(Dated: July 1, 2010)

In high density QCD the hadron production stems from decay of mini-jets that have the transverse momenta of the order of the saturation scale. It is shown in this paper that this idea is able to describe in a unique fashion both the inclusive hadron production for $\sqrt{s} \geq 546$ GeV including the first data from LHC and the deep inelastic scattering at HERA. Recently reported data from ALICE, CMS and ATLAS including inclusive charged-hadron transverse-momentum and multiplicity distribution in $pp$ collisions are well described in our approach. We provide predictions for the upcoming LHC measurements.

I. INTRODUCTION

The first LHC data\cite{1-4} on inclusive hadron production call for a theoretical understanding of these processes based on QCD. At first sight the inclusive hadron production is a typical process that occurs at long distances where one has to use the non-perturbative methods of QCD. Therefore, the field of long distance processes seems to be a relevant subject to the domain of high-energy phenomenology with the main ingredients: soft Pomeron and secondary Reggeons. Such phenomenology is able to describe inclusive hadron production data (see Ref.\cite{5} and references therein) but cannot be considered satisfactory since both soft Pomerons and Reggeons cannot be explained in terms of QCD ingredients; quarks and gluons. It should be also mentioned that the increase with energy of the average transverse momentum of the produced hadron observed experimentally\cite{2, 3} cannot be explained in the Reggeon approach.

However, high density QCD\cite{6-12} leads to a completely different picture of inclusive hadron production. In this approach the system of parton (gluons) at high energy forms a new state of matter: Color Glass Condensate (CGC). In the CGC picture, at high energy the density of partons $\rho_p$ with the typical transverse momenta less than $Q_s$ reaches a maximum value, $\rho_p \propto 1/\alpha_s \gg 1$ ($\alpha_s$ is the strong coupling constant). $Q_s$ is the new momentum scale (saturation momentum) that increases with energy. At high energies/small Bjorken-$x$, $Q_s \gg \mu$ where $\mu$ is the scale of soft interaction. Therefore, $\alpha_s(Q_s) \ll 1$ and this fact allows us to treat this system on solid theoretical basis. On the other hand, even though the strong coupling $\alpha_s$ becomes small due to the high density of partons, saturation effects, the fields interact strongly because of the classical coherence. This leads to a new regime of QCD with non-linear features which cannot be investigated in a more traditional perturbative approach.

In the framework of the CGC approach the secondary hadrons are originated from the decay of gluon mini-jets with the transverse momentum equal to the saturation scale $Q_s(x)$. The first stage of this process is under theoretical control and determines the main characteristics of the hadron production, especially as far as energy, rapidity and transverse momentum dependence are concerned. The jet decay, unfortunately, could be treated mostly phenomenologically. However, we can hope that the phenomenological uncertainties would be reduced to several constants whose values will be extracted from the experiment.

Actually, such a description has passed the first check with the experimental data: the KLN paper\cite{13} explains the main features of inclusive hadron production in heavy ion-ion and hadron-ion as well as proton-proton collisions\cite{14} at RHIC. In this paper we wish to improve the KLN approach by introducing two new elements: the probability to find gluon with fixed transverse momentum that describes the deep inelastic scattering (DIS) data and that satisfies the Balitsky-Kovchegov\cite{9, 11} non-linear equation; and a different description of inclusive hadron production at low transverse momenta of gluons. Over all success of our description indicates universality of the saturation physics which can be further tested at LHC and future collider experiment.

In the next section we discuss the $k_t$-factorization and main formulas that we use. In particular, we consider the interrelation between the color dipole scattering amplitude and the unintegrated gluon density that follows from the recent development of high density QCD\cite{15}. An important improvement here to the previous works based on the KLN approach is the explicit inclusion of the impact-parameter dependence of the saturation scale. Section III is devoted to comparison with the experimental data and to discussion of various predictions for higher LHC energies. As a conclusion, in Sec. IV we highlight our main results and predictions for LHC.
The gluon jet production in hadron-hadron collisions can be described by $k_t$-factorization given by [13],

$$
\frac{d\sigma}{dy \, d^2p_T} = \frac{2\alpha_s}{\alpha_s(2\pi)^2} \frac{1}{p_T^2} \int d^2\vec{k}_T \, \phi_G^{h_i}(x_1; \vec{k}_T) \phi_G^{h_i}(x_2; \vec{p}_T - \vec{k}_T),
$$

(1)

where $x_{1,2} = (p_T/\sqrt{s})e^{\pm y}$, and $p_T$ and $y$ is the transverse momentum and rapidity of the produced gluon jet. $\phi_G^{h_i}$ are the probability to find a gluon that carries $x_i$ fraction of energy with $k_T$ transverse momentum and $C_F = (N_c^2 - 1)/2N_c$ is the $SU(N_c)$ Casimir operator in the fundamental representation with the number of colors equals $N_c$.

For a proof of $k_t$-factorization see Ref. [17] and also Refs. [16–20] which confirm the former proof. We need to recall that the proof for the $k_t$-factorization was given for the scattering of a diluted system of partons, say for virtual photon, with a dense one. Our main idea is that we have gluon saturation for proton-proton scattering or in other words, we are dealing with interactions of two dense systems of partons (gluons). Therefore, the $k_t$-factorization has to be considered here as an assumption. It should be noticed that the proof given in Refs. [15–20] shows that the $k_t$-factorization is valid in the situation where two scales of hardness: the transverse momentum of the produced gluon ($p_T$) and the saturation scale are both larger than the scale of the soft interaction ($\mu$). For dense-dense system scattering we have actually three scales: $p_T$ and two saturation scales. However, only for the kinematic region where both $x_1$ and $x_2$ are small and for $p_T$ which is smaller than both saturation scales we have to make an assumption about $k_t$-factorization. In other cases that one of the saturation scales is small, we are dealing with diluted-dense system scattering. We believe that the $k_T$-factorization is currently the best tools at our disposal for the processes considered in this paper.

