)) have had a major impact on earth system dynamics; yet, reconstructing secular trends of past \( P_{\text{CO}_2} \) remains a prevalent challenge in paleoclimate studies. The current long-term \( P_{\text{CO}_2} \) reconstructions rely largely on the compilation of many different proxies, often with discrepancies among proxies, particularly for periods older than 100 million years (Ma). Here, we reconstructed Phanerozoic \( P_{\text{CO}_2} \) from a single proxy: the stable carbon isotopic fractionation associated with photosynthesis (\( \varepsilon_p \)) that increases as \( P_{\text{CO}_2} \) increases. This concept has been widely applied to alkeneones, but here, we expand this concept both spatially and temporally by applying it to all marine phytoplankton via a diageneric product of chlorophyll, phytane. We obtained data from 306 marine sediments and oils, which showed that \( \varepsilon_p \) ranges from 11 to 24\( \% \), agreeing with the observed range of maximum fractionation of Rubisco (i.e., 25 to 28\( \% \)). The observed secular \( P_{\text{CO}_2} \) trend derived from phytane-based \( \varepsilon_p \) mirrors the available compilations of \( P_{\text{CO}_2} \) over the past 420 Ma, except for two periods in which our higher estimates agree with the warm climate during those time periods. Our record currently provides the longest secular trend in \( P_{\text{CO}_2} \) based on a single marine proxy, covering the past 500 Ma of Earth history.

INTRODUCTION
Carbon dioxide shapes climate, breathes life into the biosphere, and turns the cogs of the carbon cycle both in the present and in the past. The past atmospheric concentrations of carbon dioxide (expressed in partial pressure; \( P_{\text{CO}_2} \)) are reconstructed from indirect measurements (i.e., proxies) such as stomatal densities and indices in plant fossils, the boron isotopic composition of marine carbonate, and the stable carbon isotope composition (\( \delta^{13}C \)) of marine phytoplankton, paleosols, and liverworts (1). Each proxy has strengths and limitations, such as its time span of application, associated estimation error, and sensitivity to specific \( P_{\text{CO}_2} \) levels (2). The reconstruction of secular trends of \( P_{\text{CO}_2} \) over long time scales (>10 million years (Ma) ago) often relies on compiling many different proxies to generate a continuous record (1). Thus, a single well-constrained proxy that spans the Phanerozoic may strengthen and support our understanding of \( P_{\text{CO}_2} \).

The stable carbon isotope fractionation associated with oxygenic photosynthesis (\( \varepsilon_p \)) is a proxy that has the potential to span the Phanerozoic. Isotopic fractionation occurs when the \( \text{CO}_2 \)-fixing enzyme Rubisco (ribulose 1,5-biphosphate carboxylase oxygenase) favors \( ^{12}C \) over \( ^{13}C \) during inorganic carbon fixation, making the photosynthesates’ isotopic composition (\( \delta^{13}C \)) depleted in \( ^{13}C \) compared to its surrounding environmental \( \text{CO}_2 \) (3). Higher \( \text{CO}_2 \) concentrations lead to greater fractionation and vice versa, resulting in a dynamic \( \delta^{13}C \) of photoautotrophic biomass (4, 5). This concept is reverse engineered to reconstruct past \( P_{\text{CO}_2} \) by calculating \( \varepsilon_p \) from the \( \delta^{13}C \) of organic matter (OM) derived from photoautotrophic biomass and the \( \delta^{13}C \) of \( \text{CO}_2 \) derived from fossilized carbonates (e.g., planktonic foraminifera) (6).

\( \varepsilon_p \) has been extensively tested as a \( P_{\text{CO}_2} \) proxy since it was first estimated using the \( \delta^{13}C \) of geoporphyrins (7) and later using the \( \delta^{13}C \) of bulk OM (8). In subsequent studies, factors that influence \( \varepsilon_p \) other than \( \text{CO}_2 \) concentrations have been explored in laboratory cultures [e.g., growth rate (9) and cell size (10)] and environmental conditions, such as seasonality, light, and temperature (11). In addition, brought to the forefront in more recent studies, alkeneones (and theoretically other phytoplankton) may underestimate \( P_{\text{CO}_2} \) due to other factors such as cell size and carbon acquisition strategies (12–14). The impact of some factors remains difficult to constrain, such as the assumption that the primary source of carbon is passively diffused \( \text{CO}_2 \) into the cell; under low \( \text{CO}_2 \) conditions, many phytoplankton implement active uptake of bicarbonate (15), a potential concern given the substantial \( \delta^{13}C \) difference between bicarbonate (0\( \% \)) and \( \text{CO}_2 \) (8–18\( \% \)) and even further complicated by active uptake elevating \( \text{CO}_2 \) at the site of carboxylation.

