Summary The p73 gene has been mapped to 1p36.33, a region which is frequently deleted in a wide variety of neoplasms including tumours of neuroectodermal origin. The p73 protein shows structural and functional homology to p53. For these reasons, p73 was considered as a positional and functional candidate tumour suppressor gene. Thus far, mutation analysis has provided no evidence for involvement of p73 in oligodendrogliomas, lung carcinoma, oesophageal carcinoma, prostatic carcinoma and hepatocellular carcinoma. In neuroblastoma, two mutations have been observed in a series of 140 tumours. In view of the occurrence of 1p deletions in Merkel cell carcinoma (MCC) and the location of p73 in 1p, we decided to search for mutations in the p73 gene in five MCC cell lines and ten MCC tumours to test potential tumour suppressor function for this gene in MCC. In view of the possible complementary functions of p73 and TP53, we also examined the status of the TP53 gene. Sequence analysis of the entire coding region of the p73 gene revealed previously reported polymorphisms in four MCCs. In one MCC tumour, a mis-sense mutation located in the NH2-terminal transactivation region of the p73 gene was found. These results show that p73, analogous to neuroblastoma, is infrequently mutated in MCC. This is the first report in which the role of TP53 in MCC has been investigated by sequencing the entire coding region of TP53. TP53 mis-sense mutations and one non-sense mutation were detected in three of 15 examined MCCs, suggesting that TP53 mutations may play a role in the pathogenesis or progression of a subset of MCCs. Moreover, typical UVB induced C to T mutations were found in one MCC cell line thus providing further evidence for sun-exposure in the aetiology of this rare skin cancer. © 2000 Cancer Research Campaign

Keywords: Merkel cell carcinoma; 1p36; p73; TP53; mutation

Merkel cell carcinoma (MCC) is a rare aggressive neuroendocrine skin tumour, mostly affecting elderly individuals. The majority of primary MCCs occur on sun-exposed areas of the skin, implicating UV exposure in its aetiology. The tumour is thought to originate from Merkel cells, which have properties of both epithelial and neuroendocrine cells. They are located in the basal epidermis and are likely to play a role in signal transduction as receptors for mechanical stimuli in all animals (Ratner et al, 1993).

Until now, little was known about the genetic basis of MCC. Only 13 cytogenetic studies have been reported in the literature (Mitelman et al, 1998). No consistent translocations have been observed but structural abnormalities involving the short arm of chromosome 1 have been noted in 40% of all examined cases. Chromosome region 1p36, which is frequently deleted in a variety of neoplasms including neuroendocrine tumours such as neuroblastoma, is often affected in MCC tumours with 1p rearrangements (Van Gele et al, 1998). Several candidate tumour suppressor genes have been mapped to 1p36 but as yet no direct involvement of these genes in tumours with 1p36 loss could be found (Schwab et al, 1996).

The p73 gene, located on 1p36.33, has also been considered as a candidate tumour suppressor gene. p73 shows significant sequence similarity to the transactivation, DNA-binding and oligomerization domain of TP53 (Kaghad et al, 1997). Jost et al (1997) showed that overexpression of p73 can activate the transcription of TP53-responsive genes like p21WAF1/CIP1 and inhibit cell growth in the same way as TP53 by inducing apoptosis. Mutation analyses for the p73 gene have been performed in lung carcinoma, oligodendrogliomas, prostatic carcinoma, neuroblastomas, colorectal carcinoma, oesophageal carcinoma and hepatocellular carcinoma (Kovalev et al, 1998; Mai et al, 1998a, 1998b; Nimura et al, 1998; Nomoto et al, 1998; Sunahara et al, 1998; Takahashi et al, 1998; Ichimiya et al, 1999; Mihara et al, 1999). Except for two mutations in primary neuroblastomas resulting in amino acid substitutions in the C-terminal region of p73 (Ichimiya et al, 1999), no other mutations have been reported.

We decided to perform mutation analysis of the p73 gene in order to investigate the possible involvement of p73 in MCC oncogenesis. Five MCC cell lines and ten MCC tumours with known 1p status were examined for mutations in the p73 gene by direct sequence analysis. In view of the possible complementary functions of p73 and TP53, the status of TP53 was also investigated.