The unintegrated gluon density $\phi_G^{h_i}(x_1; \vec{k}_T)$ and color dipole-proton forward scattering amplitude $N(x_i, r_T; b)$ are related in a very specific way [13]. This relation reads as follows

$$
\phi_G^{h_i}(x_1; \vec{k}_T) = \frac{1}{\alpha_s(2\pi)^2} \int d^2\vec{b} \, d^2\vec{r}_T e^{i\vec{k}_T \cdot \vec{r}_T} \nabla_T^2 N_G^{h_i}(y_i = \ln(1/x_i); r_T; b),
$$

(2)

with

$$
N_G^{h_i}(y_i = \ln(1/x_i); r_T; b) = 2N(y_i = \ln(1/x_i); r_T; b) - N^2(y_i = \ln(1/x_i); r_T; b),
$$

(3)

where $N_G^{h_i}(y_i = \ln(1/x_i); r_T; b)$ is the dipole-hadron ($h_i$) forward scattering amplitude which satisfies the Balitsky-Kovchegov equation. In the above, $r_T$ denotes the transverse dipole size and $b$ is the impact parameter of the scattering.

Eq. (3) looks very natural at large $N_c$. Indeed, for the color dipole amplitude in the Glauber form $N = 1 - \exp(-\Omega/2)$ ($\Omega$ is the opacity), equation Eq. (3) leads to $N_G = 1 - \exp(-\Omega)$ as it should be for the scattering of the two dipoles of the same sizes. We recall that a colorless gluon-probe just creates such two quark-antiquark dipoles, and the $N_G$ is directly related to the gluon density.

Substituting Eq. (2) in Eq. (1), and after analytically performing some integrals, we obtain [13]

$$
\frac{d\sigma}{dy \, d^2p_T} = \frac{2C_F}{\alpha_s(2\pi)^2} \frac{1}{p_T^2} \int d^2\vec{b} \, d^2\vec{r}_T e^{i\vec{k}_T \cdot \vec{r}_T} \nabla_T^2 N_G^{h_1}(y_1 = \ln(1/x_1); r_T; b) \nabla_T^2 N_G^{h_2}(y_2 = \ln(1/x_2); r_T; |\vec{b} - \vec{B}|).
$$

(4)

In the above equation, $\vec{B}$ is the impact parameter between center of two hadrons and $\vec{b}$ is the impact parameter of the produced mini-jet from the center of the hadron, see Fig. 1.

**A. Choice of color dipole scattering amplitude**

As it can be seen from Eq. (4), we need here an impact-parameter dependent color-dipole forward amplitude. We will show later that the inclusion of the impact-parameter is very important in our approach and should not be

---

1 Ref. [21] states that Eq. (1) is not correct. Unfortunately, there is no discussions in the paper why their result is so different from the other published papers. However, Braun has recently shown that Ref. [21] actually leads to the $k_t$-factorization [22].
FIG. 1: Mini-jet production in hadron-hadron collisions in the transverse plane. The impact-parameter between two hadrons is $\vec{B}$.

The dipole-proton forward scattering amplitude $N(Y; r; b)$ (with $Y = \ln(1/x)$) can be in principle found by solving the perturbative nonlinear small-$x$ Balitsky-Kovchegov (BK) or Jalilian-Marian-Iancu-McLerran-Weigert-Leonidov-Kovner (JIMWLK) quantum evolution equations. Unfortunately, numerical solution to these non-linear equations in the presence of the impact-parameter is very challenging and is not yet available. Moreover, a numerical solution does not give us the full control on the phenomenological parameters that have been used and we certainly lose the transparency and simplicity of physical interpretation if we rely only on the numerical solutions. Therefore, we choose a different approach to the solution of the BK equation that was suggested in Ref. [24]. First, we recall that the BK equation predicts the geometric scaling behavior [25], namely the amplitude $N(Y; r; b)$ is not a function of three variables but it is a function of only one variable $Z_2 = r^2 Q_s^2(x) \cdot \ln^2 Z$ where $Q_s(x)$ is the saturation momentum. We also know the behavior of the scattering amplitude deeply in the saturation region ($Z \gg 1$)

$$N(Y; r; b) = 1 - \exp \left( - \frac{\chi(\gamma_{cr})}{2(1 - \gamma_{cr})} \ln^2 Z \right),$$

where $\chi(\gamma)$ is the BFKL kernel

$$\omega(\gamma) = \tilde{\alpha}_s \chi(\gamma) = \tilde{\alpha}_s \left\{ 2\psi(1) - \psi(\gamma) \right\} - \psi(1 - \gamma) \right\},$$

with a notation $\tilde{\alpha}_s = \alpha_s N_c / \pi$. In above, we define $\psi(x) = d \ln \Gamma(x) / dx$ and $\Gamma(x)$ is the Euler function. The parameter $\gamma_{cr}$ is the solution to the following equation

$$\frac{d\chi(\gamma_{cr})}{d\gamma_{cr}} = - \frac{\chi(\gamma_{cr})}{1 - \gamma_{cr}}.$$

In Ref. [26] a solution was found for the entire kinematic region for a simplified BFKL kernel, namely, instead of Eq. (6), the following kernel was used,

$$\omega(\gamma) = \tilde{\alpha}_s \begin{cases} \frac{1}{\gamma} & \text{for } Z = rQ_s(x) \leq 1; \\ \frac{1}{1 - \gamma} & \text{for } Z = rQ_s(x) > 1; \end{cases}$$

which describes only leading twist contribution to the full BFKL kernel of Eq. (6). The lesson from this solution is very instructive: for $r^2 Q_s^2(x) \leq 1$, the amplitude $N$ satisfies the DGLAP (BFKL) linear evolution equation with the

\begin{footnotesize}
\footnote{Notice that here we assumed that the geometric scaling is also valid in the presence of impact-parameter dependence of the saturation scale. It should be stressed that the proof of the geometric scaling behavior could be easily generalized to the case of the scattering amplitude that depends on the impact-parameter $b$. In the analytical solution of Ref. [26] which gives the theoretical basis for the chosen parametrization of the dipole-amplitude here, the $b$-dependence is taken into account, therefore, this solution gives a theoretical example of the general proof.}
\end{footnotesize}
boundary condition \( N(Y; r; b) = N_0 = \text{Constant} \) for \( r^2 = 1/Q_s^2(x) \) while for \( r^2 Q_s^2(x) > 1 \) we have solution that has the form of Eq. \( (5) \). Using these general features of the solution we choose the model suggested in Ref. \( \cite{27} \) which improves the earlier studies on this line \( \cite{24, 25} \). In this model the color dipole-proton forward scattering amplitude is given by

