Supporting Information

ABSTRACT: Seven phenylalanine derivatives with small ortho substitutions were genetically encoded in Escherichia coli and mammalian cells at an amber codon using a previously reported, rationally designed pyrrolysyl-tRNA synthetase mutant (PyRS-(N346A/C348A)) coupled with tRNAPyl. Ortho substitutions of the phenylalanine derivatives reported herein include three halides, methyl, methoxy, nitro, and nitrile. These compounds have the potential for use in multiple biochemical and biophysical applications. Specifically, we demonstrated that α-cyano-phenylalanine could be used as a selective sensor to probe the local environment of proteins and applied this to study protein folding/unfolding. For six of these compounds this constitutes the first report of their genetic incorporation in living cells. With these compounds the total number of substrates available for PyRS(N346A/C348A) is increased to nearly 40, which demonstrates that PyRS(N346A/C348A) is able to recognize phenylalanine with a substitution at any side-chain aromatic position as a substrate. To our knowledge, PyRS(N346A/C348A) is the only aminoacyl-tRNA synthetase with such a high substrate promiscuity.

The genetic incorporation of non-canonical amino acids (NCAAs) into recombinant proteins has provided researchers with powerful tools for the study of protein structure and function. The ability to genetically incorporate NCAAs with bioorthogonal functional groups, coupled with click chemistry, allows for the introduction of site-selective protein modifications that have been used for fluorescence labeling1−11 and photo-cross-linking12−15 as well as for the study of posttranslational modifications that are traditionally difficult or impossible to obtain in bacterial expression systems.16−18 Other analytic probes that have been site-selectively introduced using the genetic incorporation approach include infrared, Raman, NMR, and EPR spectroscopic probes and heavy atoms for X-ray crystallographic studies.19−21 Generally, NCAAs are introduced into a protein through the suppression of an in frame nonsense or quadruplet codon by a suppressor tRNA coupled with an evolved aminoacyl-tRNA synthetase (aaRS). One widely used synthetase for this purpose is the tyrosyl-tRNA synthetase-tRNATyr pair, which was derived from E. coli tyrosyl-tRNA synthetase-tRNA^Tyr pair, the EcLeuRS-tRNATyr_CUA pair derived from E. coli leucyl-tRNA synthetase-tRNA^Leu_CUA pair, and the pyrrolysyl-tRNA synthetase (PyRS)-tRNAPyl_CUA pair, which naturally exists in certain methanogenic archaea and some bacteria. Both EcTyrRS-tRNATyr_CUA and EcLeuRS-tRNATyr_CUA pairs can be applied in eukaryotic cells but not in bacterial systems.11,22−26 However, tRNAPyl_CUA is a naturally occurring amber suppressor tRNA that is specifically recognized by PyRS but does not cross-interact with endogenous aaRSs in both bacterial and eukaryotic cells.7−31

To date, the PyRS-tRNAPyl_CUA pair has been successfully used for the genetic incorporation of NCAAs into recombinant proteins expressed in bacteria and a variety of eukaryotes including mammalian cells and multicellular organisms.32,33 While the ability of the PyRS-tRNAPyl_CUA pair to be used in both bacterial and eukaryotic cells is advantageous in that it allows for the same NCAA to be used in different model systems, the method still has limitations. The incorporation of a new NCAA typically requires selection of large libraries of aaRS with randomized active site mutations. Schultz and co-workers have developed a powerful method for the directed evolution of aaRSs involving both positive and negative selections based on the ability to suppress a nonsense mutation in the presence of the desired NCAA.34 However, this process still requires

multiple rounds of selection for each new substrate. Therefore, a single aaRS with broad substrate promiscuity is ideal to facilitate rapid progress and widespread use of the genetic NCAAs in mammalian cells. Aside from 

facilitate the genetic incorporation of phenylalanine derivatives with large meta substitutions (Tuley and Liu, unpublished data). PyrRS(N346A/C348A) displays high activities toward these NCAAs while remaining relatively orthogonal toward canonical amino acids. Here we reveal that the same enzyme is also able to mediate the genetic incorporation of seven ortho-substituted phenylalanine derivatives, which brings the total substrate availability of this enzyme close to 40 and leads to the conclusion that PyrRS(N346A/C348A) is able to recognize phenylalanine derivatives with a substitution at any side-chain aromatic position as a substrate. To our knowledge, PyrRS(N346A/C348A) is the only aaRS with such a high substrate promiscuity. We also demonstrate, for the first time, the ability of PyrRS(N346A/C348A) to facilitate the genetic incorporation of phenylalanine derivatives in mammalian cells. From a nitro-phenylalanine, 38 which has been genetically encoded in E. coli using an evolved M/TyrRS-tRNA^Pyl^CUA pair, this constitutes the first report of the genetic incorporation for all of these ortho-substituted phenylalanine derivatives. 39 One of the ortho-substituted phenylalanine derivatives, o-cyano-phenylalanine (oCNF) is a small, environmentally sensitive, fluorescent probe that can be used as a sensor to probe the local environment of proteins, and we applied this to study protein folding/unfolding.

