Fully-Functional Static and Dynamic Succinct Trees *

Gonzalo Navarro† Kunihiko Sadakane‡

Abstract

We propose new succinct representations of ordinal trees, which have been studied extensively. It is known that any \( n \)-node static tree can be represented in \( 2^n + o(n) \) bits and a number of operations on the tree can be supported in constant time under the word-RAM model. However the data structures are complicated and difficult to dynamize. We propose a simple and flexible data structure, called the range min-max tree, that reduces the large number of relevant tree operations considered in the literature to a few primitives that are carried out in constant time on sufficiently small trees. The result is extended to trees of arbitrary size, achieving \( 2^n + O(n/\text{polylog}(n)) \) bits of space, which is optimal for some operations. The redundancy is significantly lower than any previous proposal. For the dynamic case, where insertion/deletion of nodes is allowed, the existing data structures support very limited operations. Our data structure builds on the range min-max tree to achieve \( 2^n + O(n/\log n) \) bits of space and \( O(\log n) \) time for all the operations. We also propose an improved data structure using \( 2^n + O(\log n \log \log n/\log n) \) bits and improving the time to the optimal \( O(\log n/\log \log n) \) for most operations. We extend our support to forests, where whole subtrees can be attached to or detached from others, in time \( O(\log^{1+\epsilon} n) \) for any \( \epsilon > 0 \).

Our techniques are of independent interest. An immediate derivation gives improved solution to range minimum/maximum queries where consecutive elements differ by \( \pm 1 \), achieving \( O(n + n/\text{polylog}(n)) \) bits of space. A second one stores an array of numbers supporting operations sum and search and limited updates, in optimal time \( O(\log n/\log \log n) \). A third one allows representing dynamic bitmaps and sequences supporting rank/select and indels, within zero-order entropy bounds and optimal time \( O(\log n/\log \log n) \) for all operations on bitmaps and polylog-sized alphabets, and \( O(\log n \log \sigma/(\log \log n)^2) \) on larger alphabet sizes \( \sigma \). This improves upon the best existing bounds for entropy-bounded storage of dynamic sequences, compressed full-text self-indexes, and compressed-space construction of the Burrows-Wheeler transform.

1 Introduction

Trees are one of the most fundamental data structures, needless to say. A classical representation of a tree with \( n \) nodes uses \( O(n) \) pointers or words. Because each pointer must distinguish all the nodes, it requires \( \log n \) bits\(^1\) in the worst case. Therefore the tree occupies \( \Theta(n \log n) \) bits. This causes a space problem for storing a large set of items in a tree. Much research has been devoted to

reducing the space to represent static trees \[26, 33, 34, 36, 19, 20, 6, 12, 9, 10, 28, 24, 3, 21, 47, 27, 11\] and dynamic trees \[35, 45, 8, 1\], achieving so-called succinct data structures for trees.

A succinct data structure stores objects using space close to the information-theoretic lower bound, while simultaneously supporting a number of primitive operations on the objects in constant time. Here the information-theoretic lower bound for storing an object from a universe with cardinality \(L\) is \(\log L\) bits because in the worst case this number of bits is necessary to distinguish any two objects.

In this paper we are interested in ordinal trees, in which the children of a node are ordered. The information-theoretic lower bound for representing an ordinal tree with \(n\) nodes is \(2n - \Theta(\log n)\) bits because there exist \((2^n - 1)/(2n - 1) = 2^n/\Theta(n^2)\) such trees \[33\]. The size of a succinct data structure storing an object from the universe is typically \((1 + o(1))\log L\) bits. We assume that the computation model is the word RAM with word length \(\Theta(\log n)\) in which arithmetic and logical operations on \(\Theta(\log n)\)-bit integers and \(\Theta(\log n)\)-bit memory accesses can be done in constant time.

Basically there exist three types of succinct representations of ordinal trees: the balanced parentheses sequence (BP) \[26, 33\], the level-order unary degree sequence (LOUDS) \[26, 10\], and the depth-first unary degree sequence (DFUDS) \[6, 27\]. An example of them is shown in Figure 1. LOUDS is a simple representation, but it lacks many basic operations, such as the subtree size of a given node. Both BP and DFUDS build on a sequence of balanced parentheses, the former using the intuitive depth-first-search representation and the latter using a more sophisticated one. The advantage of DFUDS is that it supports a more complete set of operations by simple primitives, most notably going to the \(i\)-th child of a node in constant time. In this paper we focus on the BP representation, and achieve constant time for a large set of operations, including all those handled with DFUDS. Moreover, as we manipulate a sequence of balanced parentheses, our data structure can be used to implement a DFUDS representation as well.

1.1 Our contributions

We propose new succinct data structures for ordinal trees encoded with balanced parentheses, in both static and dynamic scenarios.

**Static succinct trees.** For the static case we obtain the following result.

**Theorem 1** For any ordinal tree with \(n\) nodes, all operations in Table 1 except insert and delete are carried out in constant time \(O(c)\) with a data structure using \(2n + O(n/\log^c n)\) bits of space on a \(\Theta(\log n)\)-bit word RAM, for any constant \(c > 0\). The data structure can be constructed from the balanced parentheses sequence of the tree, in \(O(n)\) time using \(O(n)\) bits of space.

The space complexity of our data structures significantly improves upon the lower-order term achieved in previous representations. For example, the extra data structure for level, ancestors requires \(O(n \log \log n / \sqrt{\log n})\) bits \[36\], or \(O(n(\log \log n)^2 / \log n)\) bits \[27\], and that for child requires \(O(n/(\log \log n)^2)\) bits \[28\]. Ours requires \(O(n/\log^c n)\) bits for all of the operations. We show in the Conclusions that this redundancy is optimal for some operations.

The simplicity and space-efficiency of our data structures stem from the fact that any query operation in Table 1 is reduced to a few basic operations on a bit vector, which can be efficiently

---

\(^2\)This data structure is for DFUDS, but the same technique can be also applied to BP.
solved by a range min-max tree. This approach is different from previous studies in which each operation needs distinct auxiliary data structures. Therefore their total space is the summation of all the data structures. For example, the first succinct representation of BP [33] supported only findclose, findopen, and enclose (and other easy operations) and each operation used different data structures. Later, many further operations such as lmost_leaf [34], lca [17], degree [9], child and child_rank [28], level_ancestor [36], were added to this representation by using other types of data structures for each. There exists another elegant data structure for BP supporting findclose, findopen, and enclose [19]. This reduces the size of the data structure for these basic operations, but still has to add extra auxiliary data structures for other operations.

**Dynamic succinct trees.** Our approach is suitable for the dynamic maintenance of trees. Former approaches in the static case use two-level data structures to reduce the size, which causes difficulties in the dynamic case. On the other hand, our approach using the range min-max tree is easily applied in this scenario, resulting in simple and efficient dynamic data structures. This is illustrated by the fact that all the operations are supported. The following theorem summarizes our results.

**Theorem 2** On a $\Theta(\log n)$-bit word RAM, all operations on a dynamic ordinal tree with $n$ nodes can be carried out within the worst-case complexities given in Table 2 using a data structure that requires $2n + O(n\log \log n / \log n)$ bits. Alternatively, the operations of the table can be carried out in $O(\log n)$ time using $2n + O(n / \log n)$ bits of space.

Note we achieve time complexity $O(\log n / \log \log n)$ for most operations, including insert and delete, if we solve degree, child, and child_rank naively. Otherwise we can achieve $O(\log n)$ complexity for these, yet also for insert and delete. The time complexity $O(\log n / \log \log n)$ is optimal: Chan et al. [8, Thm. 5.2] showed that just supporting the most basic operations of Table 1 (findopen, findclose, and enclose, as we will see) plus insert and delete, requires this time even in the amortized sense, by a reduction from Fredman and Saks’s lower bounds on rank queries [17].

Moreover, we are able to attach and detach whole subtrees, in time $O(\log^{1+\epsilon} n)$ for any constant $\epsilon > 0$ (see Section 2.3 for the precise details). These operations had never been considered before in succinct tree representations.

**Byproducts.** Our techniques are of more general interest. A subset of our data structure is able to solve the well-known “range minimum query” problem [4]. In the important case where consecutive elements differ by $\pm 1$, we improve upon the best current space redundancy of $O(n \log \log n / \log n)$ bits [14].

**Corollary 1** Let $E[0,n-1]$ be an array of numbers with the property that $E[i] - E[i-1] \in \{-1, +1\}$ for $0 < i < n$, encoded as a bit vector $P[0,n-1]$ such that $P[i] = 1$ if $E[i] - E[i-1] = +1$ and $P[i] = 0$ otherwise. Then, in a RAM machine we can preprocess $P$ in $O(n)$ time and $O(n)$ bits such that range maximum/minimum queries are answered in constant $O(c)$ time and $O(n / \log^c n)$ extra bits on top of $P$.

---

3In the conference version of this paper [49] we erroneously affirm we can obtain $O(\log n / \log \log n)$ for all these operations, as well as level_ancestor, level_next/level_prev, and level_lmost/level_rmost, for which we can actually obtain only $O(\log n)$. 

3
Another direct application, to the representation of a dynamic array of numbers, yields an improvement to the best current alternative \[29\] by a \( \Theta(\log \log n) \) time factor. If the updates are limited, further operations \textit{sum} (that gives the sum of the numbers up to some position) and \textit{search} (that finds the position where a given sum is exceeded) can be supported, and our complexity matches the lower bounds for \textit{searchable partial sums} by Pătraşcu and Demaine \[40\] (if the updates are not limited one can still use previous results \[29\], which are optimal in that general case). We present our result in a slightly more general form.

**Lemma 1** A sequence of \( n \) variable-length constant-time self-delimiting\footnote{This means that one can distinguish the first code \( x_i \) from a bit stream \( x_i \alpha \) in constant time.} bit codes \( x_1 \ldots x_n \), where \(|x_i| = O(\log n)\), can be stored within \((\sum |x_i|)(1 + o(1))\) bits of space, so that we can (i) compute any sequence of codes \( x_i, \ldots, x_j \), (ii) update any code \( x_i \leftarrow y \), (iii) insert a new code \( z \) between any pair of codes, and (iv) delete any code \( x_d \) from the sequence, all in \( O(\log n/\log \log n) \) time (plus \( j - i \) for (i)). Moreover, let \( f(x) \) be a nonnegative integer function computable in constant time from the codes. If the updates and indels are such that \(|f(y) - f(x_i)|, f(z), f(x_d) = O(\log n)\), then we can also support operations \( \text{sum}(i) = \sum_{j=1}^{i} f(x_i) \) and \( \text{search}(s) = \max\{i, \text{sum}(i) \leq s\} \) within the same time.

For example we can store \( n \) numbers \( 0 \leq a_i < 2^k \) within \( kn + o(kn) \) bits, by using their \( k \)-bit binary representation \( [a_i]_2 \) as the code, and their numeric value as \( f([a_i]_2) = a_i \), so that we support \textit{sum} and \textit{search} on the sequence of numbers. If the numbers are very different in magnitude we can \( \delta \)-encode them to achieve \((\sum \log a_i)(1 + o(1)) + O(n)\) bits of space. We can also store bits, seen as 1-bit codes, in \( n + o(n) \) bits and and carry out \textit{sum} = \textit{rank} and \textit{search} = \textit{select}, insertions and deletions, in \( O(\log n/\log \log n) \) time.

A further application of our results to the compressed representation of sequences achieves a result summarized in the next theorem.

**Theorem 3** Any sequence \( S[0, n-1] \) over alphabet \([1, \sigma]\) can be stored in \( nH_0(S) + O(n \log \sigma / \log^\epsilon n + \sigma \log^2 n) \) bits of space, for any constant \( 0 < \epsilon < 1 \), and support the operations \textit{rank}, \textit{select}, \textit{insert}, and \textit{delete}, all in time \( O\left(\frac{\log n}{\log \log n} \left(1 + \frac{\log \sigma}{\log \log n}\right)\right)\). For polylogarithmic-sized alphabets, this is the optimal \( O(\log n/\log \log n); \) otherwise it is \( O\left(\frac{\log n \log \sigma}{\log \log n^2}\right)\).

This time complexity slashes the the best current result \[22\] by a \( \Theta(\log \log n) \) factor. The optimality of the polylogarithmic case stems again from Fredman and Saks’ lower bound on \textit{rank} on dynamic bitmaps \[17\]. This result has immediate applications to building compressed indexes for text, building the Burrows-Wheeler transform within compressed space, and so on.

### 1.2 Organization of the paper

In Section 2 we review basic data structures used in this paper. Section 3 describes the main ideas for our new data structures for ordinal trees. Sections 4 and 5 describe the static construction. In Sections 6 and 7 we give two data structures for dynamic ordinal trees. In Section 8 we derive our new results on compressed sequences and applications. In Section 9 we conclude and give future work directions.
Table 1: Operations supported by our data structure. The time complexities are for the dynamic case; in the static case all operations are performed in constant time. The first group is composed of basic operations, used to implement the others, but which could have other uses.

| operation                  | description                                                                 | time complexity     |
|----------------------------|-----------------------------------------------------------------------------|---------------------|
| `inspect(i)`               | $P[i]$                                                                      | $\mathcal{O}(\log n / \log \log n)$ |
| `findclose(i)/findopen(i)` | position of parenthesis matching $P[i]$                                     | $\mathcal{O}(\log n / \log \log n)$ |
| `enclose(i)`               | position of tightest open parent. enclosing $i$                           | $\mathcal{O}(\log n / \log \log n)$ |
| `rank\{_\}(i)/rank\{\}_(i)`| number of open/close parentheses in $P[0, i]$                             | $\mathcal{O}(\log n / \log \log n)$ |
| `select\{\}(i)/select\{\}_i`| position of $i$-th open/close parenthesis                                | $\mathcal{O}(\log n / \log \log n)$ |
| `rmqi(i,j)/RMQi(i,j)`      | position of min/max excess value in range $[i, j]$                        | $\mathcal{O}(\log n / \log \log n)$ |
| `pre_rank(i)/post_rank(i)` | preorder/postorder rank of node $i$                                       | $\mathcal{O}(\log n / \log \log n)$ |
| `pre_order(i)/post_order(i)`| the node with preorder/postorder $i$                                       | $\mathcal{O}(\log n / \log \log n)$ |
| `isleaf(i)`                | whether $P[i]$ is a leaf                                                   | $\mathcal{O}(\log n / \log \log n)$ |
| `isancestor(i,j)`          | whether $i$ is an ancestor of $j$                                         | $\mathcal{O}(\log n / \log \log n)$ |
| `depth(i)`                 | depth of node $i$                                                          | $\mathcal{O}(\log n / \log \log n)$ |
| `parent(i)`                | parent of node $i$                                                         | $\mathcal{O}(\log n / \log \log n)$ |
| `first_child(i)/last_child(i)`| first/last child of node $i$                                              | $\mathcal{O}(\log n / \log \log n)$ |
| `next_sibling(i)/prev_sibling(i)` | next/previous sibling of node $i$                                       | $\mathcal{O}(\log n / \log \log n)$ |
| `subtree_size(i)`          | number of nodes in the subtree of node $i$                               | $\mathcal{O}(\log n / \log \log n)$ |
| `level_ancestor(i,d)`      | ancestor $j$ of $i$ s.t. $\text{depth}(j) = \text{depth}(i) - d$         | $\mathcal{O}(\log n)$ |
| `level_next(i)/level_prev(i)`  | next/previous node of $i$ in BFS order                                   | $\mathcal{O}(\log n)$ |
| `level_last(d)/level_rmost(d)` | leftmost/rightmost node with depth $d$                              | $\mathcal{O}(\log n)$ |
| `lca(i,j)`                 | the lowest common ancestor of two nodes $i, j$                           | $\mathcal{O}(\log n / \log \log n)$ |
| `deepest_node(i)`          | the (first) deepest node in the subtree of $i$                           | $\mathcal{O}(\log n / \log \log n)$ |
| `height(i)`                | the height of $i$ (distance to its deepest node)                         | $\mathcal{O}(\log n / \log \log n)$ |
| `degree(i)`                | $q = $ number of children of node $i$                                     | $\mathcal{O}(q \log n / \log \log n)$ | $\mathcal{O}(\log n)$ |
| `child(i,q)`               | $q$-th child of node $i$                                                  | $\mathcal{O}(q \log n / \log \log n)$ |
| `child_rank(i)`            | $q = $ number of siblings to the left of node $i$                        | $\mathcal{O}(q \log n / \log \log n)$ |
| `in_rank(i)`               | inorder of node $i$                                                       | $\mathcal{O}(\log n / \log \log n)$ |
| `in_select(i)`             | node with inorder $i$                                                     | $\mathcal{O}(\log n / \log \log n)$ |
| `leaf_rank(i)`             | number of leaves to the left of leaf $i$                                  | $\mathcal{O}(\log n / \log \log n)$ |
| `leaf_select(i)`           | $i$-th leaf                                                                | $\mathcal{O}(\log n / \log \log n)$ |
| `lmost_leaf(i)/rmost_leaf(i)`  | leftmost/rightmost leaf of node $i$                                      | $\mathcal{O}(\log n / \log \log n)$ |
| `insert(i,j)`              | insert node given by matching parent. at $i$ and $j$                    | $\mathcal{O}(\log n / \log \log n)$ |
| `delete(i)`                | delete node $i$                                                           | $\mathcal{O}(\log n / \log \log n)$ | $\mathcal{O}(\log n)$ |
2 Preliminaries

Here we describe the balanced parentheses sequence and basic data structures used in this paper.

