Abstract
Background: Chemokines are important mediators in immune cell recruitment, contributing to allergy development. However, extensive studies of chemokines in the circulation in relation to the presence and development of allergic diseases remain scarce. Our aim was to investigate associations of circulating allergy-related chemokines with the development of asthma and sensitization cross-sectionally and longitudinally in a population-based cohort.

Methods: The chemokines CCL17, CCL22, CXCL10, CXCL11 and CCL18 were measured in plasma samples from children in the Manchester Asthma and Allergy Study. Samples were available from cord blood at birth (n = 376), age 1 (n = 195) and age 8 (n = 334). Cross-sectional and longitudinal association analyses were performed in relation to asthma and allergic sensitization, as well as allergic phenotype clusters previously derived using machine learning in the same study population.

Results: In children with asthma and/or allergic sensitization, CCL18 levels were consistently elevated at 1 and/or 8 years of age. In a longitudinal model including information on asthma from 4 time points (5, 8, 11 and 16 years of ages), we observed a significant association between increasing CCL18 levels at age 1 and a higher risk of asthma from early school age to adolescence (OR = 2.9, 95% CI 1.1–7.6, p = .028). We observed similar associations in longitudinal models for allergic sensitization. Asthma later in life was preceded by increased CXCL10 levels after birth and decreased CXCL11 levels at birth.

Conclusion: Elevated CCL18 levels throughout childhood precede the development of asthma and allergic sensitization. The Th1-associated chemokines CXCL10 and
1 | INTRODUCTION

Worldwide, allergic diseases affect development and well-being of many children and adolescents, while also posing a considerable socio-economic burden.\(^1\) Allergic diseases are heterogeneous and may present with similar symptoms but different underlying causes, the features of which are just beginning to be characterized.\(^2\) Both sensitization and asthma are considered heterogeneous traits, with distinct clusters being unveiled using unsupervised machine learning techniques.\(^3,4\) While numerous immune biomarkers have been investigated as potential determinants of heterogeneity and development of allergic phenotypes, thus far none has proven unequivocal utility in a clinical setting.

Allergic inflammation depends on chemokine-facilitated recruitment of immune cells to the allergic reaction site.\(^5\) The development of allergic symptoms and sensitization early in life is preceded by elevated cord blood levels of the Th2-associated chemokines CCL17 and CCL22, respectively,\(^6,7\) with similar findings from sensitized children with allergic symptoms, and children developing recurrent wheeze\(^8\) and asthma.\(^7\) Likewise, increased levels of Th1-associated chemokines CXCL10 and/or CXCL11 have been observed in both viral-induced\(^9\) and moderate-to-severe asthma.\(^10\) Multiple studies have also revealed elevated early-life Th1-associated chemokine levels predicting outcomes such as wheezing and asthma.\(^8,11\) In contrast, sensitized children revealed lower circulating levels of CXCL11 at birth and 2 years of age,\(^8\) suggesting diverse mechanisms of action of these chemokines in allergy development. CCL18 is under dual regulation of both Th2 and Treg cells,\(^12\) and at steady state, it is mainly a regulatory chemokine, which is up-regulated in allergic conditions such as allergic rhinitis, atopic dermatitis and asthma.\(^12\) Indeed, we have previously showed elevated levels of CCL18 in children developing eczema and recurrent wheeze in the first years of life.\(^8\)

Although the chemokines CXCL10, CXCL11, CCL17, CCL22 and CCL18 have previously been characterized as important mediators in allergy development, thus far they have not been studied in a larger population-based cohort to establish their role in a longitudinal setting. To this end, we measured circulating levels of these chemokines at three time points throughout childhood (at birth, 1 year and 8 years of age) in a population-based birth cohort\(^13\) and related these chemokines to allergic outcomes from infancy to 16 years of age. Furthermore, we ascertained the relationship between these chemokines and previously described clusters of allergic diseases derived using machine learning in this cohort.\(^14-17\)

We hypothesized that levels of the allergy-related chemokines will precede the development of different allergic phenotypes throughout childhood.

2 | METHODS

Details on the materials, methods, definitions of variables and statistical approach may be found in the Supplementary Appendix. Briefly, 905 plasma samples originating from the time of birth (cord blood, \(n = 376\)), 1 year (\(n = 195\)) and 8 years (\(n = 334\)) from the Manchester Asthma and Allergy Study (MAAS) were analysed for their chemokine content (Figure S1). Plasma levels of CCL18 were measured using an in-house DuoSet ELISA kit (R & D Systems), and an in-house multiplex bead assay was set up for the analysis of circulating CCL17, CCL22, CXCL10 and CXCL11.