MATERIALS AND METHODS

Samples

Tumour samples were collected at the University Hospitals of Ghent and Leuven, Belgium and the University of Nebraska...
Medical Center, Ohama, NE, USA. One part of the sample was snap-frozen in liquid nitrogen and another part was stored at −80°C until analysis. MCC tumour cell line UISO was kindly provided by Dr SG Ronan and Prof Dr TK Das Gupta (Illinois, USA). Cell line MKL-1 was given by Prof Dr ST Rosen (Illinois, USA). Cell lines MCC13, MCC14/2 and MCC26 were a gift from Dr JH Leonard (Queensland, Australia). All cell lines were grown in RPMI-1640 medium (Gibco-BRL, 52400-025). DNA of the tumour samples and cell lines was prepared by standard proteinase K digestion, phenol–chloroform extraction, and ethanol precipitation protocols. Constitutional DNA of the patients was isolated by using the Qiagen blood and cell culture Midi Kit (Westburg, 13343). RNA extraction from the tumour samples and cell lines was done with RNeasy Midi Kits (Westburg, 75144).

Fluorescence in situ hybridization

In order to determine the copy number of chromosome 1 and presence or absence of 1p deletions, fluorescence in situ hybridization (FISH) was performed on metaphases or interphase nuclei according to Van Roy et al (1994). DNA probes used were (FISH) was performed on metaphases or interphase nuclei. NT: not tested. b Refers to the polymorphism of G/C and A/T alleles in exon 1 of reverse transcriptase products, 50 µm dNTP, 300 nM primers, 10% dimethylsulphoxide, 5 µl of buffer 1 and 3.5 units of Taq and Pwo enzyme mix. The PCR amplification consisted of 35 cycles of 95°C for 0.5 min, 58°C for 1 min, 68°C for 2.5 min after starting with a denaturing step at 95°C for 1 min and ending at 68°C for 10 min. The PCR products were purified by spin dialysis sequentially on S4000 and P10 resins. Subsequently, the PCR products were directly completely sequenced on an ABI PRISM™ 377 sequencer (Perkin-Elmer) using specific nested sequencing primers and the Big Dye Terminator Sequencing Kit. Cases 6, 7, 8, 9 and 10 (see Table 1) were sequenced on an ALF™ Express automated DNA sequencer (Pharmacia) using a Thermo Sequenase fluorescent labelled primer cycle sequencing kit with 7-deaza-dGTP (Amersham, RPN 2438). To confirm the p73 nucleotide change found in case 4 the following primer pair sense: 5'-CCAGTTCAACTCGTGA-GCAC-3' and antisense: 5'-CCACTTTTCCGCTTATCC-3', located in exon 4, were used to amplify genomic tumour DNA and constitutional DNA of the patient. PCR conditions were the same as those described above. The PCR products were sequenced using the same primers as those to amplify genomic DNA.