The \( \delta^{13}C \) of total organic carbon (TOC) to calculate \( \varepsilon_p \), in principle, provides a long-term record for \( P_{\text{CO}_2} \) (8). Using TOC does raise concerns regarding isotopic heterogeneity in different organisms due to kinetic isotope effects and Rayleigh distillation effects with branching points in biosynthetic pathways, leading to distinct \( \delta^{13}C \) values for carbohydrates, proteins, and lipids (17). These \( \delta^{13}C \) differences among biosynthetic products can be further influenced by diagenetic conditions, such as carbohydrate sulfurization (18), and mixing with terrestrial OM. Abating concerns of using TOC, compound-specific isotope analysis is used on shorter time scales, primarily relying on alkeneone biomarkers, the long-chain unsaturated methyl and ethyl \( n \)-ketones produced by a select group of Haptophytes. However, \( \varepsilon_p \) of alkeneones only reconstructs \( P_{\text{CO}_2} \) during the evolutionary history of alkeneone-producing Haptophytes, which are not common in the geologic record until the mid-Miocene (19).

To extend the \( P_{\text{CO}_2} \) reconstruction over the Phanerozoic, we estimated \( \varepsilon_p \) here using the general phytoplanktonic molecular fossil phytane. Phytane is derived from chlorophyll-a, the omnipresent photoautotrophic pigment that absorbs and transfers light into chemical energy during photosynthesis and that has been...
present for at least the past 2.15 billion years (Ga) (20). Phytane has been found in similarly ancient rocks and petroleum (21). Furthermore, all photosynthetic phytoplankton will contribute to this general biomarker, thereby averaging the $\varepsilon_p$ of the phytoplankton community at the time of synthesis. The $\varepsilon_p$ calculated from phytane has been previously explored as a proxy for $P_{CO_2}$ at selected sites during specific time periods (22–25) and has been shown to mimic $P_{CO_2}$ trends. Here, we explore its potential for reconstructing secular trends of $P_{CO_2}$ over the Phanerozoic.

RESULTS

We generated $\delta^{13}C$ values of phytane ($\delta^{13}C_{phytane}$) from 41 oils and 29 sediments. Furthermore, we compiled $\delta^{13}C_{phytane}$ values from the literature. New and compiled data yielded 308 data points in total (table S1).

Only marine sediments and oils were used for our compilation to constrain the $\delta^{13}C_{phytane}$ to marine phytoplankton in a more stable and homogenous environment, avoiding the potential decoupling of $P_{CO_2}$ that may occur in local carbon cycles of terrestrial and lacustrine settings. By using only marine settings, this also excludes the additional confounding influence of $C_3$ and $C_4$ higher plants; chlorophyll breaks down relatively quickly, eliminating effective transport of terrestrial phytol to the ocean. Immature oils lacking signs of biodegradation were selected on the basis of the confidence in source rock identification to constrain age. Furthermore, these oils were selected on the basis of the lack of terrestrial biomarkers (e.g., oleanane, taraxastane, and bicadinanes) and the lack of local environmental irregularities (e.g., high salinity) to minimize spurious influences on the overall baseline signal for $P_{CO_2}$ (for more details, see Supplementary Text). To attain the general baseline trend for the $\delta^{13}C_{phytane}$ from marine phytoplankton over the Phanerozoic, short-term isotope anomalies were excluded [e.g., carbon isotope excursion events (CIEs) with isotopic spikes of $\geq 2\%$ in less than 100 thousand years (ka)] such as the negative CIE of the Paleocene/Eocene boundary (26). Data before and after CIEs (when the excursion has a clear end point) are included in this compilation.

In our dataset, most $\delta^{13}C_{phytane}$ is from extractable free phytane. Sulfur-bound phytane (i.e., phytane released from sulfur-bound moieties present in sediments that were deposited in anoxic environments) is also included. Sulfur-bound phytane is different than free phytane in that during early diagenesis, inorganic reduced sulfur species selectively react with labile functionalized lipids such as phytol or phytadienes (27). That is, sulfur-bound phytane is an excellent addition to this record: It may more accurately reflect the $\delta^{13}C$ of the original phytol, whereas free phytane may have small influences by fluctuating inputs of terrestrial OM or archaeal-derived ether lipids (25, 28).