\[
N(Y; r; b) = \begin{cases} 
N_0 \left( \frac{Z}{s} \right)^{2(\gamma_s + \frac{1}{1-x} \ln \left( \frac{s}{r} \right))} & \text{for } Z = rQ_s(x) \leq 2; \\
1 - \exp \left( -A \ln^2 (BZ) \right) & \text{for } Z = rQ_s(x) > 2;
\end{cases} \tag{9}
\]

where the saturation scale \( Q_s(x; b) \) (denoted by \( Q_s(x) \) for brevity) is given by

\[
Q_s(x; b) = \left( \frac{x_0}{x} \right)^{\frac{1}{2}} \exp \left\{ -\frac{b^2}{4(1 - \gamma_{cr})B_{CGC}} \right\}. \tag{10}
\]

As we have already mentioned Eq. \( (9) \) as well as Eq. \( (10) \) has the form of the solution to the BK equation at a fixed QCD coupling. For \( Z < 1 \) the effective anomalous dimension \( \gamma_s + \frac{1}{1-x} \ln \left( \frac{s}{r} \right) \) with \( \gamma_s = 1 - \gamma_{cr} \) follows from the BFKL (and DGLAP) equation in the vicinity of the saturation line (see Ref. \( \cite{24} \) for the detailed derivation).

For the leading order BFKL kernel with frozen QCD coupling the parameters of Eq. \( (9) \) and Eq. \( (10) \) have the following values

\[
1 - \gamma_{cr} = 0.63; \quad \lambda = \tilde{\alpha}_s \frac{\chi(\gamma_{cr})}{1 - \gamma_{cr}} = 4.88 \tilde{\alpha}_s; \quad \kappa = \frac{\chi''(\gamma_{cr})}{\chi'(\gamma_{cr})} = 9.9. \tag{11}
\]

The parameters \( A \) and \( B \) can be found from matching of \( N \) and its logarithmic derivatives at \( Z = 2 \) while \( N_0 \) and \( B_{CGC} \) remain fitting parameters.

Generally speaking, the model given by Eqs. \( (9)\)-(11) can be viewed as an approximation to the solution of the BK equation. However, because the \( b \)-dependent numerical solution to the BK equation is not yet available \( \cite{23} \), we are doomed to resort to such an approximation. This model differs from other saturation models on the market since it apparently incorporates all known properties of the exact solution to the BK equation including the \( b \)-dependence of the scattering amplitude (see Ref. \( \cite{20} \)).

The advantage of Eqs. \( (9)\)-(11) is that these equations give the possibility to take into account the next-to-leading order (NLO) corrections. Two features of the non-linear low-\( x \) equations can be calculated in the next-to-leading order using the kernel of the linear equation: the energy behavior of the saturation scale \( \cite{24, 25, 32, 33} \) and the behavior of the solution deeply in the saturation domain \( \cite{26} \). It has been shown that the NLO correction to the BFKL equation (and therefore BK equation) are large and it changes considerably the value of \( \lambda \) from \( \lambda \approx 0.9 \) to \( \lambda \approx 0.3 \) for \( \tilde{\alpha}_s = 0.2 \) \( \cite{25, 30} \). The value of \( \gamma_s \) in Eq. \( (10) \) is also affected by the NLO corrections as well as by the running QCD coupling \( \cite{29, 31} \). It is therefore generally believed that the higher order corrections to the NLO BK equation should be important. The actual calculation of higher-order corrections to these non-linear evolution equations still remains as a challenge. Since the general behavior of the amplitude Eq. \( (9) \) will remain unchanged after inclusion of higher-order corrections, we effectively incorporate the higher-order corrections by taking the value of parameters \( \lambda, \gamma_s, N_0 \) and \( B_{CGC} \) obtained from a fit to the DIS data at low Bjorken-\( x \) \( x < 0.01 \) \( \cite{27} \). Therefore, the saturation model that we use here also gives a good description of the HERA data at low-\( x \). In order to simulate the behavior of gluon density at large \( x \rightarrow 1 \), we product the unintegrated gluon density with \( (1 - x)^4 \) as prescribed by quark counting rules \( \cite{34} \). This factor stems from the correct description of the HERA data on DIS.

### B. Physical observables

The rapidity distributions of the mini-jets can be calculated using Eq. \( (11) \).

\[
\frac{dN_{\text{mini-jet}}}{d\eta} = h[\eta] \frac{1}{\sigma_{\text{nd}}} \int d^2 p_T \frac{d\sigma}{dy d^2 p_T} [\text{Eq. } (1)], \tag{12}
\]

where \( \eta \) is the pseudorapidity and \( h[\eta] \) is the Jacobian which takes account of the difference between rapidity \( y \) and the measured pseudo-rapidity \( \eta \) \( \cite{13} \).

\[
h(\eta, p_T) = \frac{\cosh \eta}{\sqrt{\frac{m_{\text{jet}}^2 + p_T^2}{p_T^2} + \sinh^2 \eta}}, \tag{13}
\]
where $m_{jet}$ is the mass of mini-jet. One also has to express rapidity $y$ in Eq. (1) in terms of pseudo-rapidity $\eta$. This relation is given by

$$
y(\eta, p_T) = \frac{1}{2} \ln \left( \frac{m_{jet}^2 + p_T^2}{\eta^2} + \sinh^2 \eta \right).
$$

The distribution Eq. (1) refers to the radiated gluons with zero mass while what is actually measured experimentally is the distribution of final hadrons. We therefore should make an assumption about hadronization of gluons which is entirely non-perturbative process that has to be modeled in any approach due to lack of understanding of the confinement of quarks and gluon in QCD. However, it is well-known that the general assumption about hadronization leads to the appearance of mass of the mini-jet which is approximately equal to $m_{jet}^2 \approx 2\mu p_T$ (see Ref. [13]) where $\mu$ is the scale of soft interaction. The mini-jet mass effectively incorporates the non-perturbative soft hadronization in the pseudo-rapidity space. Accordingly, one should also correct the kinematics everywhere in Eq. (1) due to the presence of a non-zero mini-jet mass, namely replacing $p_T \rightarrow \sqrt{p_T^2 + m_{jet}$ in $x_1, x_2$ and also in the denominator of $1/p_T^2$. One can see that Eq. (1) has infrared divergence at $p_T \rightarrow 0$ for the kinematic region $k_T \gg p_T$ when $m_{jet} = 0$. In Ref. [13] it was suggested to integrate over $k_T \leq p_T$. The reason is that such an integration reproduces the factorization formula at large $p_T \gg \mu$ for the DGLAP evolution. However, as we explained above it is more natural to replace $p_T$ by $\sqrt{p_T^2 + m_{jet}^2}$ in Eq. (1) which consequently also regulates the denominator due to the presence of a non-zero mini-jet mass (the appearance of such mass is the general property of the hadronization processes).