2.1 Succinct data structures for rank/select

Consider a bit string $S[0, n-1]$ of length $n$. We define rank and select for $S$ as follows. $\text{rank}_c(S, i)$ is the number of occurrences $c \in \{0, 1\}$ in $S[0, i]$, and $\text{select}_c(S, i)$ is the position of the $i$-th occurrence of $c$ in $S$. Note that $\text{rank}_c(S, \text{select}_c(S, i)) = i$ and $\text{select}_c(S, \text{rank}_c(S, i)) \leq i$.

There exist many succinct data structures for rank/select \cite{26, 32, 44}. A basic one uses $n + o(n)$ bits and supports rank/select in constant time on the word RAM with word length $O(\log n)$. The space can be reduced if the number of 1’s is small. For a string with $m$ 1’s, there exists a data structure for constant-time rank/select using $nH_0(S) + O(n \log \log n / \log n)$, where $H_0(S) = \frac{n}{m} \log \frac{n}{m} + \frac{n-m}{m} \log \frac{n}{n-m} = m \log \frac{n}{m} + O(m)$ is called the empirical zero-order entropy of the sequence. The space overhead on top of the entropy has been recently reduced \cite{42} to $O(n t^4 / \log^4 n + n^{3/4})$ bits, while supporting rank and select in $O(t)$ time. This can be built in linear worst-case time.\footnote{They use a predecessor structure by Pătraşcu and Thorup \cite{41}, more precisely their result achieving time $O(\frac{n \log \log n}{\log n})$, which is a simple modification of van Emde Boas’ data structure.}

A crucial technique for succinct data structures is table lookup. For small-size problems we construct a table which stores answers for all possible sequences and queries. For example, for rank and select, we use a table storing all answers for all 0,1 patterns of length $\frac{1}{2} \log n$. Because there exist only $2^{\frac{1}{2} \log n} = \sqrt{n}$ different patterns, we can store all answers in a universal table (i.e., not depending on the bit sequence) that uses $\sqrt{n} \cdot \text{polylog}(n) = o(n / \text{polylog}(n))$ bits, which can be accessed in constant time on a word RAM with word length $\Theta(\log n)$.

The definition of rank and select on bitmaps generalizes to arbitrary sequences over an integer alphabet $[1, \sigma]$, as well as the definition of zero-order empirical entropy of sequences, to $H_0(S) = \sum_{1 \leq c \leq \sigma} \frac{n_c}{n} \log \frac{n}{n_c}$, where $c$ occurs $n_c$ times in $S$. A compressed representation of general sequences that supports rank/select is achieved through a structure called a wavelet tree \cite{23}. This is a complete binary tree that partitions the alphabet $[1, \sigma]$ into contiguous halves at each node. The node then stores a bitmap telling which branch did each letter go. The tree has height $\lceil \log \sigma \rceil$, and it reduces rank and select operations to analogous operations on its bitmap in a root-to-leaf or leaf-to-root traversal. If the bitmaps are represented within their zero-order entropy, the total space adds up to $nH_0(S) + o(n \log \sigma)$ and the operations are supported in $O(\log \sigma)$ time. This can be improved to $O(\lceil \log \frac{\sigma}{\log \log n} \rceil)$, while maintaining the same asymptotic space, by using a multiary

Figure 1: Succinct representations of trees.
wavelet tree of arity $\Theta(\sqrt{\log n})$, and replacing the bitmaps by sequences over small alphabets, which still can answer rank/select in constant time [13].

2.2 Succinct tree representations

A rooted ordered tree $T$, or ordinal tree, with $n$ nodes is represented by a string $P[0, 2n - 1]$ of balanced parentheses of length $2n$. A node is represented by a pair of matching parentheses $[]$ and all subtrees rooted at the node are encoded in order between the matching parentheses (see Figure 1 for an example). A node $v \in T$ is identified with the position $i$ of the open parenthesis $P[i]$ representing the node.

There exist many succinct data structures for ordinal trees. Among them, the ones with maximum functionality [11] support all the operations in Table 1 except insert and delete, in constant time using $2n + O(n \log \log n) / \log \log n$-bit space. Our static data structure supports the same operations and reduces the space to $2n + O(n/polylog(n))$ bits.

2.3 Dynamic succinct trees

We consider insertion and deletion of internal nodes or leaves in ordinal trees. In this setting, there exist no data structures supporting all the operations in Table 1. The data structure of Raman and Rao [45] supports, for binary trees, parent, left and right child, and subtree_size of the current node in the course of traversing the tree in constant time, and updates in $O((\log \log n)^{1+\epsilon})$ time. Note that this data structure assumes that all traversals start from the root. Chan et al. [8] gave a dynamic data structure using $O(n)$ bits and supporting findopen, findclose, enclose, and updates, in $O(\log n / \log \log n)$ time. They also gave another data structure using $O(n)$ bits and supporting findopen, findclose, enclose, lca, leaf_rank, leaf_select, and updates, in $O(\log n)$ time.

Furthermore, we consider the more sophisticated operation (which is simple on classical trees) of attaching a new subtree as the new child of a node, instead of just a leaf. The model is that this new subtree is already represented with our data structures. Both trees are thereafter blended and become a unique tree. Similarly, we can detach any subtree from a given tree so that it becomes an independent entity represented with our data structure. This allows for extremely flexible support of algorithms handling dynamic trees, far away from the limited operations allowed in previous work. This time we have to consider a maximum possible value for $\log n$ (say, $w$, the width of the system-wide pointers). Then we require $2n + O(n \log w / w + \sqrt{2^w})$ bits of space and carry out the queries in time $O(w / \log w)$ or $O(w)$, depending on the tree. Insert or delete takes $O(w^{1+\epsilon})$ for any constant $\epsilon > 0$ if we wish to allow attachment and detachment of subtrees, which then can also be carried out in time $O(w^{1+\epsilon})$.

2.4 Dynamic compressed bitmaps and sequences

Let $B[0, n - 1]$ be a bitmap. We want to support operations rank and select on $B$, as well as operations insert($B$, $i$, $b$), which inserts bit $b$ between $B[i]$ and $B[i + 1]$, and delete($B$, $i$), which deletes position $B[i]$ from $B$. Chan et al. [8] handle all these operations in $O(\log n / \log \log n)$ time (which is optimal [17]) using $O(n)$ bits of space (actually, by reducing the problem to a particular dynamic tree). Mäkinen and Navarro [29] achieve $O(\log n)$ time and $nH_0(B) + O(n \log \log n / \sqrt{\log n})$ bits of space. The results can be generalized to sequences. González and Navarro [22] achieve $nH_0 + O(n \log \sigma / \sqrt{\log n})$ bits of space and $O(\log n(1 + \log \log n / \log \log n))$ time to handle all the operations.
on a sequence over alphabet \([1, \sigma]\). They give several applications to managing dynamic text collections, construction of static compressed indexes within compressed space, and construction of the Burrows-Wheeler transform \([7]\) within compressed space. We improve all these results in this paper, achieving the optimal \(O(\log n/\log \log n)\) on polylog-sized alphabets and reducing the lower-order term in the compressed space by a \(\Theta(\log \log n)\) factor.

3 Fundamental concepts

In this section we give the basic ideas of our ordinal tree representation. In the next sections we build on these to define our static and dynamic representations.

We represent a possibly non-balanced parentheses sequence by a 0,1 vector \(P[0,n-1]\) \((P[i] \in \{0,1\})\). Each opening/closing parenthesis is encoded by \(= 1, \sigma = 0\).

First, we remind that several operations of Table 1 either are trivial in a BP representation, or are easily solved using \(\text{enclose}, \text{findclose}, \text{findopen}, \text{rank}, \text{and select}\)\([33]\). These are:

- \(\text{inspect}(i) = P[i]\) (or \(\text{rank}_1(P, i) - \text{rank}_1(P,i - 1)\) if there is no access to \(P[i]\))
- \(\text{isleaf}(i) = [P[i+1] = 0]\)
- \(\text{isancestor}(i,j) = i \leq j \leq \text{findclose}(P, i)\)
- \(\text{depth}(i) = \text{rank}_1(P, i) - \text{rank}_0(P, i)\)
- \(\text{parent}(i) = \text{enclose}(P, i)\)
- \(\text{pre_rank}(i) = \text{rank}_1(P, i)\)
- \(\text{pre_select}(i) = \text{select}_1(P, i)\)
- \(\text{post_rank}(i) = \text{rank}_0(P, i)\)
- \(\text{post_select}(i) = \text{select}_0(P, i)\)
- \(\text{first_child}(i) = i + 1\) (if \(P[i+1] = 1\), else \(i\) is a leaf)
- \(\text{last_child}(i) = \text{findopen}(P, \text{findclose}(P, i) - 1)\) (if \(P[i+1] = 1\), else \(i\) is a leaf)
- \(\text{next_sibling}(i) = \text{findclose}(i) + 1\) (if \(P[\text{findclose}(i) + 1] = 1\), else \(i\) is the last sibling)
- \(\text{prev_sibling}(i) = \text{findopen}(i - 1)\) (if \(P[i - 1] = 0\), else \(i\) is the first sibling)
- \(\text{subtree_size}(i) = (\text{findclose}(i) - i + 1)/2\)

Hence the above operations will not be considered further in the paper. Let us now focus on a small set of primitives needed to implement most of the other operations. For any function \(g(\cdot)\) on \([0,1]\), we define the following.

**Definition 1** For a 0,1 vector \(P[0,n-1]\) and a function \(g(\cdot)\) on \([0,1]\),

\[
\text{sum}(P, g, i, j) \overset{\text{def}}{=} \sum_{k=i}^{j} g(P[k])
\]

\[
\text{fwd_search}(P, g, i, d) \overset{\text{def}}{=} \min\{j \mid \text{sum}(P, g, i, j) = d\}
\]

\[
\text{bwd_search}(P, g, i, d) \overset{\text{def}}{=} \max\{j \mid \text{sum}(P, g, j, i) = d\}
\]

---

\(\sigma\) As later we will use these constructions to represent arbitrary segments of a balanced sequence.
The following function is particularly important.

**Definition 2** Let $\pi$ be the function such that $\pi(1) = 1, \pi(0) = -1$. Given $P[0, n - 1]$, we define the excess array $E[0, n - 1]$ of $P$ as an integer array such that $E[i] = \text{sum}(P, \pi, 0, i)$.

Note that $E[i]$ stores the difference between the number of opening and closing parentheses in $P[0, i]$. When $P[i]$ is an opening parenthesis, $E[i] = \text{depth}(i)$ is the depth of the corresponding node, and is the depth minus 1 for closing parentheses. We will use $E$ as a conceptual device in our discussions, it will not be stored. Note that, given the form of $\pi$, it holds that $|E[i + 1] - E[i]| = 1$ for all $i$.

The above operations are sufficient to implement the basic navigation on parentheses, as the next lemma shows. Note that the equation for $\text{findclose}$ is well known, and the one for $\text{level\_ancestor}$ has appeared as well [36], but we give proofs for completeness.

**Lemma 2** Let $P$ be a BP sequence encoded by $\{0, 1\}$. Then $\text{findclose}$, $\text{findopen}$, $\text{enclose}$, and $\text{level\_ancestor}$ can be expressed as follows.

\[
\begin{align*}
\text{findclose}(i) &= \text{fwd\_search}(P, \pi, i, 0) \\
\text{findopen}(i) &= \text{bwd\_search}(P, \pi, i, 0) \\
\text{enclose}(i) &= \text{bwd\_search}(P, \pi, i, 2) \\
\text{level\_ancestor}(i, d) &= \text{bwd\_search}(P, \pi, i, d + 1)
\end{align*}
\]

**Proof.** For $\text{findclose}$, let $j > i$ be the position of the closing parenthesis matching the opening parenthesis at $P[i]$. Then $j$ is the smallest index $> i$ such that $E[j] = E[i] - 1 = E[i] - 1$ (because of the node depths). Since by definition $E[k] = E[i - 1] + \text{sum}(P, \pi, i, k)$ for any $k > i$, $j$ is the smallest index $> i$ such that $\text{sum}(P, \pi, i, j) = 0$. This is, by definition, $\text{fwd\_search}(P, \pi, i, 0)$.

For $\text{findopen}$, let $j < i$ be the position of the opening parenthesis matching the closing parenthesis at $P[i]$. Then $j$ is the largest index $< i$ such that $E[j] = E[i]$ (again, because of the node depths). Since by definition $E[k - 1] = E[i] - \text{sum}(P, \pi, k, i)$ for any $k < i$, $j$ is the largest index $< i$ such that $\text{sum}(P, \pi, j, i) = 0$. This is $\text{bwd\_search}(P, \pi, i, 0)$.

For $\text{enclose}$, let $j < i$ be the position of the opening parenthesis that most tightly encloses the opening parenthesis at $P[i]$. Then $j$ is the largest index $< i$ such that $E[j] = E[i] - 2$ (note that now $P[i]$ is an opening parenthesis). Now we reason as for $\text{findopen}$ to get $\text{sum}(P, \pi, j, i) = 2$.

Finally, the proof for $\text{level\_ancestor}$ is similar to that for $\text{enclose}$. Now $j$ is the largest index $< i$ such that $E[j - 1] = E[i] - d - 1$, which is equivalent to $\text{sum}(P, \pi, j, i) = d + 1$.

\[\text{\footnote{Note $E[j] - 1 = E[i]$ could hold at incorrect places, where $P[j]$ is a closing parenthesis.}}\]
Building on the previous ideas, we give a simple data structure to compute \( f\text{wd}\_\text{search}, \ f\text{wd}\_\text{search}, \ \text{sum}, \ \text{rmqi}, \ \text{RMQi}, \ \text{degree}, \ \text{child}, \ \text{and} \ \text{child\_rank} \), for the rest of the paper.

Our data structure for queries on a 0,1 vector \( P \) is basically a search tree in which each leaf corresponds to a range of \( P \), and each node stores the last, maximum, and minimum values of prefix sums for the concatenation of all the ranges up to the subtree rooted at that node.

**Definition 3** A range min-max tree for a vector \( P[0,n-1] \) and a function \( g(\cdot) \) is defined as follows. Let \( [\ell_1,r_1],[\ell_2,r_2],\ldots,[\ell_q,r_q] \) be a partition of \([0,n-1]\) where \( \ell_1 = 0, r_1 = 1 = \ell_{i+1}, r_q = n-1 \). Then the \( i \)-th leftmost leaf of the tree stores the sub-vector \( P[\ell_i,r_i] \), as well as \( e[i] = \text{sum}(P,g,0,r_i), m[i] = e[i-1] + \text{rmqi}(P,g,\ell_i,r_i) \) and \( M[i] = e[i-1] + \text{RMQi}(P,g,\ell_i,r_i) \). Each internal node \( u \) stores in \( e[u]/m[u]/M[u] \) the last/minimum/maximum of the \( e/m/M \) values stored in its child nodes. Thus, the root node stores \( e = \text{sum}(P,g,0,n-1), m = \text{rmqi}(P,g,0,n-1) \) and \( M = \text{RMQi}(P,g,0,n-1) \).

**Example 1** An example of range min-max tree is shown in Figure 2. Here we use \( g = \pi \), and thus the nodes store the minimum/maximum values of array \( E \) in the corresponding interval.

## 4 A simple data structure for polylogarithmic-size trees

Building on the previous ideas, we give a simple data structure to compute \( f\text{wd}\_\text{search}, \ f\text{wd}\_\text{search}, \ \text{sum} \) in constant time for arrays of polylogarithmic size. Then we consider further operations.