Wang and co-workers previously determined the crystal structure of a PyrRS mutant (OmeRS) in complex with O-methyl-tyrosine. 40 Figure 1 presents the active site structure of this enzyme—substrate complex superimposed on the wild-type PyrRS with pyrrolysyl-AMP bound. The two overlaid structures clearly show that the N346 side chain is adjacent to the ortho position of the O-methyl-tyrosine side-chain phenyl group. Removing the N346 side chain would potentially leave space for adding an additional substitution to this position. Since PyrRS(N346A/C348A) is expected to bind to a phenylalanine derivative in a similar fashion as OmeRS, we suspect that PyrRS(N346A/C348A) may well recognize an ortho-substituted phenylalanine derivative and, together with tRNA^Pyl^CUA, mediate its incorporation at an amber mutation site. We exploited an E. coli cell system harboring plasmids pEVOL-pyt-PyrRS(N346A/C348A) and pET-pyt-sGFPs2TAG to assess the ability of the PyrRS(N346A/C348A)-tRNA^Pyl^CUA pair to incorporate ortho-substituted phenylalanine derivatives in response to an amber mutation. The plasmid pEVOL-pyt-PyrRS(N346A/C348A) contains genes coding for PyrRS(N346A/C348A) and tRNA^Pyl^CUA, while pET-pyt-sGFPs2TAG contains genes coding for tRNA^Pyl^CUA and superfolder green fluorescent protein (sfGFP) with an amber mutation at its S2 position and a 6 x His tag at the C-terminus. 35 Growing cells in GMML medium (a minimal medium supplemented with 1% glycerol and 0.3 mM l-leucine) led to translation termination at the amber mutation site of sfGFP; therefore no full-length sfGFP was expressed. However, supplementing the medium with 2 mM of one of seven ortho-substituted phenylalanine derivatives (1–7, shown in Figure 2A) promoted overexpression of full-length sfGFP (Figure 2B). Incorporation of NCAAs was confirmed via electrospray ionization mass spectrometry (ESI-MS) (Figure 2C). For each of the seven NCAAs, the detected molecular weight agreed well with the theoretical value (Table 1). Except for 6, this is the first report of the genetic incorporation of these NCAAs in living cells, and for all of the NCAAs this is the first report of their incorporation using an aaRS derive from PyrRS.

Along with 1–7, two additional amino acids were tested, namely, o-trifluoromethyl-phenylalanine (8) and o-fluorophenylalanine (9) (Supplementary Figure 1). In GMML supplemented with 2 mM NCAAs, we obtained minimal expression of full-length sfGFP. The mass spectra of the purified protein suggested the incorporation of both 8 and phenylalanine at the S2 site (Supplementary Figure 2), indicating the recognition of 8 by PyrRS(N346A/C348A) is not significantly better than that of phenylalanine itself. Minimal incorporation of phenylalanine at an amber codon is a typical observation for evolved M/TyrRS-tRNA^Pyl^CUA and PyrRS-tRNA^Pyl^CUA pairs. 41 In a previous study, we found that while PyrRS(N346A/C348A) was able to incorporate m-fluorophenylalanine at an amber codon, ESI-MS analysis of the expressed protein indicated that this NCAA was also incorporated at phenylalanine codons. 36 Given the size similarity of fluorine and a proton, we attributed the misincorporation of m-fluoro-phenylalanine at phenylalanine sites to an inability of the endogenous phenylalanyl-tRNA synthetase to distinguish between the two substrates. Similarly, when testing the incorporation of 9 at the S2 site of sfGFP, we found that the miss-incorporation rate was high. Indeed, major ESI-MS peaks of the purified protein suggest the incorporation of 9 into sfGFP at multiple sites (Supplementary Figure 3). Taken together, these observations suggest that while the PyrRS(N346A/C348A)-tRNA^Pyl^CUA pair is able to direct the genetic incorporation of a monofluorinated phenylalanine at amber codons, E. coli cells with a more stringent phenylalanyl-tRNA synthetase that excludes monofluorinated phenylalanine as a substrate will need to be engineered for cleaner incorporation.