In Eq. (12) we do not take into account the fragmentation of the produced gluon (mini-jet) into hadrons. We rely on the principle of Local Parton-Hadron Duality (LPHD) [35, 36] namely the form of the rapidity distribution will not be distorted by the jet decay and only a numerical factor will differ the mini-jet spectrum from the hadron one. We believe that it is better to use the LPHD scheme than to deal with the fragmentation’s functions for which we have no theoretical justifications at low $p_T$. It should be stressed that the same idea has been used in the KLN approach which describes the rapidity distribution of heavy-ion collisions data in a wide range of energies. This idea has also worked perfectly in $e^+e^-$ annihilation into hadrons [35, 36].

We should stress that the value of inelastic non-singlet diffractive (NSD) cross-section $\sigma_{nsd}$ cannot be calculated in our approach and has to be taken from the fragmentation models such as in Refs. [35, 36]. The NSD cross-section $\sigma_{nsd}$ is defined as $\sigma_{nsd} = \sigma_{tot} - \sigma_{el} - \sigma_{sd} - \sigma_{dd}$ where $\sigma_{el}$, $\sigma_{sd}$ and $\sigma_{dd}$ are the cross sections of elastic, single and double diffraction, respectively. However, the experimental data on $\sigma_{dd}$ is very limited [35, 36]; $\sigma_{el}$ is measured with rather large errors [35, 41] and even for the total cross-section $\sigma_{tot}$ [41] we have two values at the Tevatron energies [42]. Therefore, we should stress that in this way we can only predict $dN_{ch}/dy$ rather than $dN_{ch}/dy$. In order to overcome this problem, here we choose a different strategy: the physical meaning of $\sigma_{nsd}$ in Eq. (12) is the area of interaction which can be calculated in our approach. Indeed, using Eq. (4) one can calculate the average impact parameter for the inclusive production of the mini-jet

$$
\langle b_{jet}^2 \rangle = \frac{\int \frac{d^4p_T}{p_T} \int d^2\vec{b} \int d^2\vec{B} \int d^2r_T \left( b^2 + |\vec{b} - \vec{B}|^2 \right) e^{i\vec{k}_T \cdot \vec{r}_T} \nabla_T^2 N_G^h \left( y_1 = \ln(1/x_1); r_T; |\vec{b} - \vec{B}| \right) \nabla_T^2 N_G^{h_2} \left( y_2 = \ln(1/x_2); r_T; |\vec{b} - \vec{B}| \right)}{\int \frac{d^4p_T}{p_T} \int d^2\vec{b} \int d^2\vec{B} \int d^2r_T e^{i\vec{k}_T \cdot \vec{r}_T} \nabla_T^2 N_G^h \left( y_1 = \ln(1/x_1); r_T; b \right) \nabla_T^2 N_G^{h_2} \left( y_2 = \ln(1/x_2); r_T; |\vec{b} - \vec{B}| \right)}.
$$

The NSD cross-section $\sigma_{nsd}$ is then equal to the average interaction area up to a constant $\sigma_{NSD} = M \pi \langle b_{jet}^2 \rangle$. The pre-factor $M$ will be determined and discussed later. We should draw the reader attention that such a picture for the inelastic cross-section corresponds, in a sense, to the geometric-scaling behavior of the scattering amplitude. Indeed, the high-density QCD deals with the partonic wave-function of a fast hadron which describes a coherent system of partons (quarks and gluon). At high energy the coherence of partons is destroyed during a short time, and the partons, distributed as in the wave function, are produced. These partons contribute to the inelastic cross-section. The elastic (diffractive) cross-section corresponds to a rare event where the target does not destroy (or destroyed only partially) the coherence of the gluons in the wave-function (see for example Ref. [13]). The geometric-scaling behavior as well as the saturation phenomenon, in general, means that partons are distributed uniformly in the transverse plane in the wave-function of a fast hadron in such way that the wave-function generates a uniform distribution of the produced partons after the interaction with the target. Therefore, the NSD (inelastic) cross-section is proportional to the area
occupied by partons. Actually, such a view on the inelastic cross-section was suggested in the KLN approach \cite{13} but for nucleus-nucleus and hadron-nucleus collision. Therefore, we generalize this approach to hadron-hadron scattering. We believe that if the LHC data at higher energy will support this idea, it will be a strong argument in favor of the saturation approach. The relation $\sigma_{NSD} = \sigma_{el} - \sigma_{d} - \sigma_{dd}$ shows the obvious fact that the prediction for elastic and diffractive scattering are much more complicated and less transparent in the saturation approach. This is well-known fact at least for diffractive production \cite{14}.

The average transverse momentum of the mini-jet is defined in the usual way:

$$\langle p_{\text{jet}, T} \rangle = \int d\eta h[\eta] \int d^2 p_T |p_T| \frac{d\sigma}{d\eta d^2 p_T} \left[ \text{Eq. (1)} \right] / \int d\eta h[\eta] \int d^2 p_T \frac{d\sigma}{d\eta d^2 p_T} \left[ \text{Eq. (1)} \right].$$

(16)

The advantage of this quantity is that it can be calculated without usual uncertainties associated with the soft interaction physics. The average transverse momentum of the jet can be directly related to the saturation scale via Eqs. (1,9,16) and it has the following simple form at large $Q_s \gg m_{\text{jet}}$,

$$\langle p_{\text{jet}, T} \rangle \propto \frac{Q_s}{\ln\left(Q_s^2/m_{\text{jet}}^2 + 1\right) + Q_s},$$

(17)

where the parameter $Q$ is of order one and takes into account the contribution of integrals in Eq. (16) for $p_T > Q_s$.