Let \( g(\cdot) \) be a function on \( \{0,1\} \) taking values in \( \{1,0,-1\} \). We call such a function \( \pm 1 \) function. Note that there exist only six such functions where \( g(0) \neq g(1) \), which are indeed \( \phi, -\phi, \psi, -\psi, \pi, -\pi \).
Let $w$ be the bit length of the machine word in the RAM model, and $c \geq 1$ any constant. We have a (not necessarily balanced) parentheses vector $P[0, n - 1]$, of moderate size $n \leq N = w^c$. Assume we wish to solve the operations for an arbitrary $\pm 1$ function $g(\cdot)$, and let $G[i]$ denote $\text{sum}(P, g, 0, i)$, analogously to $E[i]$ for $g = \pi$.

Our data structure is a range min-max tree $T_{nM}$ for vector $P$ and function $g(\cdot)$. Let $s = \frac{1}{2}w$. We imaginarily divide vector $P$ into $\lceil n/s \rceil$ chunks of length $s$. These form the partition alluded in Definition 3 $\ell_i = s \cdot (i - 1)$. Thus the values $m[i]$ and $M[i]$ correspond to minima and maxima of $G$ within each chunk, and $e[i] = G[r_i]$.

Furthermore, the tree will be $k$-ary and complete, for $k = \Theta(w/(c \log w))$. Thus the leaves store all the elements of arrays $m$ and $M$. Because it is complete, the tree can be represented just by three integer arrays $e'[0, \mathcal{O}(n/s)], m'[0, \mathcal{O}(n/s)],$ and $M'[0, \mathcal{O}(n/s)]$, like a heap.

Because $-w^c \leq e'[i], m'[i], M'[i] \leq w^c$ for any $i$, arrays $e'$, $m'$ and $M'$ occupy $\frac{k}{k-1} \cdot \frac{n}{s} \cdot \lceil \log(2w^c + 1) \rceil = \mathcal{O}(nc \log w/w)$ bits each. The depth of the tree is $\lceil \log_k (n/s) \rceil = \mathcal{O}(c)$.

The following fact is well known; we reprove it for completeness.

Lemma 4 Any range $[i, j] \subseteq [0, n - 1]$ in $T_{nM}$ is covered by a disjoint union of $\mathcal{O}(ck)$ subranges where the leftmost and rightmost ones may be subranges of leaves of $T_{nM}$, and the others correspond to whole nodes of $T_{nM}$.

Proof. Let $a$ be the smallest value such that $i \leq r_a$ and $b$ be the largest such that $j \geq \ell_b$. Then the range $[i, j]$ is covered by the disjoint union $[i, j] = [i, r_a][\ell_{a+1}, r_{a+1}] \ldots [\ell_b, j]$ (we can discard the special case $a = b$, as in this case we have already one leaf covering $[i, j]$). Then $[i, r_a]$ and $[\ell_b, j]$ are the leftmost and rightmost leaf subranges alluded in the lemma; all the others are whole tree nodes.

It remains to show that we can reexpress this disjoint union using $\mathcal{O}(ck)$ tree nodes. If all the $k$ children of a node are in the range, we replace the $k$ children by the parent node, and continue recursively level by level. Note that if two parent nodes are created in a given level, then all the other intermediate nodes of the same level must be created as well, because the original/created nodes form a range at any level. At the end, there cannot be more than $2k - 2$ nodes at any level, because otherwise $k$ of them would share a single parent and would have been replaced. As there are $c$ levels, the obtained set of nodes covering $[i, j]$ is of size $\mathcal{O}(ck)$.
Example 2 In Figure 3 (where \( s = k = 3 \)), the range \([3, 18]\) is covered by \([3, 5], [6, 8], [9, 17], [18, 18]\). They correspond to nodes \( d, e, f \), and a part of leaf \( k \), respectively.

Computing \( \text{fwd\_search}(P, g, i, d) \) is done as follows (\( \text{bwd\_search} \) is symmetric). First we check if the chunk of \( i \), \([l_k, r_k]\) for \( k = \lfloor i/s \rfloor \), contains \( \text{fwd\_search}(P, g, i, d) \) with a table lookup using vector \( P \), by precomputing a simple universal table of \( 2^8 \log s = \mathcal{O}(\sqrt{2^w \log w}) \) bits\(^8\). If so, we are done. Else, we compute the global target value we seek, \( d' = G[i - 1] + d = e[k] - \text{sum}(P, g, i, r_k) + d \) (again, the sum inside the chunk is done in constant time using table lookup). Now we divide the range \([r_k + 1, n - 1]\) into subranges \( I_1, I_2, \ldots \) represented by range min-max tree nodes \( u_1, u_2, \ldots \) as in Lemma 4 (note these are simply all the right siblings of my parent, all the right siblings of my grandparent, and so on). Then, for each \( I_j \), we check if the target value \( d' \) is between \( m[u_j] \) and \( M[u_j] \), the minimum and maximum values of subrange \( I_j \). Let \( I_k \) be the first \( j \) such that \( m[u_j] \leq d' \leq M[u_j] \), then \( \text{fwd\_search}(P, g, i, d) \) lies within \( I_k \). If \( I_k \) corresponds to an internal tree node, we iteratively find the leftmost child of the node whose range contains \( d' \), until we reach a leaf. Finally, we find the target in the chunk corresponding to the leaf by table lookups, using \( P \) again.

Example 3 In Figure 3, where \( G = E \) and \( g = \pi \), computing \( \text{findclose}(3) = \text{fwd\_search}(P, \pi, 3, 0) = 12 \) can be done as follows. Note this is equivalent to finding the first \( j > 3 \) such that \( E[i] = E[3 - 1] + 0 = 1 \). First examine the node \( [3/s] = 1 \) (labeled \( d \) in the figure). We see that the target 1 does not exist within \( d \) after position 3. Next we examine node \( e \). Since \( m[e] = 3 \) and \( M[e] = 4 \), \( e \) does not contain the answer either. Next we examine the node \( f \). Because \( m[f] = 1 \) and \( M[f] = 3 \), the answer must exist in its subtree. Therefore we scan the children of \( f \) from left to right, and find the leftmost one with \( m[\cdot] \leq 1 \), which is node \( h \). Because node \( h \) is already a leaf, we scan the segment corresponding to it, and find the answer 12.

The sequence of subranges arising in this search corresponds to a leaf-to-leaf path in the range min-max tree, and it contains \( \mathcal{O}(ck) \) ranges according to Lemma 4. We show now how to carry out this search in time \( \mathcal{O}(c) \) rather than \( \mathcal{O}(ck) \).

According to Lemma 4, the \( \mathcal{O}(ck) \) nodes can be partitioned into \( \mathcal{O}(c) \) sequences of sibling nodes. We will manage to carry out the search within each such sequence in \( \mathcal{O}(1) \) time. Assume we have to find the first \( j \geq i \) such that \( m[u_j] \leq d' \leq M[u_j] \), where \( u_1, u_2, \ldots, u_k \) are sibling nodes in \( T_{mM} \). We first check if \( m[u_j] \leq d' \leq M[u_j] \). If so, the answer is \( u_i \). Otherwise, if \( d' < m[u_i] \), the answer is the first \( j > i \) such that \( m[u_j] \leq d' \), and if \( d' > M[u_i] \), the answer is the first \( j > i \) such that \( M[u_j] \geq d' \).

Lemma 5 Let \( u_1, u_2, \ldots \) a sequence of \( T_{mM} \) nodes containing consecutive intervals of \( P \). If \( g(\cdot) \) is a \( \pm 1 \) function and \( d < m[u_1] \), then the first \( j \) such that \( d \in [m[u_j], M[u_j]] \) is the first \( j > 1 \) such that \( d \geq m[u_j] \). Similarly, if \( d > M[u_1] \), then it is the first \( j > 1 \) such that \( d \leq M[u_j] \).

Proof. Since \( g(\cdot) \) is a \( \pm 1 \) function and the intervals are consecutive, \( M[u_j] \geq m[u_{j - 1}] - 1 \) and \( m[u_j] \leq M[u_{j - 1}] + 1 \). Therefore, if \( d \geq m[u_j] \) and \( d < m[u_{j - 1}] \), then \( d < M[u_j] + 1 \), thus \( d \in [m[u_j], M[u_j]] \); and of course \( d \notin [m[u_k], M[u_k]] \) for any \( k < j \) as \( j \) is the first index such that \( d \geq m[u_j] \). The other case is symmetric. \( \square \)

\(^8\)Using integer division and remainder a segment within a chunk can be isolated and padded in constant time.
Thus the problem is reduced to finding the first \( j > i \) such that \( m[j] \leq d' \), among (at most) \( k \) sibling nodes (the case \( M[j] \geq d' \) is symmetric). We build a universal table with all the possible sequences of \( k \) values \( m[\cdot] \) and all possible \( -w^c \leq d' \leq w^c \) values, and for each such sequence and \( d' \) we store the first \( j \) in the sequence such that \( m[j] \leq d' \) (or we store a mark telling that there is no such position in the sequence). Thus the table has \((2w^c+1)^{k+1}\) entries, and \( \log(k+1) \) bits per entry. By choosing the constant of \( k = \Theta(w/(c \log w)) \) so that \( k \leq \frac{w}{2 \log(2w^c+1)} - 1 \), the total space is \( O(\sqrt{2^w \log w}) \) (and the arguments for the table fit in a machine word). With the table, each search for the first node in a sequence of siblings can be done in constant rather than \( O(k) \) time, and hence the overall time is \( O(c) \) rather than \( O(ck) \). Note that we store the \( m'[\cdot] \) values in heap order, and therefore the \( k \) sibling values to input to the table are stored in contiguous memory, thus they can be accessed in constant time. We use an analogous universal table for \( M[\cdot] \).

Finally, the process to solve \( \text{sum}(P,g,i,j) \) in \( O(c) \) time is simple. We descend in the tree up to the leaf \([\ell_k,r_k]\) containing \( j \). We obtain \( \text{sum}(P,g,0,\ell_k-1) = c[k-1] \) and compute the rest, \( \text{sum}(P,g,\ell_k,j) \), in constant time using a universal table we have already introduced. We repeat the process for \( \text{sum}(P,g,0,i-1) \) and then subtract both results.

We have proved the following lemma.

**Lemma 6** In the RAM model with \( w \)-bit word size, for any constant \( c \geq 1 \) and a 0,1 vector \( P \) of length \( n < w^c \), and a \( \pm 1 \) function \( g(\cdot) \), \( \text{find}_{\text{search}}(P,g,i,j) \), \( \text{bwd}_{\text{search}}(P,g,i,j) \), and \( \text{sum}(P,g,i,j) \) can be computed in \( O(c) \) time using the range min-max tree and universal lookup tables that require \( O(\sqrt{2^w \log w}) \) bits.

### 4.1 Supporting range minimum queries

Next we consider how to compute \( \text{rmqi}(P,g,i,j) \) and \( \text{RMQi}(P,g,i,j) \).

**Lemma 7** In the RAM model with \( w \)-bit word size, for any constant \( c \geq 1 \) and a 0,1 vector \( P \) of length \( n < w^c \), and a \( \pm 1 \) function \( g(\cdot) \), \( \text{rmqi}(P,g,i,j) \) and \( \text{RMQi}(P,g,i,j) \) can be computed in \( O(c) \) time using the range min-max tree and universal lookup tables that require \( O(\sqrt{2^w \log w}) \) bits.

**Proof.** Because the algorithm for \( \text{RMQi} \) is analogous to that for \( \text{rmqi} \), we consider only the latter. From Lemma[1] the range \([i,j]\) is covered by a disjoint union of \( O(ck) \) subranges, each corresponding to some node of the range min-max tree. Let \( \mu_1, \mu_2, \ldots \) be the minimum values of the subranges. Then the minimum value in \([i,j]\) is the minimum of them. The minimum values in each subrange are stored in array \( m' \), except for at most two subranges corresponding to leaves of the range min-max tree. The minimum values of such leaf subranges are found by table lookups using \( P \), by precomposing a universal table of \( O(\sqrt{2^w \log w}) \) bits. The minimum value of a subsequence \( \mu_{\ell}, \ldots, \mu_r \) which shares the same parent in the range min-max tree can be also found by table lookups. The size of such universal table is \( O((2w^c+1)^k \log k) = O(\sqrt{2^w}) \) bits (the \( k \) factor is to account for queries that span less than \( k \) values, so we can specify the query length). Hence we find the node containing the minimum value \( \mu \) among \( \mu_1, \mu_2, \ldots \), in \( O(c) \) time. If there is a tie, we choose the leftmost one.

If \( \mu \) corresponds to an internal node of the range min-max tree, we traverse the tree from the node to a leaf having the leftmost minimum value. At each step, we find the leftmost child of the current node having the minimum, in constant time using our precomputed table. We repeat the process from the resulting child, until reaching a leaf. Finally, we find the index of the minimum
value in the leaf, in constant time by a lookup on our universal table for leaves. The overall time complexity is $O(c)$. □

### 4.2 Other operations

The previous development on `fwd_search`, `bwd_search`, `rmqi`, and `RMQi`, has been general, for any $g(\cdot)$. Applied to $g = \pi$, they solve a large number of operations, as shown in Section 3. For the remaining ones we focus directly on the case $g = \pi$.

It is obvious how to compute $degree(i)$, $child(i, q)$ and $child\_rank(i)$ in time proportional to the degree of the node. To compute them in constant time, we add another array $n'[\cdot]$ to the data structure. In the range min-max tree, each node stores the minimum value of a subrange for the node. In addition to this, we store in $n'[\cdot]$ the number of the minimum values of each subrange in the tree.

**Lemma 8** The number of children of node $i$ is equal to the number of occurrences of the minimum value in $E[i + 1, findclose(i) − 1]$.

**Proof.** Let $d = E[i] = depth(i)$ and $j = findclose(i)$. Then $E[j] = d − 1$ and all excess values in $E[i + 1, j − 1]$ are $\geq d$. Therefore the minimum value in $E[i + 1, j − 1]$ is $d$. Moreover, for the range $[i_k, j_k]$ corresponding to the $k$-th child of $i$, $E[i_k] = d + 1$, $E[j_k] = d$, and all the values between them are $> d$. Therefore the number of occurrences of $d$, which is the minimum value in $E[i + 1, j − 1]$, is equal to the number of children of $i$. □

Now we can compute $degree(i)$ in constant time. Let $d = depth(i)$ and $j = findclose(i)$. We partition the range $E[i + 1, j − 1]$ into $O(ck)$ subranges, each of which corresponds to a node of the range min-max tree. Then for each subrange whose minimum value is $d$, we sum up the number of occurrences of the minimum value ($n'[\cdot]$). The number of occurrences of the minimum value in leaf subranges can be computed by table lookup on $P$, with a universal table using $O(\sqrt{2^w} \log w)$ bits. The time complexity is $O(c)$ if we use universal tables that let us process sequences of (up to) $k$ children at once, that is, telling the minimum $m[\cdot]$ value within the sequence and the number of times it appears. This table requires $O((2w^c + 1)^k k \log k) = O(\sqrt{2^w})$ bits.

Operation $child\_rank(i)$ can be computed similarly, by counting the number of minima in $E[parent(i), i − 1]$. Operation $child(i, q)$ follows the same idea of $degree(i)$, except that, in the node where the sum of $n'[\cdot]$ exceeds $q$, we must descend until the range min-max leaf that contains the opening parenthesis of the $q$-th child. This search is also guided by the $n'[\cdot]$ values of each node, and is done also in $O(c)$ time. Here we need another universal table that tells at which position the number of occurrences of the minimum value exceeds some threshold, which requires $O((2w^c + 1)^k (2w^c + 1) \log k) = O(\sqrt{2^w} \log w)$ bits.

For operations $leaf\_rank$, $leaf\_select$, $lmost\_leaf$ and $rmost\_leaf$, we define a bit-vector $P_i[0, n − 1]$ such that $P_i[i] = 1 \iff P[i] = 1 \land P[i + 1] = 0$. Then $leaf\_rank(i) = rank_1(P_i, i)$ and $leaf\_select(i) = select_1(P_i, i)$ hold. The other operations are computed by $lmost\_leaf(i) = select_1(P_i, rank_1(P_i, i − 1) + 1)$ and $rmost\_leaf(i) = select_1(P_i, rank_1(P_i, findclose(i)))$.

We recall the definition of inorder of nodes, which is essential for compressed suffix trees.

