In connection with a new ongoing project, it recently came to the knowledge of the author group that a substantial proportion of the plasma samples used in our study had already been thawed prior to the conduct of our study. Prior thawing of these samples was done in connection with an earlier unrelated study conducted by other researchers. This new knowledge prompted an examination of whether, and how, this previous thawing of part of the samples in our study had an impact on the results and conclusions that we had reported in the article.

As can be seen in (the new) Corrigendum Table 1, for the first trimester samples the proportion that had not been thawed was 89% (297/333) in the control group, whereas in the case group only 21% (77/367) had not been thawed before; for the second trimester samples the proportion that had not been thawed was 89% (297/333) in the control group, whereas in the case group only 21% (77/367) had not been thawed before. As can be seen in the columns to the right in this table, plasma concentrations of EPA+DHA were substantially lower in samples that had been thawed. This applied to the right in this table, plasma concentrations of EPA+DHA were substantially lower in samples that had been thawed. This applied to both and second trimester samples, and patterns were similar for cases and controls.

Accounting for thawing by adjustment in a multivariable model

In Corrigendum Table 2, Panels A-i and B-i, we report associations between plasma fatty acids and early preterm risk using logistic regression to adjust for thawing and storing temperatures (see section 3.3 in original article). As we had reported in Table 2 Panel A of the original paper, for the 1st sample, before adjustment for thawing, women in the lowest quintile (Q1) appeared to have 5.54 times (95% confidence interval 3.86 to 8.02 to 15.79, p < 0.0001) increased odds of early preterm birth, whereas women in the second to the lowest quintile (Q2) appeared to have 2.05 (95% CI 1.36 to 3.09, p = 0.0006) times increased odds, compared to women in the aggregated highest three quintiles (Q3+Q4+Q5). In this new analysis, after adjustment for differential thawing and storing temperatures, the odds ratio estimates for the lowest quintile for the 1st sample attenuated from 5.54 to 1.29 times (95% confidence interval 0.73 to 2.23, p = 0.38) and from 2.05 to 0.84 (95% CI 0.47 to 1.49, p = 0.57), respectively, meaning that the observed associations for the 1st sample disappeared after this adjustment (Corrigendum Table 2, Panels A-i). For the 2nd sample (Panel B-i), before any adjustment, women in the lowest quintile appeared to have 9.33 times (95% confidence interval 6.42 to 13.74, p < 0.0001) increased odds of early preterm birth, whereas women in the second to the lowest quintile appeared to have 2.73 (95% CI 1.78 to 4.20, p < 0.0001) times increased odds, compared to women in the aggregated highest three quintiles. After the additional adjustment, however, the odds ratio estimates were attenuated from 9.33 to 2.13 times (95% confidence interval 1.18 to 3.79, p = 0.01) and from 2.73 to 1.12 (95% CI 0.57 to 2.14, p = 0.73), respectively. In the article, we had also reported on results obtained from analyses where the EPA+DHA measurements had been based on the mean of the 1st and 2nd sample. In these analyses, after co-variate adjustment, women in Q1 appeared to have a 10.27 times (95% confidence interval 6.80 to 15.79, p < 0.0001) increased risk, whereas women in Q2 appeared to have a 2.86 (95% CI 1.79 to 4.59, p < 0.0001) times increased risk of early preterm birth, compared to women in Q3+Q4+Q5; these results were reported in the abstract. However, when further adjustment is made for thawing and freezer temperatures, these two estimates changed to 1.42 (0.65 to 3.03, p = 0.4) and 1.11 (0.50 to 2.41, p = 0.8), respectively.
Limiting the analysis to only comprise plasma samples that had not been thawed prior to our study reduced numbers available for analysis, particularly in the case groups. Restriction resulted in the following estimates (adjusted for temperature differences): For the 1st sample (Corrigendum Table 2, Panel A-ii), the odds ratio for early preterm birth in the lowest quintile v. the aggregated highest three quintiles was 0.87 (95% CI 0.37 to 1.91, \( p = 0.7 \)), whereas the odds ratio for early preterm birth in the second to the lowest quintile v. the aggregated highest three quintiles was 0.85 (95% CI 0.40 to 1.72, \( p = 0.7 \)). For the 2nd sample (Panel B-ii), the corresponding figures were 1.95 (95% CI 0.98 to 3.78, \( p = 0.06 \)) and 1.23 (95% CI 0.58 to 2.50, \( p = 0.6 \)), respectively.