In order to calculate the transverse momentum of hadrons which is measured experimentally, we need to recall that $p_{\text{hadron}, T} = z p_{\text{jet}, T} + p_{\text{intrinsic}, T}$ which leads to

$$\langle p_{\text{hadron}, T} \rangle = \sqrt{(zp_{\text{jet}, T})^2 + \langle p_{\text{intrinsic}, T} \rangle^2},$$

(18)

where $z$ is the fraction of energy of the jet carried by the hadron. $\langle p_{\text{intrinsic}, T} \rangle$ is the average intrinsic transverse momentum of the hadron in the mini-jet. In other words, this is the transverse momentum of the hadron in the mini-jet that has only longitudinal momentum.

In the framework of the LHPD, the $p_T$ spectrum of the produced hadron is equal to

$$\frac{dN_{\text{hadron}}}{d^2 p_T} = \int d\eta h[\eta] \frac{1}{\sigma_{n,sd}} \frac{d\sigma}{d\eta d^2 p_{\text{jet}, T}} \left[ \text{Eq. (1)} \right. \left. \text{with } p_{\text{jet}, T} = p_T/z \right],$$

(19)

where in the above $p_T$ is the transverse momentum of the produced hadron.

In the CGC scenario, the gluon saturation scale is proportional to the density of partons (see Refs. \cite{13, 14}). The parton density is proportional to the multiplicity and, therefore, we can use the following expression for the saturation momentum in the event with the multiplicity of the hadrons $n$:

$$Q_s(x) \rightarrow Q_s(n; x) = \frac{n}{\langle n \rangle} Q_s(x),$$

(20)

where $\langle n \rangle$ is the average multiplicity that has been measured in inclusive production without any selection related to multiplicity and $Q_s(x)$ is the saturation scale for inclusive hadron production or $Q_s(n = \langle n \rangle > x)$. Using Eq. (17) again one can relate the saturation scale at a given multiplicity to the average transverse momentum of the produced mini-jets at large $Q_s \gg m_{\text{jet}}$,

$$\langle p_{\text{jet}, T} \rangle \propto \frac{Q_s(n; x)}{\ln\left(Q_s^2(n; x)/m_{\text{jet}}^2 + 1\right) + Q_s}.$$  

(21)

III. COMPARISON WITH THE EXPERIMENTAL DATA AND PREDICTION FOR HIGHER ENERGIES

In the derivation of the $k_t$-factorization it was assumed that the strong coupling $\alpha_s$ is a constant. As a generalization, in Eq. (1) we replace $\alpha_s$ by $\alpha_s(p_T)$, where $p_T$ is the transverse momentum of the mini-jet and in Eq. (2) we also replace $1/\alpha_s$ by $1/\alpha_s(Q_s(x))$ where $Q_s(x)$ is the saturation scale in hadron $h$. This seems to be the most natural way of introducing the running coupling which still preserves the form of Eq. (1) apart from the over-all factor outside of integrals which now depends on kinematics. Indeed the inclusion of running strong-coupling leads to improvement of our description. For the running strong coupling $\alpha_s$, we employ the same scheme as used by the KLN approach.
namely we use the leading-order running coupling with smooth freezing below the virtuality \( Q^2 \approx 0.8 \text{ GeV}^2 \) at the value of \( \alpha_s^{IR} \approx 0.5 \). This is in accordance with many evidence from jet physics which indicates that the QCD coupling may stay reasonably small, \( \alpha_s^{IR} = 0.4 \div 0.6 \) in the infrared region \([45]\).

The impact-parameter dependence in our formulation emerges from the employed impact-parameter dependent saturation scale, see Eqs. \([9,10]\). In this model, the profile of the saturation scale in the proton is assumed to be a Gaussian. It is difficult to interpret the parameter \( \eta = 0, 8 \text{ GeV} \) dependence of the anomalous dimension. Nevertheless, in order to have a intuitive picture, one may take \( 2B_{CGC} \) as relative average squared transverse radius of the proton. The value of \( B_{CGC} = 7.5 \text{ GeV}^{-2} \) was obtained as a fit in order to describe the slope of \( t \)-distribution of diffractive processes at HERA \([27]\), which in turn fix the normalization of the color dipole-proton cross-section. In Fig. 2 (right), we show the average impact parameter of jet \( \langle b^2 \rangle \) from center of the hadrons. Notice that for obtaining \( \langle b^2 \rangle \), the over-all coefficient in Eq. \([15]\) will be dropped out and we are left with no free parameter. The \( \langle b^2 \rangle \) is about \( 2.5B_{CGC} \) and it slightly increases with energy.

The mass of mini-jet \( m_{jet} \) is proportional to the saturation scale \( m_{jet}^2 \approx 2\mu_{PT} \) since the typical transverse momentum of the mini-jets is the saturation scale \( Q_s \) and \( \mu \) is the scale of soft interaction. The saturation scale in the CGC-b model Eq. \([8]\) changes slowly with energy. For our interested range of energy considered in this paper at midrapidity \( \eta = 0 \) and \( p_T = 1 \text{ GeV} \) for the central collisions \( b = 0 \), we have \( Q_s \approx 0.6 \div 0.8 \text{ GeV} \). Taking the scale of soft interaction equal to pion mass \( \mu \approx m_\pi = 0.14 \text{ GeV} \), we have \( m_{jet} \approx 0.4 \div 0.5 \text{ GeV} \). We will first assume a fixed value for the mini-jet mass \( m_{jet} = 0.4 \text{ GeV} \). To estimate the effect of the mini-jet mass, we will later consider a case with a different value for \( m_{jet} \).