The chemokine levels were thereafter associated with asthma and allergic sensitization, and CCL18 levels were additionally related to multivariable outcomes. To study whether chemokine levels predicted asthma or allergic sensitization, binomial logistic regression analyses were performed on natural log-transformed chemokine data. Longitudinal analyses were performed using generalized estimating equations (GEE). Population-averaged GEE models were developed to investigate whether the effect of natural log-transformed chemokine levels on the development of asthma or sensitization changed over time. All models were adjusted for parental atopy, parental smoking and gender. Resulting coefficients represent the increased/decreased odds of the respective outcome per log-unit increase in chemokine levels.

KEYWORDS

allergy, asthma, CCL18, chemokine, CXCL10, CXCL11, sensitization

CXCL11 also associated with the development of both outcomes, with differential temporal effects.

Key Message

Chemokines are highly involved in the development of allergic disease, by promoting recruitment to the allergic reaction site. While previous studies have shown associations of childhood chemokine levels with the development of allergic manifestations, we were in this study able to show longitudinal impact of chemokine levels in infancy and childhood on the development of sensitization and asthma both contemporaneously and later in life. This suggests chemokines as important biomarkers for allergic disease, which could potentially be useful in a clinical setting for predicting development of sensitization and asthma.
Analyses were conducted in GraphPad Prism 8, IBM SPSS Statistics version 25 and Stata 15 software.

3 | RESULTS

3.1 | Kinetics of circulating chemokines

The plasma measurements revealed distinctive expression patterns for the five chemokines (Figure 1). The Th2-associated chemokine CCL17 displayed significantly lower levels at 1 and 8 years of age, compared to at birth (Figure 1A). In contrast, the Th2-associated chemokine CCL22 revealed higher concentrations at age 8 compared to earlier in life (Figure 1B). For the Th2/Treg-associated chemokine CCL18 and the Th1-associated chemokine CXCL10, significantly higher levels were evident at 1 and 8 years of age compared to at birth (Figure 1C and D). However, the expression was significantly lower at age 8 than at age 1 for both chemokines. The Th1-associated chemokine CXCL11 showed significantly higher levels at age 8 compared to the earlier time points (Figure 1E).

3.2 | CXCL10, CXCL11 and CCL18 levels associate with asthma and sensitization

As the investigated chemokines have previously been related to allergy development, we performed cross-sectional analyses in relation to the outcomes of asthma (Figure 2 and S2) and sensitization (Figure 3 and S3) in childhood and adolescence. Overviews of significant differences of chemokine levels in relation to allergy outcomes are shown in Figures 2A and 3A for asthma and sensitization, respectively.

3.2.1 | Asthma

CXCL10 levels were significantly increased at 1 year of age in children with asthma at the same age (Figure S2A). Furthermore, children with asthma at 8 and 11 years of ages exhibited elevated CXCL10 levels at age 8 (Figure 2B, Figure S2B). In contrast, CXCL11 was significantly decreased in cord blood of children having asthma at age 16 (Figure S2C). For CCL18, higher levels at age 8 associated with asthma at 8 and 16 years of ages (Figure 2C, Figure S2D).

3.2.2 | Sensitization

CXCL10 levels in cord blood were significantly lower than in non-sensitized children at 1 and 16 years of ages (Figure S3A, Figure 3A). Similarly, CXCL11 levels at 1 year and at birth were significantly elevated in non-sensitized children at 1 and 16 years of age, respectively (Figure S3B and C). Children who were sensitized at 1, 8, 11 and 16 years of ages consistently displayed significantly elevated concentrations of CCL18 at 1 and/or 8 years compared to
non-sensitized children (Figure 3C, Figure S4A–C). Increased levels of the Th2-associated chemokine CCL17 at birth associated with sensitization at age 8 (Figure S4D).

3.3 | CXCL10, CXCL11 and CCL18 predict asthma and sensitization

As some of the chemokines indeed associated with the development of asthma and sensitization later in childhood, we tested the ability of the chemokine levels to predict asthma (Figure 4A) and sensitization (Figure 4B) later in childhood and adolescence using binomial logistic regression models.

3.3.1 | Asthma

Having higher CXCL11 levels at birth constituted lower odds of being asthmatic at age 16 (OR = 0.4, 95% CI 0.2–0.8, \( p = .012 \)). Furthermore, higher CCL18 levels at 8 years of age markedly increased the odds of being asthmatic at 8 (OR = 3.8, 95% CI 1.5–9.8, \( p = .006 \)) and 16 years (OR = 5.3, 95% CI 1.7–16.1, \( p = .003 \)) of ages.

