Abstract

Background: Diabetes is a chronic illness requiring continuous medical care. Depression is comorbid with diabetes and is associated with poorer glycemic control, and increased complications.

Objectives: The main aim was to assess the prevalence of depression among patients with diabetes mellitus type II to find a correlation between age, gender, HbA1C level, duration of time since the diagnosis of diabetes, number of admissions, methods of controlling diabetes, place of residence, smoking, comorbidities, and educational levels.

Materials and Methods: 169 diabetic patients participated. The methods of data collection included the Beck questionnaire Inventory and an oral interview. Then other data were obtained and were analyzed using SPSS 21.

Results: 130 patients (76.9%) were depressed (25.38% mild, 55.38% moderate, 19.23% severe). Only gender had a relationship with depression, and depression was higher in the females (P=0.041). 59.17% of the patients were illiterate and only 5.91% were academically educated, 94% had other comorbidities, and 60.94% had uncontrolled diabetes and HbA1C higher than 8.

Conclusions: Depression has high prevalence among diabetic patients, and it is affected only by gender. The control of diabetes among them is very poor, and most of them have other comorbidities.

Keywords: Depression; Diabetes mellitus Type 2; HbA1c; IGT; IFG

Background

Reports from the International Diabetes Federations (IDF) indicate that the prevalence of diabetes mellitus has reached epidemic levels globally [1]. People with diabetes have an increased risk of developing a number of serious health problems, particularly if their diabetes is poorly controlled. Chronically high blood glucose levels can lead to serious diseases affecting the heart and blood vessels, eyes, kidneys and nerves. In addition, people with diabetes have a higher risk of developing infections. In many countries, diabetes is a leading cause of cardiovascular disease, blindness, kidney failure and lower limb amputation [2].

Depression is a common illness worldwide, with an estimated 350 million people affected. Especially when long-lasting and with moderate or severe intensity, depression may become a serious health condition. It can cause the affected person to suffer greatly and function poorly at work, at school and in the family.

Effective treatments for depression, fewer than half of those affected in the world (in many countries, fewer than 10%) receive such treatments [3]. Depression is a common problem among those suffering from diabetes mellitus [4].

Depression and severe psychological distress are frequently comorbid with diabetes and are associated with reduced adherence to medication and healthy lifestyle regimens, poorer glycemic control, and increased complications [5]. Diabetes complications are also greater among individuals with depression [1]. Recent studies have shown that coexisting depression increases the risk of death among people with diabetes [6-8].

Objective

The main aim of this study is to assess the prevalence of depression among patients with diabetes mellitus type II and to find a correlation between age, gender, HbA1C level, duration of time since the diagnosis of diabetes, number of admissions, methods of controlling diabetes used, place of residence, smoking, comorbidities, and educational attainment levels.

Materials and Methods

This cross-sectional study was done on patients with diabetes mellitus type II, who had been admitted to the Shahid Rahimi Hospital in Khorramabad, west of Iran, from summer 2014 to winter 2015.
the questionnaire, which is a standard one, including 21 sections and each section containing different and separate implications.

We got other data from the patients including age, educational attainment levels, marital state, place of residence (urban or rural areas), duration of time since the diagnosis of diabetes mellitus, the method of controlling diabetes (taking tablets or insulin injection), and comorbidities. Then, the HbA1C test was administered.

According to Beck depression inventory questionnaire, we have asked about 21 part of this questionnaire (including Sadness, pessimism, past failure, loss of pleasure, guilty feelings, punishment feelings, self-dislike, self-criticalness, suicidal thoughts or wishes, crying, agitation, loss of interest, indecisiveness, worthlessness, loss of energy, changes in sleeping pattern, irritability, changes in appetite, concentration difficulty, tiredness or fatigue, loss of interest in sex) [9].

Then we have given score to each section. After that we have calculated the final score for each patient. According to the final score, we could be able to classify the depression to mild (score 5 to 9), moderate (score 10 to 18) and severe depression (more than 19) [10].

According to the formula “n=Z²p(1-p)/d²” we estimated 170 patients as the sample size. The collected data were analyzed using SPSS 21 software.

Results

There were 169 cases (69 females and 73 males). One patient was omitted, because of the lack of HbA1C test. 130 patients (76.9%) were depressed. Among the depressed patients, 25.38% had mild, 55.38% had moderate, and 19.23% had severe depression.

The results were segregated according to these items: age, sex, educational attainment levels, smoking, the number of admissions, the method of controlling diabetes (taking tablets, insulin injection), the place of residence (urban or rural areas), duration of time since the diagnosis of diabetes mellitus, comorbidities and the HbA1C test.