Reverse transcriptase polymerase chain reaction and sequencing analysis

cDNA synthesis was performed using 5 µg of total RNA incubated in a 20 µl volume reaction containing 50 mM Tris–HCl (pH 8.3), 10 mM dithiothreitol (DTT), 10 mM potassium chloride (KCl), 0.5 mM dNTP, 20 U RNAsin (Promega), 150 U Super-script II Reverse Transcriptase (Gibco-BRL) and 50 ng µl−1 oligo-d(T) primer for 1 h at 37°C. The primer pairs sense: 5'-AGGGAGAAGGCGAGGAACC; antisense: 5'-GGCAGCTTG-GGCTCCTGG; and sense: 5'-GGTGACACGGCTTCCCTG; anti-sense: 5'-GGTGGGAGGCTGTCAGTG were used to amplify the entire coding region of p73 and TP53 respectively by reverse transcription polymerase chain reaction (RT-PCR). Long range PCR was performed using the Expand™ Long Template PCR system (Boehringer Mannheim). PCR reactions were performed in a 50 µl reaction volume containing 2 µl of reverse transcriptase products, 500 µm dNTP, 300 nM primers, 10% dimethylsulphoxide, 5 µl of buffer 1 and 3.5 units of Taq and Pwo enzyme mix. The PCR amplification consisted of 35 cycles of 95°C for 0.5 min, 58°C for 1 min, 68°C for 2.5 min after starting with a denaturing step at 95°C for 1 min and ending at 68°C for 10 min. The PCR products were purified by spin dialysis sequentially on S4000 and P10 resins. Subsequently, the PCR products were directly completely sequenced on an ABI PRISM™ 377 sequencer (Perkin-Elmer) using specific nested sequencing primers and the Big Dye Terminator Sequencing Kit. Cases 6, 7, 8, 9 and 10 (see Table 1) were sequenced on an ALF™ Express automated DNA sequencer (Pharmacia) using a Thermo Sequenase fluorescent labelled primer cycle sequencing kit with 7-deaza-dGTP (Amersham, RPN 2438). To confirm the p73 nucleotide change found in case 4 the following primer pair sense: 5'-CCAGTTCAACTCGTGA-GCAC-3' and antisense: 5'-CCACTTTTCCGCTTATCC-3', located in exon 4, were used to amplify genomic tumour DNA and constitutional DNA of the patient. PCR conditions were the same as those described above. The PCR products were sequenced using the same primers as those to amplify genomic DNA.

Table 1 Summary of mutation analysis of p73 and TP53 in Merkel cell carcinoma

* 1pΔ: deletion in the short arm of chromosome 1 determined by fluorescence in situ hybridization with the telomeric D1Z2 probe performed on chromosome metaphases or interphase nuclei. NT: not tested. a Refers to the polymorphism of G/C and A/T alleles in exon 2, as determined by RT-PCR on mRNA and subsequent sequencing of products. b UISO carries an insertion on 1p36.2 of unknown origin (Van Gele et al, 1998). c NA, not available due to lack of TP53 mRNA expression, as determined by RT-PCR. d Refers to the tightly linked polymorphisms located in exon 9 and exon 14, as determined by RT-PCR on mRNA and subsequent sequencing of products.
RESULTS

Mutation analysis of p73 and TP53 in MCCs

cDNA of five MCC cell lines and ten MCC tumours was amplified by RT-PCR and, consequently, cycle-sequenced using specific nested PCR primers for the detection of mutations in p73. In addition, allelic expression for p73 was determined based upon the known linked polymorphisms in exon 2. The sequencing results and allelic expression data are summarized in Table 1. A C to T mutation at codon 110 was found in one out of ten MCC tumours for p73, resulting in a serine to leucine substitution. This nucleotide exchange was also present in the genomic DNA of the tumour but not in the constitutional DNA (Figure 1). No mutations were found in the cell lines. Silent nucleotide substitutions at codon 336 (GCC to GCT) and codon 349 (CAT to CAC) located in exon 9 and at codon 557 (GCC to GCA) and at codon 610 (GCC to GCA) located in exon 14 were found in four (40%) of the ten examined tumours. These polymorphisms were also found in the constitutional patient DNA.

The same panel of MCC cell lines and MCC tumours was also examined for mutations in the TP53 gene. Four TP53 mutations were found in two out of five MCC cell lines and one non-sense mutation was observed in one MCC tumour (see Table 1).

DISCUSSION

Thus far, mutation analyses for p73 have been performed in several types of carcinomas, oligodendrogliomas and neuroblastomas (Kovalev et al, 1998; Mai et al, 1998a; Nimura et al, 1998; Nomoto et al, 1998; Sunahara et al, 1998; Takahashi et al, 1998; Ichimiya et al 1999; Mihara et al, 1999). No mutations were found except for one somatic and one germline mutation in a series of 140 neuroblastomas (Ichimiya et al, 1999). No mutations were found in normal lung tissue and distinct patterns of allelic expression were conflicting. Nomoto et al (1998) found biallelic expression of p73 in normal lung tissue and distinct patterns of allelic expression in different normal tissues. In contrast, Mai et al (1998b) reported monoallelic expression in normal lung tissue and increased and biallelic expression in lung tumour samples. Ichimiya et al (1999) found low p73 expression in normal lung tissue and colorectal carcinoma under the same conditions. Although we performed no quantification of the p73 mRNA, we observed biallelic expression in one MCC cell line and eight MCC primary tumours. Clearly, further studies on p73 expression in normal and cancerous tissues is warranted.