Our compilation shows that over the Phanerozoic, values for the $\delta^{13}C_{phytane}$ range from $-34.7$ to $-23.2\%$ (Fig. 1). During the Late Ordovician (455 to 450 Ma), there is a marked negative shift from $-28.3$ to $-34.2\%$, followed by a data-scare Silurian. A gradual positive trend during the Devonian was observed from $-33.9\%$ at ca. 380 Ma to $-28.7\%$ at ca. 355 Ma. The Carboniferous into the Early Permian lacks substantial data from which to describe a trend. There is a large decrease from the Permian through the Triassic, from $-26.4\%$ at ca. 261 Ma to $-33.2\%$ at ca. 242 Ma. Then, a smaller increase in the Jurassic $\delta^{13}C_{phytane}$ fluctuating between ca. $-33$ and $-30\%$, is observed through the Cretaceous. A decrease and a rapid increase are observed in the Late Cretaceous, from $-33.0$ to $-26.8\%$ between ca. 98 and 93 Ma. The Paleogene shows a similar decrease, followed by an increase from $-34.7$ to $-32.6\%$. There is a data gap between 52 and 30 Ma, after which the overall trend continues positive from $-33.0$ to $-25.3\%$ at 0.1 Ma, the most positive value in the record of $-23.2\%$ at 14 Ma.

DISCUSSION

Phytane-derived $\varepsilon_p$

To calculate $\varepsilon_p$, the $\delta^{13}C$ of the photosynthetic biomass ($\delta_p$) and the $\delta^{13}C$ of dissolved $CO_2$ ($\delta_o$) have to be estimated. $\delta_p$ is derived from the $\delta^{13}C_{phytane}$ correcting for the isotopic offset between phytol and biomass. The latter factor was estimated by compiling culture studies from 22 phytoplankton species, yielding an average of $3.3 \pm 1.3\%$ SD (fig. S1 and Supplementary Text). $\delta_o$ is estimated from $\delta^{13}C$ of carbonate, correcting for the carbon isotopic fractionation between dissolved $CO_2$ with respect to $HCO_3^-$ (16). Where available (dataset S1), the $\delta^{13}C$ of carbonate is derived from planktonic foraminifera at the same (or nearby) site as the $\delta^{13}C_{phytane}$. Where unavailable, the average $\delta^{13}C$ of carbonate is obtained from the global compiled average of $\delta^{13}C$ of marine planktonic foraminiferal carbonate at the time of deposition (8, 29). Uncertainty for marine carbonate was assigned $\pm 0.4\%$ with uniform distribution. The correction for the isotopic fractionation between dissolved $CO_2$ with respect to $HCO_3^-$ requires sea surface temperature (SST). This information was obtained from SST proxies (preferably $\delta^{18}O$ from planktonic foraminifera, but otherwise from other proxies such as $U^{237}$ or TEX$_{345}$) measured from each site or nearby site (dataset S1) and assigned a $\pm 4\%$ SD of uncertainty. Where SST data are unavailable, temperature was estimated by adjusting the modern site for its paleolatitude (using www.paleolatitude.org), finding the SST at that location (e.g., seatemperature.org), and then correcting the present-day SST for global temporal SST anomalies [i.e., 0 to 56 Ma (30, 31) and 65 to 455 Ma (32)]. For further details on the calculations and uncertainty in each parameter on calculated $\varepsilon_p$, see Supplementary Text.

Figure 2 shows that calculated $\varepsilon_p$ ranges from ca. 11 to $24\%$. The vertical error bars indicate Monte Carlo simulations of uncertainty.
Estimates of \( P_{\text{CO}_2} \) based on phytane-derived \( \epsilon_p \)

To estimate the dissolved carbon dioxide (\( \text{CO}_2_{\text{aq}} \)) from \( \epsilon_p \), we use

\[
\text{CO}_2_{\text{aq}} = b/(\epsilon_f - \epsilon_p)
\]

a relationship developed by Hayes (17) and Francois et al. (39) and that is a modification of the relationship developed for higher plants from Farquhar et al. (40). This concept has been successfully tested in laboratory cultures for \( \text{CO}_2_{\text{aq}} \) ranging over 0.4 to 79 \( \mu \text{mol kg}^{-1} \), covering \( \text{CO}_2 \) concentrations lower than the glacial cycles to \( \text{CO}_2 \) much higher than inferred from the past (10, 36, 41).