3.3.2 | Sensitization

Presenting with elevated CCL18 levels at age 8 posed a three times or higher odds ratio for developing sensitization at 8 (OR = 3.3, 95% CI 1.5–7.1, \( p = .002 \)), 11 (OR = 3.0, 95% CI 1.3–6.7, \( p = .008 \)) and 16 years (OR = 4.2, 95% CI 1.7–10.5, \( p = .002 \)) of ages. In contrast, having high levels of CXCL10 at age 8 seemed protective against becoming sensitized at age 11 (OR = 0.4, 95% CI 0.2–0.8, \( p = .012 \)).

3.4 | Association between CCL18 levels and the development of asthma and sensitization

Proceeding with the chemokines showing the strongest consistent associations cross-sectionally, we set up GEE models studying each chemokine at each age separately in relation to various intervals of asthma and sensitization development to study longitudinal relationships over time. These models take into account correlations within individuals, and as the data are not independent over time, this provides an advantage of running both the GEE and logistic regression models. Consistent longitudinal patterns were only revealed for circulating levels of CCL18 at ages 1 and 8 (Figure 5).

3.4.1 | Asthma

In a longitudinal model including information on asthma from four time points (ages 5, 8, 11 and 16), we observed a significant association between increasing CCL18 levels at 1 year of age and the higher risk of asthma from early school age to adolescence (OR = 2.9, 95% CI 1.1–7.6, \( p = .028 \)). Similarly, higher CCL18 levels at 1 (OR = 3.5, 95% CI 1.3–9.8, \( p = .01 \)) and 8 years (OR = 3.0, 95% CI 1.6–5.9, \( p = .001 \))
of ages were associated with an increased risk of asthma between 8 and 16 years of ages.

3.4.2 Sensitization

In a longitudinal model including information on SPTs from five time points (3–16 years of ages), the odds of becoming sensitized increased significantly with increased CCL18 concentrations at age 1 (OR = 3.1, 95% CI 1.2–8.3, $p = .022$). Similarly, the odds ratios for developing sensitization between the 8 and 16 years of ages increased significantly with increasing CCL18 levels at 1 (OR = 3.5, 95% CI 1.3–9.9, $p = .018$) and 8 years (OR = 3.0, 95% CI 1.5–5.9, $p = .002$) of ages.

3.5 Association of CCL18 levels with clusters of allergic diseases

As we previously have derived clusters of allergic sensitization, allergic diseases and asthma exacerbations from children in the MAAS cohort using machine learning, we sought to study the
The investigated clusters. 

Age 8 compared to non-wheezers (Figure 6D).

Compared to children who were sensitized to a lesser degree (Figure 6B).

With predominant grass and tree sensitization, and as a trend compared to children sensitized towards multiple allergens as compared to children who did not present with previous eczema or recurrent wheeze (Figure 6C).

In the eczema only and the atopic march clusters compared to the investigated clusters.

In this study, we show that the levels of the chemokines CCL18, CXCL10, and CXCL11 in early life and childhood may predict outcomes of allergic disease later in childhood and adolescence.

The main finding was that the dually Th2/Treg-regulated chemokine CCL18 predicted the development of both asthma and sensitization, with consistent effects over time. This corroborates our previous findings of elevated CCL18 levels in infancy of children developing eczema and recurrent wheeze. Being constitutively expressed in the lung and lymphoid tissues during homeostatic conditions by induction of IL-4, IL-13 and IL-10, CCL18 exhibits both chemotactic and immunoregulatory properties. It promotes tolerogenic differentiation of dendritic cells, which in turn may polarize T cells into Tregs, and may polarize memory T cells into Foxp3+ T cells in vitro.

In allergic subjects, however, the tolerogenic effects of CCL18 are seemingly abrogated, despite being upregulated in allergic conditions such as atopic dermatitis and asthma. Described being due to less efficient binding of the protein on immune cells, this possibly could partly explain the loss of tolerance in allergic individuals.

Furthermore, CCL18 induces production of collagen in both the skin and the lung, implying a role in remodelling of the airways typically seen in asthmatic subjects. As alveolar macrophages are the main producers of CCL18 in the lung, where its expression is constitutive, it is tempting to speculate that these levels are augmented in asthmatic individuals owing to dysregulation of these cells. However, as our measurements were performed in plasma samples, and CCL18 may originate from one of many bodily sources, we cannot draw conclusions on tissue-specific effects of the observed elevation without performing functional studies. Furthermore, whether heightened CCL18 responses in asthmatic and sensitized children constitute causative mechanisms of allergy induction, or compensatory immune dampening responses, remains to be elucidated. We further examined chemokine expression within allergy clusters previously derived from our cohort. Indeed, CCL18 levels at age 8 were higher in the multiple early sensitization cluster compared to non-atopic subjects (Figure 6A). In relation to CRD sensitization patterns, circulating levels of CCL18 at age 8 were elevated in individuals sensitized towards multiple allergens as compared to children with predominant grass and tree sensitization, and as a trend compared to children who were sensitized to a lesser degree (Figure 6B).