**Definition 4 ([17])** The inorder rank of an internal node $v$ is defined as the number of visited internal nodes, including $v$, in a left-to-right depth-first traversal, when $v$ is visited from a child of it and another child of it will be visited next.
Note that an internal node with \( q \) children has \( q-1 \) inorder values, so leaves and unary nodes have no inorder. We define \( \text{in\_rank}(i) \) as the smallest inorder value of internal node \( i \).

To compute \( \text{in\_rank} \) and \( \text{in\_select} \), we use another bit-vector \( P_2[0,n-1] \) such that \( P_2[i] = 1 \iff P[i] = 0 \land P[i+1] = 1 \). The following lemma gives an algorithm to compute the inorder of an internal node.

**Lemma 9 ([47])** Let \( i \) be an internal node, and let \( j = \text{in\_rank}(i) \), so \( i = \text{in\_select}(j) \). Then

\[
\text{in\_rank}(i) = \text{rank}_1(P_2, \text{findclose}(P, i + 1)) \\
\text{in\_select}(j) = \text{enclose}(P, \text{select}_1(P_2, j) + 1)
\]

Note that \( \text{in\_select}(j) \) will return the same node \( i \) for any its degree(\( i \)) – 1 inorder values.

Note that we need not to store \( P_1 \) and \( P_2 \) explicitly; they can be computed from \( P \) when needed. We only need the extra data structures for constant-time \( \text{rank} \) and \( \text{select} \), which can be reduced to the corresponding \( \text{sum} \) and \( \text{fwd\_search} \) operations on the virtual \( P_1 \) and \( P_2 \) vectors.

### 4.3 Reducing extra space

Apart from vector \( P[0,n-1] \), we need to store vectors \( e', m', M' \), and \( n' \). In addition, to implement \( \text{rank} \) and \( \text{select} \) using \( \text{sum} \) and \( \text{fwd\_search} \), we would need to store vectors \( e'_\phi, e'_\psi, m'_\phi, m'_\psi, M'_\phi, \) and \( M'_\psi \), which maintain the corresponding values for functions \( \phi \) and \( \psi \). However, note that \( \text{sum}(P, \phi, 0, i) \) and \( \text{sum}(P, \psi, 0, i) \) are nondecreasing, thus the minimum/maximum within the chunk is just the value of the sum at the beginning/end of the chunk. Moreover, as \( \text{sum}(P, \pi, 0, i) = \text{sum}(P, \phi, 0, i) - \text{sum}(P, \psi, 0, i) \) and \( \text{sum}(P, \phi, 0, i) + \text{sum}(P, \psi, 0, i) = i \), it turns out that both \( e'_\phi[i] = (r_i + e[i])/2 \) and \( e'_\psi[i] = (r_i - e[i])/2 \) are redundant. Analogous formulas hold for internal nodes. Moreover, any sequence of \( k \) consecutive such values can be obtained, via table lookup, from the sequence of \( k \) consecutive values of \( e[v] \), because the \( r_i \) values increase regularly at any node. Hence we do not store any extra information to support \( \phi \) and \( \psi \).

If we store vectors \( e', m', M' \), and \( n' \) naively, we require \( \mathcal{O}(nc\log w/w) \) bits of extra space on top of the \( n \) bits for \( P \).

The space can be largely reduced by using a recent technique by Pătraşcu [42]. They define an \( aB \)-tree over an array \( A[0,n-1] \), for \( n \) a power of \( B \), as a complete tree of arity \( B \), storing \( B \) consecutive elements of \( A \) in each leaf. Additionally, a value \( \varphi \in \Phi \) is stored at each node. This must be a function of the corresponding elements of \( A \) for the leaves, and a function of the \( \varphi \) values of the children and of the subtree size, for internal nodes. The construction is able to decode the \( B \) values of \( \varphi \) for the children of any node in constant time, and to decode the \( B \) values of \( A \) for the leaves in constant time, if they can be packed in a machine word.

In our case, \( A = P \) is the vector, \( B = k = s \) is our arity, and our trees will be of size \( N = B^c \), which is slightly smaller than the \( w^c \) we have been assuming. Our values are tuples \( \varphi \in (-B^c,-B^c,0,-B^c) \ldots (B^c,B^c,B^c,B^c) \) encoding the \( m, M, n, \) and \( e \) values at the nodes, respectively. We give next their result, adapted to our case.

**Lemma 10 (adapted from Thm. 8 in [42])** Let \( |\Phi| = (2B+1)^{4c} \), and \( B \) be such that \( (B+1)\log(2B+1) \leq \frac{w}{\sqrt{c}} \) (thus \( B = \Theta(\frac{w}{c\log w}) \)). An \( aB \)-tree of size \( N = B^c \) with values in \( \Phi \) can be stored using \( N + 2 \) bits, plus universal lookup tables of \( \mathcal{O}(\sqrt{2w}) \) bits. It can obtain the \( m, M, n \) or \( e \) values of the children of any node, and descend to any of those children, in constant time. The structure can be built in \( \mathcal{O}(N+w^{3/2}) \) time, plus \( \mathcal{O}(\sqrt{2w\text{poly}(w)}) \) for the universal tables.

15
The \( w^{3/2} \) construction time comes from a fusion tree \([18]\) that is used internally on \( \mathcal{O}(w) \) values. It could be reduced to \( w^\epsilon \) time for any constant \( \epsilon > 0 \) and navigation time \( \mathcal{O}(1/\epsilon) \), but we prefer to set \( c > 3/2 \) so that \( N = B^c \) dominates it.

These parameters still allow us to represent our range min-max trees while yielding the complexities we had found, as \( k = \Theta(w/(c \log w)) \) and \( N \leq w^c \). Our accesses to the range min-max tree are either (i) partitioning intervals \([i,j]\) into \( \mathcal{O}(ck) \) subrange, which are easily identified by navigating from the root in \( \mathcal{O}(c) \) time (as the \( k \) children are obtained together in constant time); or (ii) navigating from the root while looking for some leaf based on the intermediate \( m \), \( M \), \( n \), or \( e \) values. Thus we retain all of our time complexities.

The space, instead, is reduced to \( N+2+\mathcal{O}(\sqrt{2^w}) \), where the latter part comes from our universal tables and those of Lemma 10 (our universal tables become smaller with the reduction from \( w \) and \( s \) to \( B \)). Note that our vector \( P \) must be exactly of length \( N \); padding is necessary otherwise. Both the padding and the universal tables will lose relevance for larger trees, as seen in the next section.

The next theorem summarizes our results in this section.

**Theorem 4** On a \( w \)-bit word RAM, for any constant \( c > 3/2 \), we can represent a sequence \( P \) of \( N = B^c \) parentheses, for sufficiently small \( B = \Theta(w/(c \log w)) \), computing all operations of Table 1 in \( \mathcal{O}(c) \) time, with a data structure depending on \( P \) that uses \( N+2 \) bits, and universal tables (i.e., not depending on \( P \)) that use \( \mathcal{O}(\sqrt{2^w}) \) bits. The preprocessing time is \( \mathcal{O}(N + \sqrt{2^w} \poly(w)) \) (the latter being needed only once for universal tables) and its working space is \( \mathcal{O}(N) \) bits.

In case we need to solve the operations that build on \( P_1 \) and \( P_2 \), we need to represent their corresponding \( \phi \) functions (as \( \psi \) is redundant). This can still be done with Lemma 10 using \( \Phi = (2B+1)^{6c} \) and \( (B+1) \log(2B+1) \leq \frac{w}{12\epsilon} \). Theorem 4 applies verbatim.

## 5 A data structure for large trees

In practice, one can use the solution of the previous section for trees of any size, achieving \( \mathcal{O}(\frac{k \log n}{w} \log k n) = \mathcal{O}(\frac{\log n}{w \log \log n}) = \mathcal{O}(\log n) \) time (using \( k = w/\log n \)) for all operations with an extremely simple and elegant data structure (especially if we choose to store arrays \( m_i \), etc. in simple form). In this section we show how to achieve constant time on trees of arbitrary size.

For simplicity, let us assume in this section that we handle trees of size \( w^c \) in Section 4. We comment at the end the difference with the actual size \( B^c \) handled.

For large trees with \( n > w^c \) nodes, we divide the parentheses sequence into blocks of length \( w^c \). Each block (containing a possibly non-balanced sequence of parentheses) is handled with the range min-max tree of Section 4.

Let \( m_1, m_2, \ldots, m_r; M_1, M_2, \ldots, M_r \); and \( e_1, e_2, \ldots, e_r \); be the minima, maxima, and excess of the \( r = \lceil 2n/w^c \rceil \) blocks, respectively. These values are stored at the root nodes of each \( T_{mM} \) tree and can be obtained in constant time.

### 5.1 Forward and backward searches on \( \pi \)

We consider extending \( \text{fwd} \_\text{search}(P, \pi, i, d) \) and \( \text{bwd} \_\text{search}(P, \pi, i, d) \) to trees of arbitrary size. We focus on \( \text{fwd} \_\text{search} \), as \( \text{bwd} \_\text{search} \) is symmetric.

We first try to solve \( \text{fwd} \_\text{search}(P, \pi, i, d) \) within the block \( j = \lfloor i/w^c \rfloor \) of \( i \). If the answer is within block \( j \), we are done. Otherwise, we must look for the first excess \( d' = e_{j-1} \+ \text{sum}(P, \pi, 0, i - 1 - \ldots \)
Figure 3: A tree representing the lrm\((j)\) sequences of values \(m_1 \ldots m_9\).

\(w^c \cdot (j - 1) + d\) in the following blocks (where the sum is local to block \(j\)). Then the answer lies in the first block \(r > j\) such that \(m_r \leq d' \leq M_r\). Thus, we can apply again Lemma 5 starting at \([m_{j+1}, M_{j+1}]\): If \(d' \not\in [m_{j+1}, M_{j+1}]\), we must either find the first \(r > j + 1\) such that \(m_r \leq j\), or such that \(M_r \geq j\). Once we find such block, we complete the operation with a local \(\text{fwd}\_\text{search}(P, \pi, 0, d' - e_{r-1})\) query inside it.

The problem is how to achieve constant-time search, for any \(j\), in a sequence of length \(\tau\). Let us focus on left-to-right minima, as the others are similar.

**Definition 5** Let \(m_1, m_2, \ldots, m_\tau\) be a sequence of integers. We define for each \(1 \leq j \leq \tau\) the left-to-right minima starting at \(j\) as \(\text{lrm}(j) = \langle j_0, j_1, j_2, \ldots \rangle\), where \(j_0 = j\), \(j_r < j_{r+1}\), \(m_{j_r+1} < m_{j_r}\), and \(m_{j_r+1} \ldots m_{j_{r+1} - 1} \geq m_{j_r}\).

The following lemmas are immediate.

**Lemma 11** The first element \(\leq x\) after position \(j\) in a sequence of integers \(m_1, m_2, \ldots, m_\tau\) is \(m_{j_r}\) for some \(r > 0\), where \(j_r \in \text{lrm}(j)\).

**Lemma 12** Let \(\text{lrm}(j)[p_j] = \text{lrm}(j')[p_j]\). Then \(\text{lrm}(j)[p_j + i] = \text{lrm}(j')[p_j + i]\) for all \(i > 0\).

That is, once the \(\text{lrm}\) sequences starting at two positions coincide in a position, they coincide thereafter. Lemma 12 is essential to store all the \(\tau\) sequences \(\text{lrm}(j)\) for each block \(j\), in compact form. We form a tree \(T_{\text{lrm}}\), which is essentially a trie composed of the reversed \(\text{lrm}(j)\) sequences. The tree has \(\tau\) nodes, one per block. Block \(j\) is a child of block \(j_1 = \text{lrm}(j)[1]\) (note \(\text{lrm}(j)[0] = j_0 = j\)), that is, \(j\) is a child of the first block \(j_1 > j\) such that \(m_{j_1} < m_j\). Thus each \(j\)-to-root path spells out \(\text{lrm}(j)\), by Lemma 12. We add a fictitious root to convert the forest into a tree. Note this structure is called 2d-Min-Heap by Fischer [14], who shows how to build it in linear time.

**Example 4** Figure 3 illustrates the tree built from the sequence \(\langle m_1 \ldots m_9\rangle = \langle 6, 4, 9, 7, 4, 4, 1, 8, 5\rangle\). Then \(\text{lrm}(1) = \langle 1, 2, 7\rangle\), \(\text{lrm}(2) = \langle 2, 7\rangle\), \(\text{lrm}(3) = \langle 3, 4, 5, 7\rangle\), and so on.

If we now assign weight \(m_j - m_{j_1}\) to the edge between \(j\) and its parent \(j_1\), the original problem of finding the first \(j_r > j\) such that \(m_{j_r} \leq d'\) reduces to finding the first ancestor \(j_r\) of node \(j\) such that the sum of the weights between \(j\) and \(j_r\) exceeds \(d'' = m_j - d'\). Thus we need to compute weighted level ancestors in \(T_{\text{lrm}}\). Note that the weight of an edge in \(T_{\text{lrm}}\) is at most \(w^c\).
Lemma 13 For a tree with τ nodes where each edge has an integer weight in [1, W], after \(O(\tau \log^{1+\epsilon} \tau)\) time preprocessing, a weighted level-ancestor query is solved in \(O(t + 1/\epsilon)\) time on a \(\Omega(\log(\tau W))\)-bit word RAM. The size of the data structure is \(O(\tau \log \log(\tau W) + \frac{Wv}{\log(\tau W)} + (\tau W)^{3/4})\) bits.

Proof. We use a variant of Bender and Farach’s \((O(\tau \log \tau), O(1))\) algorithm [5]. Let us ignore weights for a while. We extract a longest root-to-leaf path of the tree, which disconnects the tree into several subtrees. Then we repeat the process recursively for each subtree, until we have a set of paths. Each such path, say of length \(\ell\), is extended upwards, adding other \(\ell\) nodes towards the root (or less if the root is reached). The extended path is called a ladder, and its is stored as an array so that level-ancestor queries within a ladder are trivial. This partitioning guarantees that a node of height \(h\) has also height \(h\) in its path, and thus at least its first \(h\) ancestors are in its ladder. Moreover the union of all ladders has at most \(2\tau\) nodes and thus requires \(O(\tau \log \tau)\) bits.

For each tree node \(v\), an array of its \((\text{at most})\) \(\log \tau\) ancestors at depths \(\text{depth}(v) - 2^i\), \(i \geq 0\), is stored (hence the \(O(\tau \log \tau)\)-words space and time). To solve the query \(\text{level-ancestor}(v, d)\), where \(d' = \text{depth}(v) - d\), the ancestor \(v'\) at distance \(d'' = 2^\lceil \log d' \rceil\) from \(v\) is computed. Since \(v'\) has height at least \(d''\), it has at least its first \(d''\) ancestors in its ladder. But from \(v'\) we need only the ancestor at distance \(d' - d'' < d''\), so the answer is in the ladder.

To include the weights, we must be able to find the node \(v'\) and the answer considering the weights, instead of the number of nodes. We store for each ladder of length \(\ell\) a sparse bitmap of length at most \(\ell W\), where the \(i\)-th 1-left-to-right represents the \(i\)-th node upwards in the ladder, and the distance between two 1s, the weight of the edge between them. All the bitmaps are concatenated into one (so each ladder is represented by a couple of integers indicating the extremes of its bitmap).

This long bitmap contains at most \(2\tau\) 1s, and because weights do not exceed \(W\), at most \(2\tau W\) 0s. Using Petrașcu’s sparse bitmaps [12], it can be represented using \(O(\tau \log W + \frac{\tau Wd'}{\log^\epsilon(\tau W)} + (\tau W)^{3/4})\) bits and do \(\text{rank/select}\) in \(O(t)\) time.

In addition, we store for each node the log \(\tau\) accumulated weights towards ancestors at distances \(2^i\), using fusion trees [13]. These can store \(z\) keys of \(\ell\) bits in \(O(z \ell)\) bits and, using \(O(z^{5/6}(z^{1/6})^4) = O(z^{1.5})\) preprocessing time, answer predecessor queries in \(O(\log z)\) time (via an \(\ell^{1/6}\)-ary tree). The \(1/6\) can be reduced to achieve \(O(z^{1+\epsilon})\) preprocessing time and \(O(1/\epsilon)\) query time for any desired constant \(0 < \epsilon \leq 1/2\).