The term \( b \) accounts for all species-specific factors that may influence isotopic fractionation, in particular cell carbon allocation and bicarbonate uptake, as well as cell geometry and growth rate (9), and influencers of growth rate such as nutrient availability (e.g., \( b \) was found to be empirically related to phosphate concentrations) (42).

The factor \( b \) has almost exclusively been studied in laboratory cultures of Haptophyte algae via alkenones, a relationship then extended into the modern environment (42). In marine surface sediments and suspended matter containing alkenones, \( b \) ranges from approximately 70 to 240% kg \( \mu \text{M}^{-1} \) with a mean of 165 ± 53 (42). Given that phytane is a general biomarker averaging the entire phytoplankton community, as opposed to the select group of Haptophytes for alkenones, we calculated \( b \) from the \( \delta^{13}\text{C} \) of total OM in diverse modern marine surface sediments (Supplementary Text, table S2, and references therein). Over these 19 study sites, the average for \( b \) is 168 ± 43% kg \( \mu \text{M}^{-1} \), consistent with the alkenone studies and with the \( b \) value used in previous phytane-based \( P_{\text{CO}_2} \) estimations (22, 23). A mean value of 170% kg \( \mu \text{M}^{-1} \) with an assigned SD of ±60 is used throughout the record. Sensitivity plots (fig. S3A) show that a 1% change in \( b \) results in a 1% change in \( P_{\text{CO}_2} \) estimation. For details on these calculations and uncertainty estimations, please see Supplementary Text.

\( \epsilon_{p} \) is the maximum isotopic fractionation associated with photosynthetic carbon fixation, generally ranging from 25 to 28%o for algae in modern oceans and laboratory experiments (43, 44). Given that phytane is a general phytoplankton biomarker, the exact percentages of each species in the phytoplankton composition contributing to the phytane pool are needed to estimate the value \( \epsilon_{p} \), something that cannot be practically achieved for ancient sediments. Thus, we use the average of the laboratory culture \( \epsilon_{f} \) range (26.5 ± 1.5%o uniform distribution) for the entire phytane-based reconstruction of \( P_{\text{CO}_2} \). Sensitivity tests are conducted in Supplementary Text and shown in fig. S3B.

To estimate the atmospheric concentration of carbon dioxide from the \( \text{CO}_2_{\text{aq}} \), we used

\[
P_{\text{CO}_2} = [\text{CO}_2_{\text{aq}}]/K_0
\]

based on Henry’s law, where the solubility constant \( K_0 \), expressed in M/atm, is

\[
\ln K_0 = A_1 + A_2(100/T) + A_3 \ln(T/100) + S\% [B_1 + B_2(T/100) + B_3(T/100)^2]
\]

where \( A \) and \( B \) are constants, \( T \) is temperature in Kelvin, and \( S\% \) is salinity in \%o (45). The constants used here are \( A_1 \) to \( A_3 \) (~58.0931, 90.5069, and 22.2940) and \( B_1 \) to \( B_3 \) (0.02777, ~0.02589, and 0.00506), respectively (45). Temperatures are obtained as described above. Salinity is estimated to be 34%o and assigned a ±2%o SD uncertainty. Figure 3 shows the consideration of these factors in the error bars of these \( P_{\text{CO}_2} \) estimations. The vertical error bars show 1 SD (68%) uncertainty in \( P_{\text{CO}_2} \) estimation based on Monte Carlo simulations, culminating the uncertainty in \( b \) (-260% kg \( \mu \text{M}^{-1} \) SD), \( \epsilon_f \) (±1.5%o), and \( \epsilon_p \) (combined uncertainties of \( \delta^{13}\text{C} \) of phytane ± 0.5%o uniform distribution, the offset between biomass and phytane of ±1.3%o and \( \delta^{13}\text{C} \) of planktonic foraminifera ± 0.4%o uniform distribution, and SST ± 4°C SD). The
The glaciation paleolatitude for this time interval extends to Ordovician (ca. 10°C) relative to the estimates for the Devonian. The phytane-based record jumps from very similar values throughout the entire Phanerozoic. During the Late Ordovician (ca. 460 to 440 Ma), the phytane-based record contains ca. 310 estimated CO2 values based on Monte Carlo simulations, culminating the uncertainty in $\delta^{13}C$ of phytane $\pm 0.5\%$ uniform distribution, the offset between biomass and phytane $\pm 1.3\%$ SD, $\delta^{13}C$ of planktonic foraminifera $\pm 0.4\%$ uniform distribution, and SST $\pm 4^\circ C$ SD. Plotted for comparison, the Foster et al. compilation shows the Monte Carlo resampling and LOESS fit of ca. 1500 data points from the five most robust $P_{CO_2}$ proxies: $\delta^{13}C$ of long-chain alkenones, $\delta^{11}B$ of marine carbonate, $\delta^{13}C$ of paleosols, stomatal densities and indices in plants, and $\delta^{13}C$ of liverworts. Sixty-eight percent and 95% confidence intervals are shown in gray and light gray, respectively. The light blue bars represent glacial paleolatitude, as determined by the literature compilation of glaciogenic detritus (46).