Figure 1. Superimposed structures of the OmeRS complex with O-methyltyrosine and the PyrRS complex with pyrrolysyl-adenosyl monophosphate (Pyl-AMP). The structures are based on PDB entries 2O7H and 3QTC. The PyrRS complex with Pyl-AMP is shown in orange for the protein carbon atoms and pink for the Pyl-AMP carbon atoms. Four mutated residues in OmeRS and the p-methoxy-phenylalanine ligand are shown in cyan for the carbon atoms. Letters in parentheses indicate the four mutated residues in OmeRS.
In one of our previous publications, we showed that PylRS(N346A/C348A) recognizes phenylalanine and mediates its incorporation at an amber mutation site in coordination with tRNACUA. However, this background incorporation was suppressed when a NCAA that serves as a better substrate of PylRS(N346A/C348A) was provided. For instance, the PylRS-(N346A/C348A)-tRNACUA pair induced significant background phenylalanine incorporation at an amber mutation at F27 of sfGFP in LB medium. However, providing m-trifluoromethyl-phenylalanine obviated this background incorporation, and the expressed sfGFP had quantitative occupancy of m-trifluoromethyl-phenylalanine at F27. We used the same system to test the incorporation efficiencies of seven ortho-substituted phenylalanine derivatives (2 mM) in LB. Our data show that, except for 5, all NCAAs led to sfGFP expression significantly better (1.8−3.9-fold) than the background (Supplementary Figure 4). Further, although the sfGFP expression yield in the presence of 5 was comparable to the background, the major peak in the ESI-MS spectrum of purified sfGFP indicated occupancy of 5 at the designated amber mutation site (Supplementary Figure 5), indicating 5 was efficiently incorporated. Presumably, further optimization studies that modify expression conditions, such as increasing the concentration of 5, may lead to a higher incorporation efficiency. These data demonstrate that the practical use of the PylRS(N346A/C348A)-tRNACUA pair in LB for the genetic incorporation of NCAAs is dependent on the NCAA identities and their concentrations.

Next we asked whether the PylRS(N346A/C348A)-tRNACUA pair could be used to incorporate NCAAs into proteins in mammalian cells. Given that rich media containing high concentrations of canonical amino acids is required for mammalian cell growth, PylRS(N346A/C348A) must be more reactive toward a NCAA than phenylalanine in the medium for its practical use in mammalian cells. To test the ability of the PylRS(N346A/C348A)-tRNACUA pair to facilitate the selective incorporation of NCAAs into proteins in mammalian cells, HEK293T cells were transfected with plasmids containing genes encoding a C-terminally GFP-fused epidermal growth factor receptor (EGFR-GFP) with an amber mutation at the N128 position as well as PylRS(N346A/C348A) and tRNACUA. Cells in cultures supplemented with 5 mM of NCAAs 1−7 displayed much greater GFP fluorescence intensities compared to cells in the absence of a NCAA, suggesting enhanced suppression of the amber codon in the presence of NCAAs (Figure 3). Supplementing cultures with 5 mM 2 led to cell death. This is likely due to the insolubility of 2 in the growth medium. As expected, a low level of background protein expression was observed in the control culture, which was probably attributable to background phenylalanine incorporation at the amber mutation.

Of the seven ortho-substituted phenylalanine substrates available to PylRS(N346A/C348A), 3 has the potential to be used for protein labeling via the palladium-catalyzed Suzuki−Miyaura cross-coupling reaction, and 6 can be used to...
cleave the polypeptide backbone upon irradiation at 365 nm, as a fluorescent distance probe due to its ability to quench the fluorescence of tryptophan, and as an IR probe due to the strong vibrational absorption of the nitro group.38,44,45 7 could also be used as an IR probe due to the strong vibrational absorption of the nitrile group19 and as a sensor of protein local environment, protein folding/dynamics, and protein−ligand interactions due to the environmentally sensitive fluorescent features of the benzonitrile moiety. Indeed, an isomeric NCAA of oCNF, p-cyano-phenylalanine (pCNF), has been widely used as a reporter of protein local environment to study folding/dynamics, and protein−peptide interactions.46,47 Additionally, pCNF can be selectively excited in the presence of both tryptophan and tyrosine and has considerable spectral overlap with both fluorophores; therefore, its ability to form a Förster resonance energy transfer (FRET) with these residues was also recently explored.48,49 oCNF could potentially serve as an alternative to pCNF and, because of its naturally occurring orthogonal tRNA<sub>Pyl</sub> could be used in eukaryotic systems. Since the intermediate polarity of the nitrile group is well tolerated in both polar and nonpolar environments and the nitrile group is relatively small, replacing phenylalanine with oCNF will minimally disturb the protein’s structure and folding pattern.49 Our preliminary measurements revealed that 7 has absorption and fluorescence spectra similar to those of pCNF and displays a nearly 10-fold increase in fluorescence when going from a hydrophobic to hydrophilic solvent (Supplementary Figure 6), suggesting that 7 could be used as a probe of protein local environment.