In our case this means \(O(\tau \log \log(\tau W))\) bits of space, \(O(\tau \log^{1+\epsilon} \tau)\) construction time, and \(O(1/\epsilon)\) access time. Thus we can find in constant time, from each node \(v\), the corresponding weighted ancestor \(v'\) using a predecessor query. If this corresponds to (unweighted) distance \(2^i\), then the true ancestor is at distance \(< 2^{i+1}\), and thus it is within the ladder of \(v'\), where it is found using \(\text{rank/select}\) on the bitmap of ladders (each node \(v\) has a pointer to its 1 in the ladder corresponding to the path it belongs to).

To apply this lemma for our problem of computing \(\text{fwd\_search}\) outside blocks, we have \(W = w^c\) and \(\tau = \frac{n}{w^c}\). Then the size of the data structure becomes \(O(\frac{n \log^2 n}{w^c} + \frac{n t^2}{\log^4 n} + n^{3/4})\). By choosing \(c = \min(1/2, 1/\epsilon)\), the query time is \(O(c + t)\) and the preprocessing time is \(O(n)\) for \(c > 3/2\).

5.2 Other operations

For computing \(\text{rmqi}\) and \(\text{RMQi}\), we use a simple data structure [4] on the \(m_r\) and \(M_r\) values, later improved to require only \(O(\tau)\) bits on top of the sequence of values [16] [15]. The extra space is thus \(O(n/w^c)\) bits, and it solves any query up to the block granularity. For solving a general query
We consider all pairs \((i,j)\) of matching parentheses \((j = \text{findclose}(i))\) such that \(i\) and \(j\) belong to different blocks. If we define a graph whose vertices are blocks and the edges are the pairs of parentheses considered, the graph is outer-planar since the parenthesis pairs nest \([26]\), yet there are multiple edges among nodes. To remove these, we choose the tightest pair of parentheses for each pair of vertices. These parentheses are called pioneers. Since they correspond to edges of a planar graph, the number of pioneers is \(O(n/w^c)\).

For computing \(\text{child}, \text{child}\_\text{rank}, \text{and degree}\), it is enough to consider only nodes which completely include a block (otherwise the query is solved in constant time by considering just two adjacent blocks; we can easily identify such nodes using \(\text{findclose}\)). Furthermore, among them, it is enough to consider pioneers: Assume \((i,i')\) contains a whole block but is not a pioneer pair of parentheses. Then there exists a pioneer pair \((i,j')\) contained in \((i,i')\) where \(j\) is in the same block of \(i\) and \(j'\) is in the same block of \(i'\). Thus the block contains no children of \((i,i')\) as all descend from \((j,j')\). Moreover, all the children of \((i,i')\) start either in the block of \(i\) or in the block of \(i'\), since \((j,j')\) or an ancestor of it is a child of \((i,i')\). So again the operations are solved in constant time by considering two blocks. Such cases can be identified by doing \(\text{findclose}\) on the last child of \(i\) starting in its block and seeing if that child closes in the block of \(i'\).

Let us call \(\text{marked}\) the nodes to consider (that is, pioneers that contain a whole block). There are \(O(n/w^c)\) marked nodes, thus for \(\text{degree}\) we can simply store the degrees of marked nodes using \(O(n \log n/w^c)\) bits of space, and the others are computed in constant time as explained.

For \(\text{child}\) and \(\text{child}\_\text{rank}\), we set up a bitmap \(C[0,2n-1]\) where marked nodes \(v\) are indicated with \(C[v] = 1\), and preprocess \(C\) for \(\text{rank}\) queries so that satellite information can be associated to marked nodes. Using again Pătraşcu’s result \([42]\), vector \(C\) can be represented in at most \(2n/w^c \log(w^c) + O(n\log n/w^c + n^{3/4})\) bits, so that access and operation \(\text{rank}\) can be computed in \(O(t)\) time.

We will focus on children of marked nodes placed at the blocks fully contained in the nodes, as the others are in at most the two extreme blocks and can be dealt with in constant time. Note a block is fully contained in at most one marked node.

For each marked node \(v\) we store a list formed by the blocks fully contained in \(v\), and the marked nodes children of \(v\), in left-to-right order of \(P\). The blocks store the number of children of \(v\) that start within them, and the children marked nodes store simply a 1 (indicating they contain 1 child of \(v\)). All also store their position inside the list. The length of all the sequences adds up to \(O(n/w^c)\) because each block and marked node appears in at most one list. Their total sum of children is at most \(n\), for the same reason. Thus, it is easy to store all the number of children as gaps between consecutive 1s in a bitmap, which can be stored within the same space bounds of the other bitmaps in this section (\(O(n)\) bits, \(O(n/w^c)\) 1s).

Using this bitmap, \(\text{child}\) and \(\text{child}\_\text{rank}\) can easily be solved using \(\text{rank}\) and \(\text{select}\). For \(\text{child}(v,q)\) on a marked node \(v\) we start using \(p = \text{rank}_1(C_v, \text{select}_q(C_v, q))\) on the bitmap \(C_v\) of \(v\). This tells the position in the list of blocks and marked nodes of \(v\) where the \(q\)-th child of \(v\) lies. If it is a marked node, then that node is the child. If instead it is a block \(v'\), then the answer corresponds to the \(q'\)-th minimum within that block, where \(q' = q - \text{rank}_0(\text{select}_1(C_v, p))\). (Recall that we first have to see if \(\text{child}(v,q)\) lies in the block of \(v\) or in that of \(\text{findclose}(v)\), using a within-block query in those cases, and otherwise subtracting from \(q\) the children that start in the block of \(v\).)

For \(\text{child}\_\text{rank}(u)\), we can directly store the answers for marked blocks \(u\). Else, it might be that \(v = \text{parent}(u)\) starts in the same block of \(u\) or that \(\text{findclose}(v)\) is in the same block of
recall from Theorem 4 that we actually use blocks of size \( B \). The final result
lets us know we must finish the query in block sequence with the accumulated number of 1s in each of the
within a single block. For \( P \) in total. Once the marked nodes are identified, Pătraşcu’s compressed representation \([42]\) of bit
in the stack can be stored in
we can store a new value as the difference from the previous one using unary code. Thus the values
easy to spot marked nodes. Because
we push
which represents a part of the input of length \( B \). Padding the last block to size exactly
bits. Padding the last block to size exactly \( B \) adds up another negligible extra space.
On the other hand, in this section we have extended the results to larger trees of \( n \) nodes,
adding time \( O(t) \) to the operations. By properly adjusting \( w \) to \( B \) in these results, the overall extra
space added is \( O\left(\frac{n(c \log B + \log^2 n)}{B} + \frac{n^2 t}{\log^2 n} + \sqrt{2w} + n^{3/4}\right) \) bits. Using a computer word of \( w = \log n \)
bits, setting \( t = c \), and expanding \( B = O\left(\frac{\log n}{c \log \log n}\right) \), we get that the time for any operation is \( O(c) \)
and the total space simplifies to \( 2n + O\left(\frac{n(c \log \log n)^x}{\log^{x - 4} n}\right) \).

Construction time is \( O(n) \). We now analyze the working space for constructing the data structure.
We first convert the input balanced parentheses sequence \( P \) into a set of aB-trees, each of which represents a part of the input of length \( B \). The working space is \( O(B^c) \) from Theorem 4.
Next we compute marked nodes: We scan \( P \) from left to right, and if \( P[i] \) is an opening parenthesis,
we push \( i \) in a stack, and if it is closing, we pop an entry from the stack. At this point it is very
easy to spot marked nodes. Because \( P \) is nested, the values in the stack are monotone. Therefore
we can store a new value as the difference from the previous one using unary code. Thus the values
in the stack can be stored in \( O(n) \) bits. Encoding and decoding the stack values takes \( O(n) \) time in total.
Once the marked nodes are identified, Pătraşcu’s compressed representation \([42]\) of bit
vector \( C \) is built in \( O(n) \) space too, as it also cuts the bitmap into polylog-sized aB-trees and then
computes some directories over just \( O(n/\text{polylog}(n)) \) values.
The remaining data structures, such as the \( brm \) sequences and tree, the lists of the marked
nodes, and the \( C_u \) bitmaps, are all built on \( O(n/B^c) \) elements, thus they need at most \( O(n) \) bits
of space for construction.

By rewriting \( c - 2 - \delta \) as \( c \), for any constant \( \delta > 0 \), we get our main result on static ordinal
trees, Theorem 1.

5.3 The final result
Recall from Theorem 4 that we actually use blocks of size \( B^c \), not \( w^c \), for \( B = O\left(\frac{w}{c \log w}\right) \). The sum of the space for all the block is \( 2n + \sum(O(n/B^c)) \), plus shared universal tables that add up to \( O(\sqrt{2w}) \) bits. Padding the last block to size exactly \( B^c \) adds up another negligible extra space.

On the other hand, in this section we have extended the results to larger trees of \( n \) nodes,
adding time \( O(t) \) to the operations. By properly adjusting \( w \) to \( B \) in these results, the overall extra
space added is \( O\left(\frac{n(c \log B + \log^2 n)}{B} + \frac{n^2 t}{\log^2 n} + \sqrt{2w} + n^{3/4}\right) \) bits. Using a computer word of \( w = \log n \)
bits, setting \( t = c \), and expanding \( B = O\left(\frac{\log n}{c \log \log n}\right) \), we get that the time for any operation is \( O(c) \)
and the total space simplifies to \( 2n + O\left(\frac{n(c \log \log n)^x}{\log^{x - 4} n}\right) \).

Construction time is \( O(n) \). We now analyze the working space for constructing the data structure.
We first convert the input balanced parentheses sequence \( P \) into a set of aB-trees, each of which represents a part of the input of length \( B^c \). The working space is \( O(B^c) \) from Theorem 4.
Next we compute marked nodes: We scan \( P \) from left to right, and if \( P[i] \) is an opening parenthesis,
we push \( i \) in a stack, and if it is closing, we pop an entry from the stack. At this point it is very
easy to spot marked nodes. Because \( P \) is nested, the values in the stack are monotone. Therefore
we can store a new value as the difference from the previous one using unary code. Thus the values
in the stack can be stored in \( O(n) \) bits. Encoding and decoding the stack values takes \( O(n) \) time in total.
Once the marked nodes are identified, Pătraşcu’s compressed representation \([42]\) of bit
vector \( C \) is built in \( O(n) \) space too, as it also cuts the bitmap into polylog-sized aB-trees and then
computes some directories over just \( O(n/\text{polylog}(n)) \) values.
The remaining data structures, such as the \( brm \) sequences and tree, the lists of the marked
nodes, and the \( C_u \) bitmaps, are all built on \( O(n/B^c) \) elements, thus they need at most \( O(n) \) bits
of space for construction.

By rewriting \( c - 2 - \delta \) as \( c \), for any constant \( \delta > 0 \), we get our main result on static ordinal
trees, Theorem 1.

6 A simple data structure for dynamic trees
In this section we give a simple data structure for dynamic ordinal trees. In addition to the previous
query operations, we add now insertion and deletion of internal nodes and leaves.
6.1 Memory management

We store a 0,1 vector \( P[0, 2n - 1] \) using a dynamic min-max tree. Each leaf of the min-max tree stores a segment of \( P \) in verbatim form. The length \( \ell \) of each segment is restricted to \( L \leq \ell \leq 2L \) for some parameter \( L > 0 \).

If insertions or deletions occur, the length of a segment will change. We use a standard technique for dynamic maintenance of memory cells \[31\]. We regard the memory as an array of cells of length \( 2L \) each, hence allocation is easily handled in constant time. We use \( L + 1 \) linked lists \( s_L, \ldots, s_{2L} \) where \( s_i \) stores all the segments of length \( i \). All the segments with equal length \( i \) are packed consecutively, without wasting any extra space in the cells of linked list \( s_i \) (except possibly at the head cell of each list). Therefore a cell (of length \( 2L \)) stores (parts of) at most three segments, and a segment spans at most two cells. Tree leaves store pointers to the cell and offset where its head cell of each list). Therefore a cell (of length \( 2L \)) stores a 0,1 vector \( \sum_{i \leq j} v[Li, Lj] \) for segment, using universal tables. Migrating a node to another list is also done in \( O(L/\log n) \) time.

For this sake we store back-pointers from each segment to its leaf. Each cell stores also a pointer to a vector \( \sum_{i \leq j} v[Li, Lj] \) of length \( 2n \) for dynamic maintenance of memory cells \[31\]. We regard the memory as an array of cells of length \( 2L \) each, hence allocation is easily handled in constant time. We use \( L + 1 \) linked lists \( s_L, \ldots, s_{2L} \) where \( s_i \) stores all the segments of length \( i \). All the segments with equal length \( i \) are packed consecutively, without wasting any extra space in the cells of linked list \( s_i \) (except possibly at the head cell of each list). Therefore a cell (of length \( 2L \)) stores (parts of) at most three segments, and a segment spans at most two cells. Tree leaves store pointers to the cell and offset where its segment is stored. If the length of a segment changes from \( i \) to \( j \), it is moved from \( s_i \) to \( s_j \). The space generated by the removal is filled with the head segment in \( s_i \), and the removed segment is stored at the head of \( s_j \).

With this scheme, scanning any segment takes \( O(L/\log n) \) time, by processing it by chunks of \( \Theta(\log n) \) bits. This is also the time to compute operations \( \text{fwd} \_\text{search} \), \( \text{bwd} \_\text{search} \), \( \text{rmqi} \), etc. on the segment, using universal tables. Migrating a node to another list is also done in \( O(L/\log n) \) time. If a migration of a segment occurs, pointers to the segment from a leaf of the tree must change. For this sake we store back-pointers from each segment to its leaf. Each cell stores also a pointer to the next cell of its list. Finally, an array of pointers for the heads of \( s_L, \ldots, s_{2L} \) is necessary. Overall, the space for storing a 0,1 vector of length \( 2n \) is \( 2n + O(n \log n / L) \) bits.

The rest of the dynamic tree will use sublinear space, and thus we allocate fixed-size memory cells for the internal nodes, as they will waste at most a constant fraction of the allocated space.

6.2 A dynamic tree

We give a simple dynamic data structure representing an ordinal tree with \( n \) nodes using \( 2n + O(n/\log n) \) bits, and supporting all query and update operations in \( O(\log n) \) worst-case time.

We divide the 0,1 vector \( P[0, 2n - 1] \) into segments of length from \( L \) to \( 2L \), for \( L = \log^2 n \). We use a balanced binary tree for representing the range min-max tree. If a node of the tree corresponds to a vector \( P[i, j] \), the node stores \( i \) and \( j \), as well as \( e = \text{sum}(P, \pi, i, j) \), \( m = \text{rmq}(P, \pi, i, j) \), \( M = \text{RMQ}(P, \pi, i, j) \), and \( n \), the number of minimum values in \( P[i, j] \) regarding \( \pi \). (Data on \( \phi \) for the virtual vectors \( P_1 \) and \( P_2 \) is handled analogously.)

It is clear that \( \text{fwd} \_\text{search} \), \( \text{bwd} \_\text{search} \), \( \text{rmqi} \), \( \text{RMQi} \), \( \text{rank} \), \( \text{select} \), \( \text{degree} \), \( \text{child} \) and \( \text{child} \_\text{rank} \) can be computed in \( O(\log n) \) time, by using the same algorithms developed for small trees in Section \[4\]. These operations cover all the functionality of Table \[4\]. Note the values we store are local to the subtree (so that they are easy to update), but global values are easily derived in a top-down traversal. For example, to solve \( \text{fwd} \_\text{search}(P, \pi, i, d) \) starting at the min-max tree root \( v \) with children \( v_l \) and \( v_r \), we first see if \( j(v_l) \geq i \), in which case try first on \( v_l \). If the answer is not there or \( j(v_l) < i \), we try on \( v_r \), changing \( d \) to \( d - e(v_l) \). This will only traverse \( O(\log n) \) nodes, as seen in Section \[4\]. As another example, to compute \( \text{depth}(i) \) from \( v \) we first see if \( j(v_l) \geq i \), in which case we continue at \( v_l \), otherwise we continue at \( v_r \) and add \( e(v_l) \) to that result.

Because each node uses \( O(\log n) \) bits, and the number of nodes is \( O(n/L) \), the total space is \( 2n + O(n/\log n) \) bits. This includes the extra \( O(n \log n / L) \) term for the leaf data. Note that we need to maintain several universal tables that handle chunks of \( \frac{1}{2} \log n \) bits. These require
\(O(\sqrt{n} \cdot \text{polylog}(n))\) extra bits, which is negligible.