**CONCLUSION**

Our Phanerozoic $P_{CO_2}$ record based on the $\delta^{13}C_{phytane}$ is, to the best of our knowledge, one of the longest reconstructions based on a single proxy, extending the known $P_{CO_2}$ record. As a spatially and temporally ubiquitous compound, phytane is one of the most abundantly available phytoplanktonic biomarkers suitable for $P_{CO_2}$ reconstructions, more so considering that both sediments and oils can be used. Among marine-based proxies, this phytane record is the longest reconstruction for $P_{CO_2}$. Phytane-based $P_{CO_2}$ reconstruction yields similar estimates as compilations of $P_{CO_2}$ proxies, giving the potential to yield a more robust and consistent $P_{CO_2}$ record from a single biomarker.

**MATERIALS AND METHODS**

The isotopic composition of phytane was measured in 70 marine sediments and oils derived from marine source rocks. Marine oils were processed at Shell Global Solutions International B.V., The Netherlands. Crude oil was eluted over a AgNO$_3$-impregnated silica gel column using three column volumes of cyclohexane to yield saturated hydrocarbon fractions. To remove n-alkanes, the saturated fractions remained in cyclohexane when two layers of 0.5-Å molecular sieve were added to the samples and saturated overnight. The remaining branched/cyclic fractions were injected splitless on gas chromatography–flame ionization detector (GC-FID) at 35°C for 5 min, ramped to 325°C at 4°C/min for 15 min, and held isothermal for another 15 min. A silica capillary column (Ultra-1, 50 m × 0.22 mm; $d_e$, 0.11 μm) was used with helium as a carrier gas at a constant flow of 25 cm/s. GC–isotope ratio mass spectrometry (IRMS) was conducted using a DB-1ms column (60 m × 0.32 mm; $d_e$, 0.25 μm). The samples were injected at from 1400 to 300 μatm, amplified from the trend seen in phytane-based $ɛ_p$, but a trend that is similar to the Foster et al. estimations. This significant drop in $P_{CO_2}$ is further supported by the glaciation paleolatitude, where it significantly drops to 60° at the start of the Carboniferous and moves up to 30° by the end of the Carboniferous into the early Permian (46). Then, $P_{CO_2}$ increases from the Late Permian at 450 μatm through the Triassic at 1600 μatm. The Jurassic exhibits a gradual decrease from 1000 μatm during the Toarcian to 600 μatm in the Tithonian. From the Late Jurassic to the mid-Cretaceous, there is a gradual increase to 1300 μatm. The Cenomanian starts at 1500 μatm, the highest $P_{CO_2}$ values for the $\delta^{13}C_{phytane}$-based Phanerozoic record, which then rapidly drops to 600 μatm from ca. 98 to 85 Ma. The high values during the Cenomanian are much higher than those based on the Foster et al. compilation. This may also be attributed to the important role that temperature has when converting raw $\delta^{13}C$ values from biomarkers to $P_{CO_2}$ (see Supplementary Text and fig. S3). However, considering that this period is marked with extremely high SSTs (47), the high phytane-based $P_{CO_2}$ estimations may be appropriate. A second increase and a second drop in the record then occur in the early Paleogene from ca. 56 to 54 Ma, dropping from 1400 to 7500 μatm. Here, our $P_{CO_2}$ estimates are much higher than those of Foster et al. Our high estimates agree with high SST records during this time frame (48). Last, a decrease in $P_{CO_2}$ from ca. 1000 to 250 μatm is observed from the late Paleogene toward the Holocene (ca. 30 to 0.1 Ma), the lowest estimate for the Phanerozoic. This lowering of $CO_2$ is supported by the glaciation paleolatitude, which extended as far as 40° (46), and in agreement with the overall cooling observed in bottom water temperatures and the descent in the so-called icehouse world (49).