### Corrigendum Table 1
Sample treatment according of case and control status and in relation to EPA+DHA plasma concentrations.

| Prior thawings | Controls (n = 333) | Preterm cases (n = 367) | Mean of EPA+DHA% Controls Preterm cases |
|----------------|-------------------|------------------------|---------------------------------------|
| Number of thaws, sample 1 | n | % | n | % | Mean | SEM | Mean | SEM |
| 0 | 297 | 89 | 77 | 21 | 2.05 | 0.03 | 1.91 | 0.07 |
| 1 | 34 | 10 | 163 | 44 | 1.80 | 0.07 | 1.42 | 0.03 |
| 2+ | 2 | 1 | 127 | 35 | 1.22 | 0.18 | 1.32 | 0.03 |

| Number of thaws, sample 2 | n | % | n | % | Mean | SEM | Mean | SEM |
| 0 | 326 | 95 | 60 | 16 | 2.04 | 0.03 | 1.79 | 0.09 |
| 1 | 15 | 4 | 243 | 66 | 1.72 | 0.17 | 1.45 | 0.03 |
| 2+ | 1 | 0.3 | 127 | 35 | 1.22 | 0.18 | 1.32 | 0.03 |

### Corrigendum Table 2
Association between EPA+DHA concentrations and risk of early preterm birth. Shown are results for EPA+DHA measurements based on all 1st trimester samples (Panel A-i), based on 1st trimester samples but including only those samples that had never been thawed (Panel A-ii), based on all 2nd trimester samples (Panel B-i), and based on 2nd trimester samples but including only those samples that had never been thawed (Panel B-ii).

| Controls (n = 333) | Cases (n = 367) | Crude | Adjusted for thawing and temperature | Controls (n = 323) | Cases (n = 357) | Further adjusted for covariates |
|-------------------|----------------|-------|------------------------------------|-------------------|----------------|--------------------------------|

| 1 Analyses were adjusted for differences in thawings (0, 1, 2 times) and temperatures (-20, -80, -196°C); for the analyses restricted to samples that had never been thawed (Panels A-ii and B-ii), analyses were adjusted for temperatures. |
| 2 Further adjusted for covariates: Maternal age, maternal height, parity, maternal pre-pregnancy BMI, SES, cohabitation, residence and smoking; coded as in the original article. For the analyses restricted to samples that had never been thawed (Panels A-ii and B-ii), entering all the covariates simultaneously into the model was not possible due lack of convergence; however, taking the covariates in one by one was possible, and this had only limited effect on the estimates of association (data not shown but available from the authors). |
| 3 Cut points for defining quintiles of the samples that had never been thawed (Panel A-ii), are based on the ‘unselected’ controls (Panel A-i). |
Conclusions

Clearly, accounting for thawing substantially affected all estimates. Notably, all associations for the early sample were attenuated to include the null, whereas an association – albeit severely attenuated compared to the initially reported association – seemed to remain for the mid-pregnancy sample with a doubling of the risk in the lowest quintile compared to the aggregated highest three quintiles. These patterns are still compatible with a preventive effect of EPA+DHA against preterm birth in women with a low intake, and with the possibility that the time dynamic of this relationship may be a fast one as seen in a randomized controlled trial [1] (see Figures 1 and 2 and discussion on page 1948).

We recommend that the study be replicated based on other materials.