If insertion/deletion occurs, we update a segment, and the stored values in the leaf for the segment. From the leaf we step back to the root, updating the values as follows:

\[
i(v), j(v) = i(v_l), j(v_r)
\]

\[
e(v) = e(v_l) + e(v_r)
\]

\[
m(v) = \min(m(v_l), e(v_l) + m(v_r))
\]

\[
M(v) = \max(M(v_l), e(v_l) + M(v_r))
\]

\[
n(v) = n(v_l) \text{ if } m(v_l) < e(v_l) + m(v_r),
\]

\[
n(v_r) \text{ if } m(v_l) > e(v_l) + m(v_r),
\]

\[
n(v_l) + n(v_r) \text{ otherwise.}
\]

If the length of the segment exceeds \(2L\), we split it into two and add a new node. If, instead, the length becomes shorter than \(L\), we find the adjacent segment to the right. If its length is \(L\), we concatenate them; otherwise move the leftmost bit of the right segment to the left one. In this manner we can keep the invariant that all segments have length \(L\) to \(2L\). Then we update all the values in the ancestors of the modified leaves, as explained. If a balancing operation occurs, we also update the values in nodes. All these updates are carried out in constant time per involved node, as their values are recomputed using the formulas above. Thus the update time is also \(O(\log n)\).

When \(\lfloor \log n \rfloor\) changes, we must update the allowed values for \(L\), recompute universal tables, change the width of the stored values, etc. Mäkinen and Navarro [29] have shown how to do this for a very similar case (dynamic rank/select on a bitmap). Their solution of splitting the bitmap into three parts and moving border bits across parts to deamortize the work applies verbatim to our sequence of parentheses, thus we can handle changes in \(\lfloor \log n \rfloor\) without altering the space nor the time complexity (except for \(O(w)\) extra bits in the space due to a constant number of system-wide pointers, a technicim we ignore). We have one range min-max tree for each of the three parts and adapt all the algorithms in the obvious mannerº.

### 7 A faster dynamic data structure

Instead of the balanced binary tree, we use a B-tree with branching factor \(\Theta(\sqrt{\log n})\), as in previous work [3]. Then the depth of the tree is \(O(\log n / \log \log n)\). The lengths of segments is \(L\) to \(2L\) for \(L = \log^2 n / \log \log n\). The required space for the range min-max tree and the vector is now \(2n + O(n \log \log n / \log n)\) bits (the internal nodes use \(O(\log^{3/2} n)\) bits but there are only \(O(\frac{n}{L \sqrt{\log n}})\) of them). Now each leaf can be processed in time \(O(\log n / \log \log n)\).

Each internal node \(v\) of the range min-max tree has \(k\) children, for \(\sqrt{\log n} \leq k \leq 2\sqrt{\log n}\) (we relax the constants later). Let \(c_1, c_2, \ldots, c_k\) be the children of \(v\), and \([\ell_1, r_1], \ldots, [\ell_k, r_k]\) be their corresponding subranges. We store (i) the children boundaries \(\ell_i\), (ii) \(s_\phi[1,k]\) and \(s_\psi[1,k]\) storing \(s_\phi[i] = \text{sum}(P, \phi, \psi, \ell_i, r_i)\), (iii) \(e[1,k]\) storing \(e[i] = \text{sum}(P, \pi, \ell_i, r_i)\), (iv) \(m[1,k]\) storing \(m[i] = e[i-1] + \text{rmq}(P, \pi, \ell_i, r_i)\), \(M[1,k]\) storing \(M[i] = e[i-1] + \text{RMQ}(P, \pi, \ell_i, r_i)\), and (v) \(n[1,k]\) storing in \(n[i]\) the number of times the minimum excess within the \(i\)-th child occurs within its

ºOne can act as if one had a single range min-max tree where the first two levels were used to split the three parts (these first nodes would be special in the sense that their handling of insertions/deletions would reflect the actions on moving bits between the three parts).
subtree. Note that the values stored are local to the subtree (as in the simpler balanced binary tree version, Section 6.3) but cumulative with respect to previous siblings. Note also that storing \( s_\phi \), \( s_\psi \) and \( e \) is redundant, as noted in Section 6.3, but we need \( s_\phi/\psi \) in explicit form to achieve constant-time searching into their values, as it will be clear soon.

Apart from simple accesses to the stored values, we need to support the following operations within any node:

- \( p(i) \): the largest \( j \) such that \( \ell_{j-1} \leq i \) (or \( j = 1 \)).
- \( w_{\phi/\psi}(i) \): the largest \( j \) such that \( s_{\phi/\psi}[j-1] \leq i \) (or \( j = 1 \)).
- \( f(i,d) \): the smallest \( j \geq i \) such that \( m[j] \leq d \leq M[j] \).
- \( b(i,d) \): the largest \( j \leq i \) such that \( m[j] \leq d \leq M[j] \).
- \( r(i,j) \): the smallest \( x \) such that \( m[x] \) is minimum in \( m[i,j] \).
- \( R(i,j) \): the smallest \( x \) such that \( m[x] \) is maximum in \( m[i,j] \).
- \( n(i,j) \): the number of times the minimum within the subtrees of children \( i \) to \( j \) occurs within that range.
- \( r(i,j,t) \): the \( x \) such that the \( t \)-th minimum within the subtrees of children \( i \) to \( j \) occurs within the \( x \)-th child.
- \textit{update}: updates the data structure upon \( \pm 1 \) changes in some child.

Simple operations involving \textit{rank} and \textit{select} on \( P \) are carried out easily with \( \mathcal{O}(\log n/\log \log n) \) applications of \( p(i) \) and \( w_{\phi/\psi}(i) \). For example \( \text{depth}(i) \) is computed, starting from the root node, by finding the child \( j = p(i) \) to descend, then recursively computing \( \text{depth}(i-j) \) on the \( j \)-th child, and finally adding \( e[j-1] \) to the result. Handling \( \phi \) for \( P_1 \) and \( P_2 \) is immediate; we omit it.

Operations \textit{fwd.search}/\textit{bwd.search} can be carried out via \( \mathcal{O}(\log n/\log \log n) \) applications of \( f(i,d)/b(i,d) \). Recalling Lemma 1, the interval of interest is partitioned into \( \mathcal{O}(\sqrt{\log n} \log n/\log \log n) \) nodes of the B-tree, but these can be grouped into \( \mathcal{O}(\log n/\log \log n) \) sequences of consecutive siblings. Within each such sequence a single \( f(i,d)/b(i,d) \) operation is sufficient. For example, for \textit{fwd.search}(i,d), let us assume \( d \) is a global excess to find (i.e., start with \( d \leftarrow d + \text{depth}(i) - 1 \)). We start at the root \( v \) of the range min-max tree, and compute \( j = p(i) \), so the search starts at the \( j \)-th child, with the recursive query \( \text{fwd.search}(i-\ell_j,d-e[j-1]) \). If the answer is not found in that child, query \( j' = f(j+1,d) \) tells that it is within child \( j' \). We then enter recursively into the \( j' \)-th child of the node with \( \text{fwd.search}(i-\ell_{j'},d-e[j'-1]) \), where the answer is sure to be found.

Operations \textit{rmq}(i) and \textit{RMQi}(i) are solved in very similar fashion, using \( \mathcal{O}(\log n/\log \log n) \) applications of \( r(i,j)/R(i,j) \). For example, to compute \( \text{rmq}(i,i') \) (the extension to \( \text{rmq} \) is obvious) we start with \( j = p(i) \) and \( j' = p(i') \). If \( j = j' \) we answer with \( e[j-1] + \text{rmq}(i-\ell_j,i'-\ell_j) \) on the \( j \)-th child of the current node. Otherwise we recursively compute \( e[j-1] + \text{rmq}(i-\ell_j,\ell_{j+1}-\ell_j-1), e[j'-1] + \text{rmq}(0,i'-\ell_{j'}) \) and, if \( j+1 < j' \), \( m[r(j+1,j'-1)] \), and return the minimum of the two or three values.

For degree we partition the interval as for \textit{rmq}(i) and then use \( m[r(i,j)] \) in each node to identify those holding the global minimum. For each node holding the minimum, \( n(i,j) \) gives the number of occurrences of the minimum in the node. Thus we apply \( r(i,j) \) and \( n(i,j) \) \( \mathcal{O}(\log n/\log \log n) \)
times. Operation \textit{child\_rank} is very similar, by changing the right end of the interval of interest, as before. Finally, solving \textit{child} is also similar, except that when we exceed the desired rank in the sum (i.e., in some node \(n(i,j) \geq t\), where \(t\) is the local rank of the child we are looking for), we find the desired min-max tree branch with \(r(i,j,t)\), and continue on the child with \(t \leftarrow t - n(i,r(i,j,t) - 1)\), using one \(r(i,j,t)\) operation per level.

7.1 Dynamic partial sums

Let us now face the problem of implementing the basic operations. Our first tool is a result by Raman et al., which solves several subproblems of the same type.

\textbf{Lemma 14} [43] \textit{Under the RAM model with word size} \(\Theta(\log n)\), it is possible to maintain a sequence of \(\log n\) nonnegative integers \(x_1, x_2, \ldots\) of \(\log n\) bits each, for any constant \(0 \leq \epsilon < 1\), such that the data structure requires \(O(\log^{1+\epsilon} n)\) bits and carries out the following operations in constant time: \(\text{sum}(i) = \sum_{j=1}^{i} x_j\), \(\text{search}(s) = \max\{i, \text{sum}(i) \leq s\}\), and \(\text{update}(i, \delta)\), which sets \(x_i \leftarrow x_i + \delta\), for \(-\log n \leq \delta \leq \log n\). The data structure also uses a precomputed universal table of size \(O(n^\epsilon)\) bits for any fixed \(\epsilon > 0\). The structure can be built in \(O(\log^2 n)\) time except the table.

Then we can store \(\ell\), \(s_\phi\), and \(s_\psi\) in differential form, and obtain their values via \textit{sum}. The same can be done with \(e\), provided we fix the fact that it can contain negative values by storing \(e[i] + 2^{\lceil \log n \rceil} \cdot i\) (this works for constant-time \textit{sum}, yet not for \textit{search}). Operations \(p\) and \(w_{\phi/\psi}\) are then solved via \textit{search} on \(\ell\) and \(s\), respectively. Moreover we can handle \(\pm1\) changes in the subtrees in constant time as well. In addition, we can store \(m[i] - e[i-1]\) and \(M[i] - e[i-1]\), which depend only on the subtree, and reconstruct the values in constant time using \textit{sum} on \(e\), which eliminates the problem of propagating changes in \(e[i]\) to \(m[i+1,k]\) and \(M[i+1,k]\). Local changes to \(m[i]\) or \(M[i]\) can be applied directly.

7.2 Cartesian trees

Our second tool is the Cartesian tree [50, 48]. A Cartesian tree for an array \(B[1,k]\) is a binary tree in which the root node stores the minimum value \(B[\mu]\), and the left and the right subtrees are Cartesian trees for \(B[1,\mu-1]\) and \(B[\mu+1,k]\), respectively. If there exist more than one minimum value position, then \(\mu\) is the leftmost. Thus the tree shape has enough information to determine the position of the leftmost minimum in any range \([i,j]\). As it is a binary tree of \(k\) nodes, a Cartesian tree can be represented within \(2k\) bits using parentheses and the bijection with general trees. It can be built in \(O(k)\) time.

We build Cartesian trees for \(m[1,k]\) and for \(M[1,k]\) (this one taking maxima). Since \(2k = O(\sqrt{\log n})\), universal tables let us answer in constant time any query of the form \(r(i,j)\) and \(R(i,j)\), as these depend only on the tree shape as explained. All the universal tables we will use on Cartesian trees take \(O(2^{O(\sqrt{\log n})} \cdot \text{polylog}(n)) = o(n^\alpha)\) for any constant \(0 < \alpha < 1\).

We also use Cartesian trees to solve operations \(f(i,d)\) and \(b(i,d)\). However, these do not depend only on the tree shape, but on the actual values \(m[i,k]\). We focus on \(f(i,d)\) since \(b(i,d)\) is symmetric. Following Lemma 5, we first check whether \(m[i] \leq d \leq M[i]\), in which case the answer is \(i\). Otherwise, the answer is either the next \(j\) such that \(m[j] \leq d (if d < m[i])\), or \(M[j] \geq d (if d > M[i])\). Let us focus on the case \(d < m[i]\), as the other is symmetric. By Lemma 11, the answer belongs to \(lrmi\), where the sequence is \(m[1,k]\).
Lemma 15 Let $C$ be the Cartesian tree for $m[1,k]$. Then $lrm(i)$ is the sequence of nodes of $C$ in the upward path from $i$ to the root, which are reached from the left child.

**Proof.** The left and right children of node $i$ contain values not smaller than $i$. All the nodes in the upward path are equal to or smaller than $i$. Those reached from the right must be at the left of position $i$, as they must be either to the left or to the right of all the nodes already seen, and $i$ has been seen. Their left children are also to the left of $i$. Ancestors $j$ reached from the left are strictly smaller than $i$ and, by the previous argument, to the right of $i$, thus they belong to $lrm(i)$. Finally, the right descendants of those $j$ are not in $lrm(i)$ because they are after $j$ and equal to or larger than $m[j]$. □

The Cartesian tree can have precomputed $lrm(i)$ for each $i$, as this depends only on the tree shape, and thus are stored in universal tables. This is the sequence of positions in $m[1,k]$ that must be considered. We can then binary search this sequence, using the technique described to retrieve any desired $m[j]$, to compute $f(i,d)$ in $O(\log k) = O(\log \log n)$ time.

### 7.3 Complete trees

We arrange a complete binary tree on top of the $n[1,k]$ values, so that each node of the tree records (i) one leaf where the subtree minimum is attained, and (ii) the number of times the minimum arises in its subtree. This tree is arranged in heap order and requires $O(\log^{3/2} n)$ bits of space.

A query $n(i,j)$ is answered essentially as in Section 6. We find the $O(\log k)$ nodes that cover $[i,j]$, find the minimum $m[\cdot]$ value among the leaves stored in (i) for each covering node (recall we have constant-time access to $m$), and add up the number of times (field (ii)) the minimum of $m[i,j]$ occurs. This takes overall $O(\log k)$ time.

A query $r(i,j,t)$ is answered similarly, stopping at the node where the left-to-right sum of the fields (ii) reaches $t$, and then going down to the leaf $x$ where $t$ is reached. Then the $t$-th occurrence of the minimum in subtrees $i$ to $j$ occurs within the $x$-th subtree.

When an $m[i]$ or $n[i]$ value changes, we must update the upward path towards the root of the complete tree, using the update formula for $n(v)$ given in Section 6. This is also sufficient when $e[i]$ changes: Although this implicitly changes all the $m[i+1,k]$ values, the local subtree data outside the ancestors of $i$ are unaffected. Then the root $n(v)$ value will become an $n[\cdot']$ value at the parent of the current range min-max tree node (just as the minimum of $m[1,k]$, maximum of $M[1,k]$, excess $e[k]$, etc., which can be computed in constant time as we have seen).

Since these operations take time $O(\log k) = O(\log \log n)$ time, the time complexity of degree, child, and child_rank is $O(\log n)$. Update operations (insert and delete) also require $O(\log n)$ time, as we may need to update $n[\cdot]$ for one node per tree level. However, as we see later, it is possible to achieve time complexity $O(\log n / \log \log n)$ for insert and delete for all the other operations. Therefore, we might choose not to support operations $n(i,j)$ and $r(i,j,t)$ to retain the lower update complexity. In this case, operations degree, child, and child_rank can only be implemented naively using first_child, next_sibling, and parent.

### 7.4 Updating Cartesian trees

We already solved some simple cases of update, but not yet how to maintain Cartesian trees. When a value $m[i]$ or $M[i]$ changes (by ±1), the Cartesian trees might change their shape. Similarly, a ±1 change in $e[i]$ induces a change in the effective value of $m[i+1,k]$ and $M[i+1,k]$. We store $m$
and $M$ in a way independent of $e$, but the Cartesian trees are built upon the actual values of $m$ and $M$. Let us focus on $m$, as $M$ is similar. If $m[i]$ decreases by 1, we need to determine if $i$ should go higher in the tree. We compare $i$ with its Cartesian tree parent $j = Cparent(i)$ and, if (a) $i < j$ and $m[i] - m[j] = 0$, or if (b) $i > j$ and $m[i] - m[j] = -1$, we must carry out a rotation with $i$ and $j$. Figure 4 shows the two cases. As it can be noticed, case (b) may propagate the rotations towards the new parent of $i$, as it generates a new distance $d - 1$ that is smaller than before.