To test whether 7 could be used as a fluorescent probe of protein local environment, two sfGFP proteins were expressed: sfGFP-N135→7 and sfGFP-F27→7 with 7 incorporated at N135 and F27, respectively. N135 is solvent exposed and 7 is expected to be highly fluorescent at this site; however, F27 is buried within the hydrophobic interior of the protein, and therefore 7 incorporated at this position should display reduced fluorescence. Previous measurements indicate that mutations at these two positions do not significantly alter the folding of...
The wild-type protein displayed nine tyrosine residues, and demonstrate that tryptophan, as sfGFP contains one tryptophan residue and selectively excited in the presence of both tyrosine and solvent exposed in this protein. As a control, we also measured fluorescence spectra of the wild-type protein under the same conditions. The wild-type protein displayed fluorescence intensity similar to that of sfGFP-F27→7 with a slightly red-shifted spectrum. These results indicate that sCNF can be selectively excited in the presence of both tyrosine and tryptophan, as sfGFP contains one tryptophan residue and nine tyrosine residues, and demonstrate that 7 serves as an effective indicator of local environment within a protein.

Next we demonstrated the use of 7 for the study of protein folding using the chromodomain of M-phase phosphoprotein 8 (MPP8). MPP8 has been shown to bind specifically to methylated lysine 9 of histone 3 and overexpression of MPP8 is linked to increase tumor metastasis. The crystal structure of MPP8 revealed that F59 is located in the hydrophobic cage that forms a binding pocket for the methylated lysine (Figure 5A). The pEVOL-pylT-PylRS(N346A/C348A) plasmid was cotransformed into E. coli Top10 cells along with pBAD-sfGFP that contained sfGFP with an amber mutation at either the 27th or 135th position. Cultures were grown in a synthetic autoinduction medium supplemented with 2 mM NCAA 7 to afford full-length sfGFP-N135→7 and sfGFP-F27→7 in yields of 140 and 220 mg/L, respectively. No protein was detected in the absence of 7 (Supplementary Figure 7). Figure 4 shows the fluorescence spectra of the folded proteins in phosphate buffered saline at pH 7.5 when excited at 240 nm. In the folded state, sfGFP-F27→7 displays very little fluorescence, consistent with the positioning of 7 in the hydrophobic interior of the protein. However, sfGFP-N135→7 displays nearly an 8-fold increase in fluorescence intensity consistent with 7 being solvent exposed in this protein. As a control, we also measured the fluorescence of the wild-type protein under the same conditions. The wild-type protein displayed fluorescence intensity similar to that of sfGFP-F27→7 with a slightly red-shifted spectrum. These results indicate that sCNF can be selectively excited in the presence of both tyrosine and tryptophan, as sfGFP contains one tryptophan residue and nine tyrosine residues, and demonstrate that 7 serves as an effective indicator of local environment within a protein.

In conclusion, we have demonstrated an expanded ability of the PylRS(N346A/C348A) mutant to incorporate phenylalanine derivatives with substitutions at the ortho position. The enzyme demonstrates remarkable substrate promiscuity while retaining relative orthogonality toward canonical amino acids, making it a valuable tool for the genetic incorporation of NCAAs. Nearly 40 phenylalanine derivatives have been hitherto genetically encoded at amber codons using the PylRS(N346A/C348A)-tRNA_{CUA} pair. Fusion to sfGFP allowed for high levels of the soluble MPP8 to be expressed. The cells were grown in the synthetic autoinduction medium supplemented with 2 mM NCAA 7 to afford the full length fusion protein (Supplementary Figure 8). Figure 5B displays the fluorescence spectra of MPP8 in the presence of varying concentrations of urea. At low concentrations of the denaturant, a peak corresponding to the fluorescence of 7 was not detected, consistent with this residue being buried in the hydrophobic cage. As the concentration of urea is increased from 0 to 8 molar, an increase in 7 fluorescence at 297 nm was observed accompanied by a decrease in the tryptophan fluorescence of the protein, which is consistent with both 7 and tryptophan becoming solvent exposed. No increase in fluorescence at 297 nm was observed for the wild-type protein (Supplementary Figure 9). Figure 5C shows the two-state unfolding curve for MPP8-F59→7 obtained by exciting the protein at 240 nm and measuring the resulting fluorescence at 297 nm.
fluorescent probe of protein local environment and protein folding. oCNF shows significant differences in fluorescence intensity between hydrophobic and hydrophilic environments, and the nitrile substitution at the ortho position makes it an extremely small and noninvasive substitution in protein studies. We believe this advancement will greatly promote the adoption of the genetic NCAA incorporation approach in a broader biochemistry research field.