There was a trend towards higher levels of CCL18 at age 8 both in the eczema only and the atopic march clusters compared to the cluster consisting of healthy children (Figure 6C).

Associating chemokine levels with the developmental pattern of asthma exacerbations in the first 8 years of life, children presenting with exacerbations showed significantly higher levels of CCL18 at age 8 compared to non-wheezers (Figure 6D).

None of the other chemokines revealed any differences between the investigated clusters.

4 | DISCUSSION

In this study, we show that the levels of the chemokines CCL18, CXCL10 and CXCL11 in early life and childhood may predict outcomes of allergic disease later in childhood and adolescence.

The main finding was that the dually Th2/Treg-regulated chemokine CCL18 predicted the development of both asthma and sensitization, with consistent effects over time. This corroborates our previous findings of elevated CCL18 levels in infancy of children developing eczema and recurrent wheeze. Being constitutively expressed in the lung and lymphoid tissues during homeostatic conditions by induction of IL-4, IL-13 and IL-10, CCL18 exhibits both chemotactic and immunoregulatory properties. It promotes tolerogenic differentiation of dendritic cells, which in turn may polarize T cells into Tregs, and may polarize memory T cells into Foxp3+ T cells in vitro.

In allergic subjects, however, the tolerogenic effects of CCL18 are seemingly abrogated, despite being upregulated in allergic conditions such as atopic dermatitis and asthma. Described being due to less efficient binding of the protein on immune cells, this possibly could partly explain the loss of tolerance in allergic individuals.

Furthermore, CCL18 induces production of collagen in both the skin and the lung, implying a role in remodelling of the airways typically seen in asthmatic subjects. As alveolar macrophages are the main producers of CCL18 in the lung, where its expression is constitutive, it is tempting to speculate that these levels are augmented in asthmatic individuals owing to dysregulation of these cells. HUOMAN ET AL.

lessened in sensitized children, diminished neonatal Th1 responses seemingly pave way for the development of sensitization in these children. Additionally, reduced cord blood CXCL11 levels associated with asthma at age 16 and translated into a predicted lower risk with high CXCL11 levels at birth, supporting previous results where children with the highest quartile CXCL11 levels at birth did not become sensitized throughout the first 2 years of life. No long-term effects of CXCL10 and CXCL11 on allergy development could be demonstrated in this study. Possibly, the function of Th1 cells, and their expression of IFN-γ, may become attenuated due to immunoregulatory effects of the highly expressed CCL18 on Tregs, although the findings may also constitute altered patterns of expression in allergic conditions. Collectively, this indicates that although these chemokines are induced by the same cytokine, downstream effects seem to be differentially regulated both in terms of allergy outcome and how levels reflect temporal development of disease.

There are both limitations and strengths to the present study. We evaluated circulating chemokine levels but did not have the opportunity to evaluate functional aspects of the same mediators in different tissues. This would have added mechanistic insights into the findings presented here. Also, the generalizability of these data may be limited, as children in the cohort originate from the Greater Manchester region, with rather homogenous populations. There were differences in sample size in the different age groups, originating from losses to follow-up over time, which may have limited the power of our analyses. However, as few studies have surveyed circulating chemokines at this magnitude, we believe that the substantial sample size still is a strength of this study. Furthermore, the apparent difference in parental atopy and asthma between included and excluded individuals is most probably by chance, as all children with available plasma samples were included for chemokine analysis. This was additionally taken into account by including these variables as co-variates in our models. The consistency of the methodologies used compared to previous studies provides another advantage. Moreover, by performing both cross-sectional logistic regression and longitudinal GEE models we have taken into account different temporal perspectives throughout childhood, which is a strength of this study.

To our knowledge, this is the first study to show that childhood circulating CCL18 levels may affect allergy-related outcomes longitudinally until adolescence. Further studies would, however, need to confirm the importance of CCL18, as well as CXCL10 and CXCL11, in the prediction of long-term development of allergic manifestations in a clinical setting. Possibly, circulating chemokine levels early in life could be used as biomarkers for the prediction of allergic disease and thereby contribute to timely preventive interventions and/or treatments.

In conclusion, we have shown that the elevated levels of CCL18 throughout childhood precede the development of asthma and sensitization, findings that remained solid longitudinally. The Th1-associated chemokines CXCL10 and CXCL11 also predicted development of sensitization and asthma, with differential regulation at different time points in life. This motivates further investigations of chemokines as biomarkers for allergy development, with putative clinical utility in the prediction of allergic outcomes.
ACKNOWLEDGMENTS

We would like to thank Anne-Marie Fornander for her outstanding technical assistance on the chemokine analyses, and Carolina Gunhardsson for her efforts with the CCL18 ELISA.