In order to carry out those propagations in constant time, we store an array $d[i, k]$, so that $d[i] = m[i] - m[Cparent(i)]$ if this is $\leq k + 2$, and $k + 2$ otherwise. Since $d[1, k]$ requires $O(k \log k) = O(\sqrt{\log n} \log \log n) = o(\log n)$ bits of space, it can be manipulated in constant time using universal tables: With $d[1, k]$ and the current Cartesian tree as input, a universal table can precompute the outcome of the changes in $d[i]$ and the corresponding sequence of rotations triggered by the decrease of $m[i]$ for any $i$, so we can obtain in constant time the new Cartesian tree and the new table $d[1, k]$. The limitation of values up to $k + 2$ is necessary for the table fitting in a machine word, and its consequences will be discussed soon.

Similarly, if $m[i]$ increases by 1, we must compare $i$ with its two children: (a) the difference with its left child cannot fall below 1 and (b) the difference with its right child cannot fall below 0. Otherwise we must carry out rotations as well, depicted in Figure 5. While it might seem that case (b) can propagate rotations upwards (due to the $d - 1$ at the root), this is not the case because $d$ had just been increased as $m[i]$ grew by 1. In case both (a) and (b) arise simultaneously, we must apply the rotation corresponding to (b) and then that of (a). No further propagation occurs. Again, universal tables can precompute all these updates.

For changes in $e[i]$, the universal tables have precomputed the effect of carrying out all the changes in $m[i + 1, k]$ , updating all the necessary $d[1, k]$ values and the Cartesian tree. This is

---

Figure 4: Rotations between $i$ and its parent $j$ when $m[i]$ decreases by 1. The edges between any $x$ and its parent are labeled with $d[x] = m[x] - m[Cparent(x)]$, if these change during the rotation. The $d[i]$ values have already been updated. On the left, when $i < j$, on the right, when $i > j$. 

- The edges between any $x$ and its parent are labeled with $d[x] = m[x] - m[Cparent(x)]$, if these change during the rotation. 
- The $d[i]$ values have already been updated. On the left, when $i < j$, on the right, when $i > j$.

Figure 5: Rotations between $i$ and its children when $m[i]$ increases by 1. The edges between any $x$ and its parent are labeled with $d[x] = m[x] - m[Cparent(x)]$, if these change during the rotation. The $d[.]$ values have already been updated. On the left (right), when the edge to the left (right) child becomes invalid after the change in $d[.]$.

equivalent to precomputing the effect of a sequence of $k - i$ successive changes in $m[.]$.

Our array $d[1,k]$ distinguishes values between 0 and $k + 2$. As the changes to the structure of the Cartesian tree only depend on whether $d[i]$ is 0, 1, or larger than 1, and all the updates to $d[i]$ are by ±1 per operation, we have sufficient information in $d[.]$ to correctly predict any change in the Cartesian tree shape for the next $k$ updates. We refresh table $d[.]$ fast enough to ensure that no value of $d[.]$ is used for more than $k$ updates without recomputing it, as then its imprecision could cause a flaw. We simply recompute cyclically the cells of $d[.]$, one per update. That is, at the $i$-th update arriving at the node, we recompute the cell $i' = 1 + (i \mod k)$, setting again $d[i'] = \min(k + 2, m[i'] - m[Cparent(i')])$; note that $Cparent(i')$ is computed from the Cartesian tree shape in constant time via table lookup. Note the values of $m[.]$ are always up to date because we do not keep them in explicit form but with $e[i - 1]$ subtracted (and in turn $e$ is not maintained explicitly but via partial sums).

### 7.5 Handling splits and merges

In case of splits or merges of segments or internal range min-max tree nodes, we must insert or delete children in a node. To maintain the range min-max tree dynamically, we use Fleischer’s data structure \[16\]. This is an $(a,2b)$-tree (for $a \leq 2b$) storing $n$ numeric keys in the leaves, and each leaf is a bucket storing at most $2 \log_a n$ keys. It supports constant-time insertion and deletion of a key once its location in a leaf is known.

Each leaf owns a cursor, which is a pointer to a tree node. This cursor traverses the tree upwards, looking for nodes that should be split, moving one step per insertion received at the leaf. When the cursor reaches the root, the leaf has received at most $\log_a n$ insertions and thus it is split. Both new leaves are born with their cursor at their common parent. In addition some edges
must be marked. Marks are considered when splitting nodes (see Fleischer [16] for details). The insertion steps are as follows:

1. Insert the new key into the leaf $B$. Let $v$ be the current node where the cursor of $B$ points.

2. If $v$ has more than $b$ children, split it into $v_1$ and $v_2$, and unmark all edges leaving from those nodes. If the parent of $v$ has more than $b$ children, mark the edges to $v_1$ and $v_2$.

3. If $v$ is not the root, set the cursor to the parent of $v$. Otherwise, split $B$ into two halves, and let the cursor of both new buckets point to their common parent.

To apply this to our data structure, let $a = \sqrt{\log n}, b = 2\sqrt{\log n}$. Then the height of the tree is $O((\log n)/\log \log n)$, and each leaf should store $\Theta((\log n)/\log \log n)$ keys. Instead our structure stores $\Theta((\log^2 n)/\log \log n)$ bits in each leaf. If Fleischer’s structure handles $O(\log n)$-bit numbers, it turns out that the leaf size is the same in both cases. The difference is that our insertions are bitwise, whereas Fleischer’s insertions are number-wise (that is, in packets of $O(\log n)$ bits). Therefore we can use their structure, yet sparing the sensor moves so that one out of $\log n$ insertions triggers a move (indeed one can only split a leaf if it has actually exceeded size $2L$). Marking and unmarking of children edges is easily handled in constant time by storing a bit-vector of length $2b$ in each node.

Fleischer’s update time is constant. Ours is $O(\sqrt{\log n})$ because, if we split a node into two, we fully reconstruct all the values in those two nodes and their parent. This can be done in $O(k) = O(\sqrt{\log n})$ time, as the structure of Lemma 14, the Cartesian trees, and the complete trees can be built in linear time. Nevertheless this time is dominated by the $O((\log n)/\log \log n)$ cost of inserting a bit at the leaf.

Deletions at leaves are handled so that they have always between $L$ and $2L$ bits. Deletion of children of internal nodes may make the node arity fall below $a$. This is handled as in Fleischer’s structure, by deamortized global rebuilding. This increases only the sublinear size of the range min-max tree; the leaves are not affected. As a consequence, our tree arities are in the range $1 \leq k \leq 4\sqrt{\log n}$.

### 7.6 The final result

We have obtained the following result.

**Lemma 16** For a 0,1 vector of length $2n$, there exists a data structure using $2n + O(n \log \log n / \log n)$ bits supporting $fwd$-search and $bwd$-search in $O(\log n)$ time, and updates and all other queries except degree, child, and child_rank, in $O((\log n)/\log \log n)$ time. Alternatively, degree, child, child_rank, and updates can be handled in $O(\log n)$ time.

The complexity of $fwd$-search and $bwd$-search is not completely satisfactory, as we have reduced many operators to those. To achieve better complexities, we note that most operators that reduce to $fwd$-search and $bwd$-search actually reduce to the less general operations $findclose$, $findopen$, and $enclose$ on parentheses. Those three operations can be supported in time $O((\log n)/\log \log n)$ by adapting the technique of Chan et al. [8]. They use a tree of similar layout as ours: leaves storing $\Theta((\log^2 n)/\log \log n)$ parentheses and internal nodes of arity $k = \Theta(\sqrt{\log n})$, where Lemma 14 is used to store seven arrays of numbers recording information on matched and unmatched parentheses on the children. Those are updated in constant time upon parenthesis insertions and deletions, and
are sufficient to support the three operations. They report $O(n)$ bits of space because they do not use a mechanism like the one we describe in Section 6.1 for the leaves; otherwise their space would be $2n + O(n \log \log n / \log n)$ as well. Note, on the other hand, that they do not achieve the times we offer for lca and related operations.

This completes the main result of this section, Theorem 2.

### 7.7 Updating whole subtrees

We face now the problem of attaching and detaching whole subtrees. Now we assume $\log n$ is fixed to some sufficiently large value, for example $\log n = w$, the width of the systemwide pointers. Hence, no matter the size of the trees, they use segments of the same length, and the times are a function of $w$ and not of the actual tree size.

Now we cannot use Fleischer’s data structure [16], because a detached subtree could have dangling cursors pointing to the larger tree it belonged. As a result, the time complexity for insert function of range min-max tree from $O(\sqrt{n} \log \log n / \log n)$ as well. Note, on the other hand, that they do not achieve the times we offer for lca and related operations.

Now we merge the range min-max trees for $T_1$ and $T_2$ as follows. Let $h_1$ be the height of the range min-max tree of $T_1$, and $h_2$ be the height of the lca, say $v$, between $P_l$ and $P_r$ in the range min-max tree of $T_2$. If $h_2 > h_1$ then can simply concatenate the root of $T_1$ at the right of the ancestor of $P_l$ of height $h_1$, then split the node if it has overflowed, and finish.

If $h_2 \leq h_1$, we divide $v$ into $v_l$ and $v_r$, so that the rightmost child of $v_l$ is an ancestor of $P_l$ and the leftmost child of $v_r$ is an ancestor of $P_r$. We do not yet care about $v_l$ or $v_r$ being too small.

We repeat the process on the parent of $v$ until reaching the height $h_2 = h_1 + 1$. Let us call $u$ the ancestor where this height is reached (we leave for later the case where we split the root of $T_2$ without reaching the height $h_1 + 1$).

Now we add $T_1$ as a child of $u$, between the child ancestor of $P_l$ and that ancestor of $P_r$. All the leaves have the same depth, but the ancestors of $P_l$ and of $P_r$ at heights $h_2$ to $h_1$ might be underfull as we have cut them arbitrarily. We glue the ancestor of height $h$ of $P_l$ with the leftmost node of height $h$ of $T_1$, and that of $P_r$ with the rightmost node of $T_1$, for all $h_2 \leq h \leq h_1$. Now there are no underfull nodes, but they can have overflowed. We verify the node sizes in both paths, from height $h = h_2$ to $h_1 + 1$, splitting them as necessary. At height $h_2$ the node can be split into two, adding another child to its parent, which can thus be split into three, adding in turn two children to its parent, but from there on nodes can only be split into three and add two more children to their parent. Hence the overall process of fixing arities takes time $O(\frac{1}{\epsilon} \log^{1+\epsilon} n / \log \log n)$.
If node $u$ does not exist, then $T_1$ is not shorter than $T_2$. In this case we have divided $T_2$ into a left and right part. Let $h_2$ be the height of $T_2$. We attach the left part of $T_2$ to the leftmost node of height $h_2$ in $T_1$, and the right part of $T_2$ to the rightmost node of height $h_2$ in $T_1$. Then we fix arities in both paths analogously as before.

Detaching is analogous as well. After splitting the leftmost and rightmost leaves of the area to be detached, let $P_l$ and $P_r$ the leaves of $T$ preceding and following the leaves that will be detached. We split the ancestors of $P_l$ and $P_r$ until reaching their lca, let it be $v$. Then we can form a new tree with the detached part and remove it from the original tree $T$. Again, the paths from $P_l$ and $P_r$ to $v$ may contain underfull nodes. But now $P_l$ and $P_r$ are consecutive leaves, so we can merge their ancestor paths up to $v$ and then split as necessary.

Similarly, the leftmost and rightmost path of the detached tree may contain underfull nodes. We merge each node of the leftmost (rightmost) path with its right (left) sibling, and then split if necessary. The root may contain as few as two children. Overall the process takes $O(\log^{1+\epsilon} n)$ time.

8 Improving dynamic compressed sequences

The techniques we have developed along the paper are of independent interest. We illustrate this point by improving the best current results on sequences of numbers with sum and search operations, dynamic compressed bitmaps, and their many byproducts.

8.1 Codes, Numbers, and Partial Sums

We prove now Lemma 1 on sequences of codes and partial sums, this way improving previous results by Mäkinen and Navarro [29] and matching lower bounds [40].

Section 7 shows how to maintain a dynamic bitmap $P$ supporting various operations in time $O(\log n / \log \log n)$, including insertion and deletion of bits (parentheses in $P$). This bitmap $P$ will now be the concatenation of the (possibly variable-length) codes $x_i$. We will ensure that each leaf contains a sequence of whole codes (no code is split at a leaf boundary). As these are of $O(\log n)$ bits, we only need to slightly adjust the lower limit $L$ to enforce this: After splitting a leaf of length $2L$, one of the two new leaves might be of size $L - O(\log n)$.

We process a leaf by chunks of $b = \frac{1}{2} \log n$ bits: A universal table (easily computable in $O(\sqrt{n} \text{polylog}(n))$ time and space) can tell us how many whole codes are there in the next $b$ bits, how much their $f(\cdot)$ values add up to, and where the last complete code ends (assuming we start reading at a code boundary). Note that the first code could be longer than $b$, in which case the table lets us advance zero positions. In this case we decode the next code directly. Thus in constant time (at most two table accesses plus one direct decoding) we advance in the traversal by at least $b$ bits. If we surpass the desired position with the table we reprocess the last $O(\log n)$ codes using a second table that advances by chunks of $O(\sqrt{\log n})$ bits, and finally process the last $O(\sqrt{\log n})$ codes directly. Thus in time $O(\log n / \log \log n)$ we can access a given code in a leaf (and subsequent ones in constant time each), sum the $f(\cdot)$ values up to some position, and find the position where a given sum $s$ is exceeded. We can also easily modify a code or insert/delete codes, by shifting all the other codes of the leaf in time $O(\log n / \log \log n)$.

In internal nodes of the range min-max tree we will use the structure of Lemma 14 to maintain the number of codes stored below the subtree of each child of the node. This allows determining
in constant time the child to follow when looking for any code \(x_i\), thus access to any codes \(x_i \ldots x_j\) is supported in time \(O(\log n / \log \log n + j - i)\).

When a code is inserted/deleted at a leaf, we must increment/decrement the number of codes in the subtree of the ancestors up to the root; this is supported in constant time by Lemma 14. Splits and merges can be caused by indels and by updates. They force the recomputation of their whole parent node, and Fleischer’s technique is used to ensure a constant number of splits/merges per update. Note we are inserting not individual bits but whole codes of \(O(\log n)\) bits. This can easily be done, but now \(O(\log n / \log \log n)\) insertions/updates can double the size of a leaf, and thus we must consider splitting the leaf every time the cursor returns to it (as in the original Fleischer’s proposal, not every log \(n\) times as when inserting parentheses), and we must advance the cursor upon insertions and updates.

For supporting \textit{sum} and \textit{search} we also maintain at each node the sum of the \(f(\cdot)\) values of the codes stored in the subtree of each child. Then we can determine in constant time the child to follow for \textit{search}, and the sum of previous subtrees for \textit{sum}. However, insertions, deletions and updates must alter the upward sums only by \(O(\log n)\) so that the change can be supported by Lemma 14 within the internal nodes in constant time.

### 8.2 Dynamic bitmaps

Apart from its general interest, handling a dynamic bitmap in compressed form is useful for maintaining satellite data for a sample of the tree nodes. A dynamic bitmap \(B\) could mark which nodes are sampled, so if the sampling is sparse enough we would like \(B\) to be compressed. A \textit{rank} on this bitmap would give the position in a dynamic array where the satellite information for the sampled nodes would be stored. This bitmap would be accessed by preorder (\texttt{pre_rank}) on the dynamic tree. That is, node \(v\) is sampled iff \(B[\texttt{pre_rank}(v)] = 1\), and if so, its data is at position \(\texttt{rank}(B, \texttt{pre_rank}(v))\) in the dynamic array of satellite data. When a tree node is inserted or deleted, we need to insert/delete its corresponding bit in \(B\).

In the following we prove the next lemma, which improves and indeed simplifies previous results [8, 29]; then we explore several byproducts.

**Lemma 17** We can store any bitmap \(B[0, n-1]\) within \(nH_0(B) + O(n \log \log n / \log n)\) bits of space, while supporting the operations \textit{rank}, \textit{select}, \textit{insert}, and \textit{delete}, all in time \(O(\log n / \log \log n)\). We can also support attachment and detachment of contiguous bitmaps within time \(O(\log^{1+\epsilon} n)\) for any constant \(\epsilon > 0\), yet now \(\log n\) is a maximum fixed value across all the operations.