In order to obtain the multiplicity distribution of hadrons in \( pp \) collisions from the corresponding mini-jets production cross-section Eqs. \([11,12]\) we have to fix some unknown parameters. First, based on the gluon-hadron duality, the rapidity distribution of hadron and radiated mini-jets can be different by a factor \( C \). Second, although the \( K_t \)-factorization incorporates the small-\( x \) evolution taking into account the higher-order gluon scatterings and non-linear gluon recombination effects, nevertheless given that we resort to a phenomenological color-dipole model, there might be still some extra contributions which are missed in our formulation. The discrepancy between the exact calculation and our formulation can be then effectively taken into account with a extra \( K \)-factor. Finally, in order to obtain the charged-particle multiplicity, we should divide the mini-jet cross-section with non-singlet diffractive cross-section which as we already discussed is obtained via \( \sigma_{nsd} = M \pi \langle b^2 \rangle \) with a new unknown dimensionless parameter \( M \). Fortunately, these three unknown pre-factors \( C, K \) and \( M \) appear as a product and can be reduced to only one unknown.

![FIG. 2: Right: shows the average impact parameter of the produced mini-jet \( \langle b^2 \rangle \) given by Eq. \([16]\) as function of energy. Left: The comparison with the experimental data and prediction for \( dN_{ch}/dy \) using Eq. \([12]\) with \( \sigma_{nsd} = M \pi \langle b^2 \rangle \) for \( \eta < 2.4 \). The curves are normalized by data at \( \sqrt{s} = 546 \text{ GeV} \), see the text for the details. The experimental data are from Refs. \([1,2,46]\). The error bars on the UA5 and ALICE data points are statistical. We show only systematic errors for the CMS data points.](image-url)
FIG. 3: Right: Energy dependence of the charged hadrons multiplicity in the central region of rapidity \( \eta = 0 \) in \( pp \) collisions. The theoretical curve (Saturation model LR) is our prediction coming from the saturation model for the NSD interactions. The band indicates about 2\% theoretical error. The total theoretical uncertainties is less 6\% at high energies (see the text for the details). We also show the KLN prediction [13] with the same error band as ours. Left: Our prediction for the energy dependence of the average transverse momentum of charged hadrons. The CMS data [2] points and the theoretical curves in the left panel are for \( |\eta| < 2.4 \). The experimental data are from Refs. [2, 4, 46–50]. The experimental error bars indicate systematic uncertainties.

parameter which will be determined with a fit to the experimental data for the charged particle multiplicity \( \frac{dN_{ch}}{d\eta} \) at midrapidity for the lowest energy considered here \( \sqrt{s} = 546 \) GeV. Therefore, we obtain \( \frac{KC}{M} = 2.32 \) at \( \sqrt{s} = 546 \) GeV. We assume that this over-all normalization factor is energy-independent. We expect that the energy-dependence of the normalization factor to be proportional to \( 1 + O(1/\ln(1/x)) \). Then for higher energy \( \sqrt{s} > 546 \) GeV, we do not have any free parameters in our calculation and our results may be considered as predictions of the model. Notice that we have employed a color-dipole model that its free parameters was obtained from a fit to the HERA data for \( x_B < 0.01 \) and \( Q^2 \in [0.25, 45] \), therefore our formulation is less reliable at lower energies (now used here). In Fig. 2 (left), we show the charged multiplicity distribution for \( pp \) collisions at various energies. Our model gives a good description of all available data for \( \sqrt{s} \geq 546 \) GeV including the recently released data from ALICE [1], CMS [2] and ATLAS [3] at 0.9 and 2.36 TeV. We also show our predictions for the LHC energies at 7, 10 and 14 TeV. It is seen that as the energy increases the peak of rapidity distribution at forward (backward) becomes more pronounced. This effect has been also observed in Ref. [51] where it was shown that the rapidity dependence of the invariant cross-section for both identified hadrons and direct photon has a peak at forward rapidities and this peak will be further enhanced by saturation effects [51].

In Fig. 3 (right) we show the charged-hadron pseudorapidity density in the central region \( \eta = 0 \) as a function of center-of-mass energy in \( pp \) collisions. Notice that since our prescription is valid only for the NSD interactions we do not show the corresponding data for the inelastic event selection. We have also shown recently reported charged-particle pseudorapidity density from ALICE [4] at 7 TeV in \( |\eta| < 1 \) for inelastic collisions with at least one charged particle in that region (denoted by INEL > 0). Again this point is out of the scope of our calculation and we did not expect to explain it.

The main source of possible theoretical error in our calculation are due to the uncertainties associated with assuming a fixed value for the mini-jet mass for all energies and the uncertainty in value of energy-independent normalization factor \( KC/M \) obtained from a fit. The value of mini-jet mass is controlled by the saturation scale and as we already discussed, it can be \( m_{\text{jet}} \leq 0.65 \) GeV for our interested range of energy here. Notice that the saturation scale in our model varies very slowly with energy. The upper limit of the theoretical uncertainty band in Fig. 3 (right) corresponds to a higher mini-jet mass \( m_{\text{jet}} = 0.5 \) GeV. The experimental systematic and statistical errors in the data point taken for fixing the normalization also induce uncertainty in the value of pre-factor \( KC/M \) obtained from a fit. This error is included in the band shown in Fig. 3 (right) and is less than the uncertainties coming from modeling the mini-jet mass. Overall we expect less than 6\% theoretical error in our calculation at higher energies.
Our approach improves saturation based (KLN approach) calculation\cite{13} in several ways, including: we used a correct relation between the unintegrated gluon-density and the forward dipole-nucleon amplitude Eqs (23) in the $k_t$-factorization Eq (1). As it is seen this relation is not a simple Fourier transform of the dipole-amplitude which is commonly used in literature and also depend on the impact-parameter. The impact-parameter dependence in these equations is not trivial and in principle should not be assumed as an over-all factor. We then employed an impact-parameter dependent saturation model which was obtained from a fit to low Bjorken-$x$ HERA data. In this sense, we had no freedom in modeling the saturation physics compared to the KLN approach. Moreover, since we have an impact-parameter formulation here, we could calculate the average relative interaction area at higher energies and thereby could also determine the relative increase of the NSD cross-section. It should be recalled that in the KLN approach the information about $\sigma_{\text{nsd}}$ was taken from the models for the soft high-energy interactions which is alien to the saturation approach. In both approaches, lower energy data for pp was used to fix the overall normalization factor. Therefore, we expect that the discrepancies between our predictions and the KLN to be more pronounced at higher energies. This is indeed the case as it can be seen in Fig. 3.