Fig. 3. Phanerozoic $P_{CO_2}$ from phytane. Estimated Phanerozoic $P_{CO_2}$ (on a log scale) from literature (pink) and data from this study (blue), and from sediment (square) and oil (circle). Horizontal error bars indicate uncertainty in age. Vertical error bars indicate 1 SD (68%) uncertainty in $P_{CO_2}$ estimation based on Monte Carlo simulations, culminating the uncertainty in b (±60% kg µM$^{-1}$ SD), $ɛ_p$ (±1.5% uniform distribution), and $ɛ_p$ (combined uncertainty in $δ^{13}C$ of phytane $± 0.5\%$ uniform distribution, the offset between biomass and phytane $± 1.3\%$ SD, $δ^{13}C$ of planktonic foraminifera $± 0.4\%$ uniform distribution, and SST $± 4^\circ C$ SD). Plotted for comparison, the Foster et al. compilation shows the Monte Carlo resampling and LOESS fit of ca. 1500 data points from the five most robust $P_{CO_2}$ proxies: $δ^{13}C$ of long-chain alkenones, $δ^{11}B$ of marine carbonate, $δ^{13}C$ of paleosols, stomatal densities and indices in plants, and $δ^{13}C$ of liverworts. Sixty-eight percent and 95% confidence intervals are shown in gray and light gray, respectively. The light blue bars represent glacial paleolatitude, as determined by the literature compilation of glaciogenic detritus (46).
220°C into a 70°C oven for 1 min and ramped to 250°C at a rate of 4°C/min and then to 300°C at a rate of 20°C/min for 20 min at a flow rate of 30 cm/s using helium as a carrier gas. The reference gas was normal CO₂ with a predetermined isotopic composition.

Twenty-nine marine sediments from Deep Sea Drilling Project Site 467 offshore of southern California from the Middle Miocene to Lower Pliocene (50) were processed at NIOZ Royal Netherlands Institute for Sea Research, The Netherlands. Powdered sediments (15 to 20 g) were extracted with dichloromethane (DCM):MeOH (9:1, v/v) on a Dionex 250 accelerated solvent extractor at 100°C, 7.6 × 10⁶ Pa. Extracts were eluted over Na₂SO₄ to remove excess water and then over an alumina-packed column to separate polar fractions (DCM:MeOH:1.1, v/v). Polar fractions were desulfurized using Raney nickel (51), eluted over alumina oxide into an apolar fraction (hexane: DCM, 9:1, v/v), and hydrogenated. Desulfurized apolar fractions were injected on a GC-MS to identify the presence of phytane and on a GC-IRMS for the isotopic determination before injection on IRMS for the isotopic fractionation. Acknowledgments: We thank D. Lea and three anonymous reviewers for constructive comments, which substantially improved the manuscript. We also thank A. Tijpke Hoekstra, M. van der Meer, J. Ossebar, and M. Verweij at the NIOZ and J. Pureven at Shell Global Solutions International B.V. for technical support. Funding: This study received funding from the Netherlands Earth System Science Center (NESSC) through a gravitation grant (024.002.001) to J.J.S.D. and S.S. from the Dutch Ministry for Education, Culture and Science. This research used samples and/or data provided by the International Ocean Discovery Program (IODP) and its predecessor the Ocean Drilling Program. Author contributions: C.R.W., S.S., and J.S.S.D. designed the study and interpreted the data. C.R.W. compiled data, analyzed sediment and oil samples, and wrote the first draft of the manuscript. J.W.H.W. provided and analyzed oil samples. B.B. wrote the script to calculate uncertainty in pCO₂ estimations. Competing interests: The authors declare that they have no competing interests. Data and materials availability: All data needed to evaluate the conclusions in the paper are present in the paper and/or the Supplementary Materials. Additional data related to this paper may be requested from the authors.