To achieve zero-order entropy space, we use Raman et al.’s \((c, o)\) encoding [44]: The bits are grouped into small chunks of \(b = \log n / 2\) bits, and each chunk is represented by two components: the \textit{class} \(c_i\), which is the number of bits set, and the \textit{offset} \(o_i\), which is an identifier of that chunk within those of the same class. Raman et al. show that, while the \(|c_i|\) lengths add up to \(O(n \log \log n / \log n)\) extra bits, the \(|o_i| = \lceil \log (b / c_i) \rceil\) components add up to \(nH_0(B) + O(n / \log n)\) bits.

We plan to store whole chunks in leaves of the range min-max tree. A problem is that the insertion or even deletion of a single bit in Raman et al.’s representation can up to double the size of the compressed representation of the segment, because it can change all the alignments. This occurs for example when moving from \(0^b 1^b 0^b 1^b \ldots\) to \(10^{b-1} 01^{b-1} 10^{b-1} 01^{b-1} \ldots\), where we switch from all \(c_i = 0 / b\) and \(|o_i| = 0\), to all \(c_i = 1 / b - 1\), and \(|o_i| = \lceil \log b \rceil\). This problem can be dealt...
with (laboriously) on binary trees [29, 22], but not on our k-ary tree, because Fleischer’s schema does not allow leaves being partitioned often enough.

We propose a different solution that ensures that an insertion cannot make the leaf’s physical size grow by more than $O(\log n)$ bits. Instead of using the same $b$ value for all the chunks, we allow any $1 \leq b_i \leq b$. Thus each chunk is represented by a triple $(b_i, c_i, o_i)$, where $o_i$ is the offset of this chunk among those of length $b_i$ having $c_i$ bits set. To ensure $O(n \log \log n / \log n)$ space overhead over the entropy, we state the invariant that any two consecutive chunks $i, i + 1$ must satisfy $b_i + b_{i+1} > b$. Thus there are $O(n/b)$ chunks and the overhead of the $b_i$ and $c_i$ components, representing each with $\lceil \log (b+1) \rceil$ bits, is $O(n \log b/b)$. It is also easy to see that the inequality $\sum |o_i| = \sum \lceil \log (b_i) \rceil = \log \Pi (b_i) + O(n / \log n) \leq \log (n^m) + O(n / \log n) = nH_0(B) + O(n / \log n)$ holds, where $m$ is the number of 1s in the bitmap.

To maintain the invariant, the insertion of a bit is processed as follows. We first identify the chunk $(b_i, c_i, o_i)$ where the bit must be inserted, and compute its new description $(b'_i, c'_i, o'_i)$. If $b'_i > b$, we split the chunk into two, $(b_1, c_1, o_1)$ and $(b_r, c_r, o_r)$, for $b_1, b_r = b'_i/2 \pm 1$. Now we check left and right neighbors $(b_{i-1}, c_{i-1}, o_{i-1})$ and $(b_{i+1}, c_{i+1}, o_{i+1})$ to ensure the invariant on consecutive chunks holds. If $b_{i-1} + b_i \leq b$ we merge these two chunks, and if $b_r + b_{i+1} \leq b$ we merge these two as well. Merging is done in constant time by obtaining the plain bitmaps, concatenating them, and reencoding them, using universal tables (which we must have for all $1 \leq b_i \leq b$). Deletion of a bit is analogous; we remove the bit and then consider the conditions $b_{i-1} + b'_i \leq b$ and $b'_r + b_{i+1} \leq b$. It is easy to see that no insertion/deletion can increase the encoding by more than $O(\log n)$ bits.

Now let us consider codes $x_i = (b_i, c_i, o_i)$. These are clearly constant-time self-delimiting and $|x_i| = O(\log n)$, so we can directly use Lemma 1 to store them in a range min-max tree within $n' + O(n' \log n' / \log n')$ bits, where $n' = nH_0(B) + O(n \log \log n / \log n)$ is the size of our compressed representation. Since $n' \leq n + O(n \log \log n / \log n)$, we have $O(n' \log \log n' / \log n') = O(n \log \log n / \log n)$ and the overall space is as promised in the lemma. We must only take care of checking the invariant on consecutive chunks when merging leaves, which takes constant time.

Now we use the sum/search capabilities of Lemma 1. Let $f_b(b_i, c_i, o_i) = b_i$ and $f_c(b_i, c_i, o_i) = c_i$. As both are always $O(\log n)$, we can have sum/search support on them. With search on $f_b$ we can reach the code containing the $j$th bit of the original sequence, which is key for accessing an arbitrary bit. For supporting rank we need to descend using search on $f_b$, and accumulate the sum on the $f_c$ values of the left siblings as we descend. For supporting select we descend using search on $f_c$, and accumulate the sum on the $f_b$ values. Finally, for insertions and deletions of bits we first access the proper position, and then implement the operation via a constant number of updates, insertions, and deletions of codes (for updating, splitting, and merging our triplets). Thus we implement all the operations within time $O(\log n / \log \log n)$.

We can also support attachment and detachment of contiguous bitmaps, by applying essentially the same techniques developed in Section 7.7. We can have a bitmap $B'[0, n'-1]$ and insert it between $B[i]$ and $B[i+1]$, or we can detach any $B[i, j]$ from $B$ and convert it into a separate bitmap that can be handled independently. The complications that arise when cutting the compressed segments at arbitrary positions are easily handled by splitting codes. Zero-order compression is retained as it is due to the sum of the local entropies of the chunks, which are preserved (small resulting segments after the splits are merged as usual).
8.3 Sequences and Text Indices

We now aim at maintaining a sequence $S[0, n-1]$ of symbols over an alphabet $[1, \sigma]$, so that we can insert and delete symbols, and also compute symbol $\text{rank}_a(S, i)$ and $\text{select}_a(S, i)$, for $1 \leq c \leq \sigma$. This has in particular applications to labeled trees: We can store the sequence $S$ of the labels of a tree in preorder, so that $S[\text{pre\_rank}(i)]$ is the label of node $i$. Insertions and deletions of nodes must be accompanied with insertions and deletions of their labels at the corresponding preorder positions, and this can be extended to attaching and detaching subtrees. Then we not only have easy access to the label of each node, but can also use $\text{rank}$ and $\text{select}$ on $S$ to find the $r$-th descendant node labeled $c$, or compute the number of descendants labeled $c$. If the balanced parentheses represent the tree in DFUDS format [6], we can instead find the first child of a node labeled $c$ using $\text{select}$.

We divide the sequence into chunks of maximum size $b = \frac{1}{\epsilon} \log_\sigma n$ symbols and store them using an extension of the $(c_i, a_i)$ encoding for sequences [13]. Here $c_i = (c_i^1, \ldots, c_i^\sigma)$, where $c_i^a$ is the number of occurrences of character $a$ in the chunk. For this code to be of length $O(\log n)$ we need $\sigma = O(\log n/\log \log n)$; more stringent conditions will arise later. To this code we add the $b_i$ component as in Section 8.2. This takes $nH_0(S) + O\left(\frac{n\sigma \log \log n}{\log n}\right)$ bits of space. In the range min-max tree nodes, which we again assume to hold $\Theta(\log^\epsilon n)$ children for some constant $0 < \epsilon < 1$, instead of a single $f_a$ function as in Section 8.2 we must store one $f_a$ function for each $a \in [1, \sigma]$, requiring extra space $O\left(\frac{n\sigma \log \log n}{\log n}\right)$. Symbol $\text{rank}$ and $\text{select}$ are easily carried out by considering the proper $f_a$ function. Insertion and deletion of symbol $a$ is carried out in the compressed sequence as before, and only $f_b$ and $f_a$ sums must be incremented/decremented along the path to the root.

In case a leaf node splits or merges, we must rebuild the partial sums for all the $\sigma$ functions $f_a$ (and the single function $f_b$) of a node, which requires $O(\sigma \log^\epsilon n)$ time. In Section 7.5 we have shown how to limit the number of splits/merges to one per operation, thus we can handle all the operations within $O(\log n/\log \log n)$ time as long as $\sigma = O(\log^{1-\epsilon} n/\log \log n)$. This, again, greatly simplifies the solution by González and Navarro [22], which used a collection of searchable partial sums with indels.

Up to here, the result is useful for small alphabets only. González and Navarro [22] handle larger alphabets by using a multiary wavelet tree (Section 2.1). Recall this is a complete $r$-ary tree of height $h = \lceil \log_\sigma n \rceil$ that stores a string over alphabet $[1, r]$ at each node. It solves all the operations (including insertions and deletions) by $h$ applications of the analogous operation on the sequences over alphabet $[1, r]$.

Now we set $r = \log^{1-\epsilon} n/\log \log n$, and use the small-alphabet solution to handle the sequences stored at the wavelet tree nodes. The height of the wavelet tree is $h = O\left(1 + \frac{\log \sigma}{(1-\epsilon) \log \log n}\right)$. The zero-order entropies of the small-alphabet sequences add up to that of the original sequence and the redundancies add up to $O\left(\frac{n \log \sigma}{(1-\epsilon) \log \log n \log \log n}\right)$. The operations time is $O\left(\frac{\log n}{\log \log n} \left(1 + \frac{\log \sigma}{(1-\epsilon) \log \log n}\right)\right)$. By slightly altering $\epsilon$, we achieve the first part of Theorem 3, where the $O(\sigma \log^\epsilon n)$ term owes to representing the wavelet tree itself, which has $O(\sigma/r)$ nodes.

For the second part, the arity of the nodes fixed to $\Theta(\log^\epsilon n)$ allows us attach and detach substrings in time $O(r \log^{1+\epsilon} n)$ on a sequence with alphabet size $r$. This has to be carried out on each of the $O(\sigma/r)$ wavelet tree nodes, reaching overall complexity $O(\sigma \log^{1+\epsilon} n)$.

The theorem has immediate application to the handling of compressed dynamic text collections, construction of compressed static text collections within compressed space, and construction of the Burrows-Wheeler transform (BWT) within compressed space. We state them here for completeness; for their derivation refer to the original articles [29, 22].
The first result refers to maintaining a collection of texts within high-entropy space, so that one can perform searches and also insert and delete texts. Here \( H_h \) refers to the \( h \)-th order empirical entropy of a sequence, see e.g. Manzini [34]. We use sampling step \( \log \sigma n \log \log n \) to achieve it.

**Theorem 5** There exists a data structure for handling a collection \( C \) of texts over an alphabet \([1, \sigma]\) within size \( nH_h(C) + o(n \log \sigma) + O(\sigma^{h+1} \log n + m \log n + w) \) bits, simultaneously for all \( h \). Here \( n \) is the length of the concatenation of \( m \) texts, \( C = T_1 T_2 \cdots T_m \), and we assume that \( \sigma = o(n) \) is the alphabet size and \( w = \Omega(\log n) \) is the machine word size under the RAM model. The structure supports counting of the occurrences of a pattern \( P \) in \( \mathcal{O}(|P| \log n \log \log n (1 + \frac{\log \sigma}{\log \log n})) \) time, and inserting and deleting a text \( T \) in \( \mathcal{O}(\log n + |T| \log n \log \log n (1 + \frac{\log \sigma}{\log \log n})) \) time. After counting, any occurrence can be located in time \( \mathcal{O}(\frac{\log^2 n}{\log \log n} (1 + \frac{\log n}{\log \log n})) \). Any substring of length \( \ell \) from any \( T \) in the collection can be displayed in time \( \mathcal{O}(\frac{\log^2 n}{\log \log n} (1 + \frac{\log n}{\log \log n}) + \ell \frac{\log n}{\log \log n} (1 + \frac{\log \sigma}{\log \log n})) \). For \( h \leq (\alpha \log \sigma n) - 1 \), for any constant \( 0 < \alpha < 1 \), the space complexity simplifies to \( nH_h(C) + o(n \log \sigma) + O(m \log n + w) \) bits.

The second result refers to the construction of the most succinct self-index for text within the same asymptotic space required by the final structure. This is tightly related to the construction of the BWT, which has many applications.

**Theorem 6** The Alphabet-Friendly FM-index [13], as well as the BWT [7], of a text \( T[0, n - 1] \) over an alphabet of size \( \sigma \), can be built using \( nH_h(T) + o(n \log \sigma) \) bits, simultaneously for all \( h \leq (\alpha \log \sigma n) - 1 \) and any constant \( 0 < \alpha < 1 \), in time \( \mathcal{O}(n \frac{\log n}{\log \log n} (1 + \frac{\log \sigma}{\log \log n})) \).

On polylog-sized alphabets, we build the BWT in \( o(n \log n) \) time. Even on a large alphabet \( \sigma = \Theta(n) \), we build the BWT in \( o(n \log^2 n) \) time. This slashes by a log \( \log n \) factor the corresponding previous result [22]. Other previous results that focus in using little space are as follows. Okanohara and Sadakane [37] achieved optimal \( \mathcal{O}(n) \) construction time with \( \mathcal{O}(n \log \sigma \log \log \sigma n) \) bits of extra space (apart from the \( n \log \sigma \) bits of the sequence). Hon et al. [25] achieve \( \mathcal{O}(n \log \log \sigma) \) time and \( \mathcal{O}(n \log \sigma) \) bits of extra space. Ours is the fastest construction within compressed space.

### 9 Concluding remarks

We have proposed flexible and powerful data structures for the succinct representation of ordinal trees. For the static case, all the known operations are done in constant time using \( 2n + \mathcal{O}(n/\text{polylog}(n)) \) bits of space, for a tree of \( n \) nodes and a polylog of any degree. This significantly improves upon the redundancy of previous representations. The core of the idea is the range min-max tree. This simple data structure reduces all of the operations to a handful of primitives, which run in constant time on polylog-sized subtrees. It can be used in standalone form to obtain a simple and practical implementation that achieves \( \mathcal{O}(\log n) \) time for all the operations. We then show how constant time can be achieved by using the range min-max tree as a building block for handling larger trees.

The simple implementation using one range min-max tree has actually been implemented and compared with the state of the art over several real-life trees [2]. It has been shown that it is by far the smallest and fastest representation in most cases, as well as the one with widest coverage.
of operations. It requires around 2.37 bits per node and carries out most operations within the microsecond on a standard PC.

For the dynamic case, there have been no data structures supporting several of the usual tree operations. The data structures of this paper support all of the operations, including node insertion and deletion, in $O(\log n)$ time, and a variant supports most of them in $O(\log n / \log \log n)$ time, which is optimal in the dynamic case even for a very reduced set of operations. They are based on dynamic range min-max trees, and especially the former is extremely simple and implementable. We expect a performance similar to that of the static version in practice. Their flexibility is illustrated by the fact that we can support much more complex operations, such as attaching and detaching whole subtrees.

Our work contains several ideas of independent interest. An immediate application to storing a dynamic sequence of numbers supporting operations sum and search achieves optimal time $O(\log n / \log \log n)$. Another application is the storage of dynamic compressed sequences achieving zero-order entropy space and improving the redundancy of previous work. It also improves the times for the operations, achieving the optimal $O(\log n / \log \log n)$ for polylog-sized alphabets. This in turn has several applications to compressed text indexing.

Pătraşcu and Viola have recently shown that $n + n/w^{\Theta(c)}$ bits are necessary to compute rank or select on bitmaps in time $O(t)$ in the worst case \(^{[39]}\). This lower bound holds also in the subclass of balanced bitmaps\(^{[10]}\) (i.e., those corresponding to balanced parenthesis sequences), which makes our redundancy on static trees optimal as well, at least for some of the operations: Since rank or select can be obtained from any of the operations depth, pre_rank, post_rank, pre_select, post_select, any balanced parentheses representation supporting any of these operations in time $O(c)$ requires $2n + 2n/w^{\Theta(c)}$ bits of space. Still, it would be good to show a lower bound for the more fundamental set of operations findopen, findclose, and enclose.

On the other hand, the complexity $O(\log n / \log \log n)$ is known to be optimal for several basic dynamic tree operations, but not for all. It is also not clear if the redundancy $O(n/r)$ achieved for the dynamic trees, $r = \log n$ for the simpler structure and $r = \log \log n / \log n$ for the more complex one, is optimal to achieve the corresponding $O(r)$ operation times. Finally, it would be good to achieve $O(\log n / \log \log n)$ time for all the operations or prove it impossible.

**Acknowledgments**

We thank Mihai Pătraşcu for confirming us the construction cost of his aB-tree and rank/select data structure \(^{[42]}\). And we thank him again for confirming us that the lower bound \(^{[39]}\) holds for balanced sequences.