The average transverse momentum of charge hadrons can be obtained from Eq. (18). In Eq. (18), the average intrinsic transverse momentum of hadron has a purely non-perturbative origin and is due to the finite-size effect of hadrons. We take $\langle p_{\text{intrinsic},T} \rangle$ equal to the pion mass, the scale of soft-interaction $\mu = m_\pi$ throughout this paper. In order to obtain the average transverse momentum of charge hadrons, we need also to know the value of the average momentum fraction of mini-jets carried by the hadrons $\langle z \rangle$. It is seen from Fig. 3 (left) that an average value of $\langle z \rangle = 0.48 \pm 0.5$ is remarkably able to describe the average transverse momentum of charge hadrons in a wide range of energies. Our theoretical curves and CMS data\cite{2} are for the range $|\eta| < 2.4$. One may also estimate the value of $\langle z \rangle$ from the fragmentation functions, having in mind that the $\langle z \rangle$ for mini-jets in parton-hadron duality picture is not necessarily the same as the corresponding average of fragmentation momentum of the produced gluons in the parton model. Nevertheless, employing recently developed AKK08 fragmentation functions\cite{52} for charged hadrons production from a gluon, one obtains $\langle z \rangle = 0.5$ on average over low $p_T$ within the range of $1 < p_T$ [GeV] $\leq 2$ (AKK’s fragmentation is valid only for $Q > 1$ GeV). In order to further test the validity of the value $\langle z \rangle \approx 0.5$ for the mini-jets, we show in Figs. 4 (top panel) our predictions obtained from Eq. (19) for the differential yield of charged hadrons in the range $|\eta| < 2.4$ and at various $|\eta|$ bins for $\sqrt{s} = 2.36$ TeV. The experimental data are recently reported from CMS collaboration\cite{2}. It is seen that our results is in quite good agreement with experimental data. We recall again that the pre-factor in Eq. (19) is the same as what we already fixed with experimental multiplicity data at low-energy $\sqrt{s} = 5.46$ GeV at $\eta = 0$. Therefore, we have no free parameters in obtaining the theoretical curves in Figs. 4 (top). In Figs. 4 (top), we have also shown our predictions for $\sqrt{s} = 7$ and 14 TeV. The fact that our model reasonably works at low $p_T$ (for $\sqrt{s} = 2.36$ TeV) is due to the fact that the saturation scale is rather large at low $p_T$, for $p_T \approx m_\pi$. 

FIG. 4: The differential yield of charged hadrons for $|\eta| < 2.4$. The experimental data are from CMS\cite{2} at 2.36 TeV for $|\eta| < 2.4$. We show also our theoretical predictions for 7 and 14 TeV with $\langle z \rangle = 0.5$ and $m_{\text{jet}} = 0.4$ GeV. The experimental error bars shown are systematic and statistical errors added linearly.
we have $Q_s \approx 1$ GeV in the central rapidity region. Notice that the LPHD in the simplified form that has been used here, is less reliable at higher $p_T$ and one should then somehow model the fragmentation of mini-jets into hadron.

In Fig. 5 it is seen a peculiar peak of the charged hadrons production rate at low $p_T \approx 0.2$ GeV. Actually the appearance of such a peak is expected in our formulation. Notice that from Eq. (12) the differential yield of charged hadrons has a form $\frac{d^2N}{d\eta dp_T} \propto \frac{2\pi p_T}{p_T^2 + (z)^2 m_{\text{jet}}^2} F(x_1,x_2,p_T)$ where $F$ is an analytic function. At $p_T = 0$ trivially we have

FIG. 5: Upper panel: The differential yield of charged hadrons in various $|\eta|$ bins for $\sqrt{s} = 2.36$ TeV. The experimental data are from CMS [2]. We also show our predictions for 7 TeV and 14 TeV with $< z >= 0.5$ and $m_{\text{jet}} = 0.4$ GeV. The experimental error bars shown are systematic and statistical errors added linearly. Lower panel: The differential yield of charged hadrons for $|\eta| = 0.1$ for two different value of mini-jet masses $m_{\text{jet}}$. The inserted plot in the lower panel figure shows the charged hadrons multiplicity again for two values of $m_{\text{jet}}$ for the same energy.
FIG. 6: The average transverse momentum of charged hadrons as a function of the number of charged particles for events with \( n_{\text{ch}} \geq 1 \) within the kinematic range \( p_T > 500 \text{ MeV} \). The experimental data are from ATLAS for \( \sqrt{s} = 0.9 \text{ TeV} \) and \( |\eta| < 2.5 \). The theoretical curves was obtained for \( |\eta| = 0 \) and with the same kinematic constraint \( p_T > 500 \text{ MeV} \) at various energies for two value of \( \langle z \rangle = 0.48, 0.5 \) corresponding to the dashed and the solid lines, respectively. We only show the systematic experimental errors.

In order to see more clearly the effect of the mini-jet mass \( m_{\text{jet}} \), in Fig. 5 (down) we compare the differential yield of charged hadrons calculated with two different values for the mini-jet mass \( m_{\text{jet}} = 0.4 \) and \( 0.8 \text{ GeV} \). We also show the multiplicity distribution in the inserted panel in Fig. 5. As we already pointed out, the mass of mini-jet is controlled by the saturation scale. Obviously from the saturation scale in our model, \( m_{\text{jet}} = 0.8 \text{ GeV} \) is too large. Therefore, it is not surprising that the description of experimental data for both multiplicity and spectra worsened for such a large mini-jet mass. Nevertheless, it is obvious from Fig. 5 that the position of the peak moves to a higher \( p_T \) for a larger mini-jet mass. Note that the CMS experimental data \(^{2}\) at \( \sqrt{s} = 2.36 \text{ TeV} \) for the average transverse momentum of charged hadrons can be reproduced with \( \langle z \rangle = 0.37 \) when \( m_{\text{jet}} = 0.8 \text{ GeV} \). Again the position of the peak in spectra is consistent with simple formula \( p_T \simeq m_{\text{jet}} \langle z \rangle \approx 0.3 \) in accordance with the full calculation shown in Fig. 5. Notice that in our model calculation shown in Fig. 5 (top), the position of the peak persists at various rapidities bin (and energies) since we have taken a fixed \( m_{\text{jet}} \) for simplification. To conclude, a precise measurement of the differential yield of charged hadrons at low \( p_T \) for higher energies at LHC will provide valuable information about the mini-jet mass and its connection with the gluon saturation.