The distribution and severity of depression for age, HbA1C level, duration of time since the diagnosis of diabetes, educational attainment levels, smoking, number of admissions, place of residence (urban or rural areas), method of controlling diabetes and comorbidities:

We could not find any significant correlations between depression and the age of the patients (p=0.385), HbA1C levels (p=0.58), duration of time since the diagnosis of diabetes mellitus (p=0.248), educational attainment levels (p=0.095), smoking (p=0.582), number of admissions (p=0.162), the method of controlling diabetes (p=0.218), the place of residence (p=0.459) and comorbidities (p=0.222) (Tables 1-3 and Figures 1-6).

Figure 4: Distribution of depression and comorbidities.
Figure 5: Distribution of depression and the place of residence.

Figure 6: Distribution of depression and treatment.
Figure 7: Distribution of Depression and Gender.

The distribution and severity of depression for gender: The prevalence of depression in diabetic women was significantly higher than in diabetic men. (83% vs. 67%) (p=0.041) (Figure 7).

Discussion

This study showed that depression is very common among patients who were admitted to the Shahid Rahimi Hospital of Khorramabad, Iran and the prevalence was 76.9%.

Most of the patients were not aware of their disease and had not consulted any doctors, and during their admission, they had not consulted any psychiatrists. So we were facing many depressed diabetic patients, who had not received any treatments.

In other studies from other countries, the prevalence of depression in diabetic patients in Spain was 5.8% [11], Taiwan 10.6% [12], Malaysia 11.5% [13], Addis Ababa 13% [14], London 22% female and 13% male [15], Pakistan 14.7% [16], Brazil 18.6% [17], Jordan 19.7% [18], Bangladesh 30.5% female and 29% male [19], the Netherlands 38% female and 35% male [20], India 38.8% and 46.1% in two studies [21,22], and in Mexico 48.27% [23].

The prevalence of depression in diabetic patients in Iran was noticeably more than other countries. This prevalence in Rasht was 37.8% [24], Dr Shariati Hospital clinic in Tehran and Iranian Diabetes Society 41.9% [25], Bandar Abbas 50% [26], Yazd 64% [27], Imam Khomeini Hospital in Tehran 70.7% [28], Semnan 71.6% [29], Firouzgar Hospital in Tehran 71.8% [30] and Uroumieh 77% [31].

The high prevalence of depression in this study may seem incredible, but unfortunately it is real and the factors like being admitted in the hospital didn't have significant effects in this high prevalence.

In this study, we interviewed the patients face to face, and we made sure that the symptoms are reliable and had started at least 2 weeks earlier before admitting to the hospital. We ignored the symptoms that were started in the hospital.

Also, the results gained from other similar studies in Iran, confirmed our results, that was 64% in Yazd [27], 70.7% in Imam Khomeini Hospital in Tehran [28], 71.6% in Semnan [29], 71.8% in Firouzgar Hospital in Tehran [30] and 77% in Urmiah [31].

In Khoram abad, there isn't any center to educate diabetic patients how care about themselves. Most of the patients were illiterate and they didn't know how to get aware about diabetes, so most of them were complicated or had other comorbidities and also depression.

On the other hand, there were not any psychological consult about diabetic patients who were admitted to the hospital and many of them became missed, so they were not referred to the psychiatrist after discharge.

Because of all reasons above, the high prevalence of depression in diabetic patients in Shahid Rahimi hospital, is true and real.

In this study, among all the factors mentioned above, only gender had a significant relationship with depression, and depression was higher in females.

The prevalence of depression in diabetic patients in this study was independent from many factors. Therefore, the control of depression will be very important and difficult and will need fundamental planning.

In addition to the conclusion above, this study had more conclusions, too:

- 59.17% of the patients were illiterate and only 5.91% were academically educated.
- So they are not able to study about diabetes, its treatment, control or its complications (Figure 8).
94% of the patients had other comorbidities (e.g. hypertension, hyperlipidemia, ischemic heart disease, diabetes complications, etc.), so they need serious medical care in contrast with patients who have no comorbidities (Figure 9).

60.94% of the patients had uncontrolled diabetes and HbA1C higher than 8 (Figure 10).

At the end of the study, we have recommended our suggestions to the internal medicine group of Shahid Rahimy Hospital and we have referred the depressed patients to the psychiatrist.

We make the following suggestions according to the conclusions above:

1. Psychiatric consultations for all diabetic patients who are admitted to hospitals.
2. Improvement of diabetic clinics in Khorrramabad and other cities of Iran and the creation of diabetic files for each patient, and encouraging the patients for follow-up and regular visits with their doctors.
3. Development of training programs about diabetes for the diabetics.
4. Improving public knowledge.