In Fig. 5 (top), we also showed our theoretical predictions for 7 and 14 TeV with a fixed \( \langle z \rangle = 0.5 \) and \( m_{\text{jet}} = 0.4 \text{ GeV} \). As we already explained due to the possible increase of mini-jet mass at higher energies, the position of peak may slightly move to higher \( p_T \) within 0.2 \( \leq p_T \leq 0.3 \) at \( \sqrt{s} = 14 \text{ TeV} \).

In Fig. 6 we show the average transverse momentum of charged hadrons as a function of the number of charged particles for events within the kinematic range \( p_T > 500 \text{ MeV} \). The experimental data are from ATLAS for \( \sqrt{s} = 0.9 \text{ TeV} \). The saturation scale at various multiplicity is given by Eq. (20) where \( \langle n \rangle \) can be conceived as a normalization and its value is taken to be the charged multiplicity at midrapidity \( \eta = 0 \) for a given center-of-mass energy (shown in Fig. 3 (right)). In order to implement in our calculation the experimental kinematic constrain \( p_T > 500 \text{ MeV} \) on the measured events, we impose that \( \langle p_{\text{intrinsic},T} \rangle > 500 \text{ MeV} \). The \( \langle p_{\text{intrinsic},T} \rangle \) has a purely non-perturbative origin.
and can be of order of hadron mass. To this end, we take \( \langle p_{\text{transverse}} \rangle = \frac{m_\rho + m_k}{2} \) where the mass of \( \rho \) and \( k \) mesons are \( m_\rho = 775 \text{ MeV} \) and \( m_k = 497 \text{ MeV} \), respectively. In Fig. 6 we show \( \langle p_T \rangle \) for two values of \( z \). It is seen that our model is able to give a very good description of the ATLAS data. We have also shown in the same plot, our predictions for the higher LHC energies.

The general behavior of the theoretical curves shown in Fig. 4(left) and Fig. 5 for the average transverse momentum of the produced hadrons is in accordance with a simple formulas given in Eqs. (17,21) showing a clear connection between the gluon saturation and the measured transverse momentum of charged hadrons.

IV. CONCLUSION

In high density QCD the main source of hadron production is the decay of gluon mini-jets with the transverse momentum of order of the saturation scale. This viewpoint is based on the fact that the system of partons (gluons) creates a new state of matter, the so-called Color Glass Condensate, in which the gluon density reaches the limited values of the order of \( 1/\alpha_s \) with new typical transverse momentum (the saturation scale). We developed a model that includes the gluon saturation and demonstrated that this model is able to describe both the inclusive hadron production at high energies including the first data from the LHC and the deep inelastic scattering data from HERA in a unique fashion.

We predicted an increase of \( dN_{\text{ch}}/d\eta \mid_{\eta=0} \), mean transverse momentum and the multiplicity of produced charged hadrons with energy which is in accordance with the first LHC data measured by ALICE [1,2], CMS [3] and ATLAS [4] collaboration, see Figs. 2,3,6. In the framework of high density QCD all these phenomena are closely related to the growth of the saturation momentum as a function of energy and of density of partons. It should be stressed that the other high-energy phenomenological approaches [5] cannot describe the dependence of the average transverse momentum of the produced hadron on energy and hadron multiplicities.

We showed that recently reported data by the CMS collaboration [2] on the differential yield of charged hadrons at low \( p_T \) for \( \sqrt{s} = 2.36 \text{ TeV} \) reveal an interesting information on the mini-jets production and its connection with the saturation. We showed that the appearance of a peak in differential yield of charged hadrons at low \( p_T \) is closely related to the mini-jet mass and the value of the saturation scale.

We provided various predictions for the upcoming LHC measurements at higher energies in \( pp \) collisions. We believe that this paper will be useful for the microscopic interpretation of the upcoming LHC data and will lead to a deeper understanding of the hadron interactions at high energy in the framework of QCD.

Concluding this paper we would like to answer the question: what can be here considered as a possible signal of the saturation (CGC) which are not contaminated with the non-perturbative physics related to unknown confinement of quarks and gluon? The main non-perturbative parameter that we have to introduce is \( m_{\text{jet}} \). The rapidity distribution \( dN_{\text{ch}}/d\eta \mid_{\eta=0} \) of hadrons as well as the multiplicity dependence of \( < p_T > \) of hadrons as well as the multiplicity dependence of \( < p_T > \) and the rapidity dependence of the maximum in \( d^2N_{\text{ch}}/dp_Td\eta \) for \( p_T \) and \( \eta \). Two factors determine the behavior of the observables at \( p_T \) at \( \eta \), the suppression of the gluon densities in projectile and the increase of the saturation momentum in the target. Since the \( (1-x)^4 \) factor reflects the well-known behavior of the structure function \( F_2 \) at large-\( x \), this factor will be the same in all other approaches while the additional increase due to the energy dependence is a typical features of the saturation approach. Notice also that at LHC energy \( \sqrt{s} = 14 \text{ TeV} \), the contribution of \( (1-x)^4 \) correction of unintegrated gluon density within the rapidities region considered here (Fig. 2) is negligible and at 7 TeV this contribution is less than 5%.

The above discussion shows that the comparison of our prediction with the high LHC energy data will be crucial for our approach. We are happy to make predictions before the experimental data from the LHC at high energy. We believe that if the coming data confirms our predictions, this will be indeed a first important step toward discovery of the CGC phase of the matter at LHC. The fact that we had to introduce several phenomenological parameters reflects our lack of theoretical knowledge for quark and gluon confinement and cannot be overcome in any models. Our experience tells us that when the data for higher energies will be published a lot of phenomenological models will appear but the CGC (saturation) approach is the only one that gives the predictions. It has happened once for nucleus-nucleus scattering at RHIC and, we hope that the situation will repeat itself at the LHC.

The particle production scheme presented in this paper can be also applied to the calculation of inclusive hadron production in heavy ion collisions at LHC. We are currently working on this problem and plan to report on this in the near future.