In the present study, one mis-sense mutation of p73 in one out of ten MCC tumours was found: a heterozygous C to T transition at nucleotide 439, resulting in a serine to leucine substitution at codon 110 within exon 4. In comparison to the mutations observed in neuroblastoma, this mutation was located in the NH2-terminal region (residues 1–112) of p73. The transcriptional transactivation function of the NH2-terminal region of p73 was shown to have an activity as strong as that of TP53 (Takada et al, 1999). Further analysis may show that the observed mis-sense mutation in MCC leads to a reduction or complete loss of the transactivation function of the NH2-terminal region of p73. The MCC tumour carrying the mutated p73 allele still expresses the remaining wild-type allele. Similar to TP53, this mis-sense mutation might exert a dominant negative effect by an increased stability of the mutant protein compared to that of wild-type protein. Further studies are needed to verify this hypothesis.

The finding of p73 mutations in neuroblastoma and MCC may also stimulate mutation analyses in other tumour types. Although the low frequency of mutations in both tumours seems to exclude a direct role for p73 in tumorigenesis, other mechanisms than mutations in p73 may lead to tissue-specific up- or down-regulation of the gene. In this respect, the available data on allelic expression of p73 are conflicting. Nomoto et al (1998) found biallelic expression of p73 in normal lung tissue and distinct patterns of allelic expression in different normal tissues. In contrast, Mai et al (1998b) reported monoallelic expression in normal lung tissue and increased and biallelic expression in lung tumour samples. Ichimiya et al (1999) found low p73 expression in normal lung tissue and colorectal carcinoma under the same conditions. Although we performed no quantification of the p73 mRNA, we observed biallelic expression in one MCC cell line and eight MCC primary tumours. Clearly, further studies on p73 expression in normal and cancerous tissues is warranted.

As yet, only one study investigated the possible role of TP53 in MCC (Schmid et al, 1997). Using immunohistochemical staining, TP53 expression was studied in 25 Merkel cell carcinomas. Only five tumours showed 5–10% TP53-immunoreactive tumour nuclei. Single-strand conformation polymorphism (SSCP) analysis
for exons 4–8 did not reveal mutations in these five tumours which lead the authors to conclude that TP53 alterations play only a minor part in the genesis of MCC. However, using this approach it could not be ruled out that the presence of mutations in the other exons of TP53 were missed. Also, missense and non-sense mutations not leading to accumulation of the gene product would be overlooked in those cases not investigated by SSCP analysis. We also investigated TP53 for the presence of mutations by sequencing of the entire coding region of the TP53 gene. TP53 mutations were found in two out of five MCC cell lines and in one out of ten tumours. In cell line MCC13, three mutations were found at dipyrimidine sites, namely a double base pair C to T transition at nucleotides 857, 858 and a single base pair C to T transition at nucleotide 967 both leading to amino acid substitutions at codon 241 and codon 278 respectively (Table 1). These type of mutations are characteristically induced by absorption of UV irradiation by the DNA (Brash et al, 1991). The mutation found in MCC14/2 is a hemizygous T to A transversion at nucleotide 950 since no wild-type sequence was present. This point mutation is translated into an amino acid substitution from valine to glutamic acid at codon 272. The amino acid changes at codon 241, 272 and 278 reside in mutational hotspots of the sequence-specific DNA-binding domain of the TP53 protein. Alterations in these residues of the TP53 protein will typically result in defective contacts with the DNA and finally lead to the loss of the ability of TP53 to act as a transcription factor. For the particular amino acid substitution at residue 241, Cho et al (1994) could show that DNA contact was not possible as the defective TP53 protein was unable to make contact with the phosphate backbone in the major groove of the DNA. The non-sense mutation at nucleotide 550 in the MCC tumour (case 4) predicted the generation of a truncated TP53 protein. Accumulation of truncated TP53 variants can result in a dominant negative effect and loss of normal TP53 function.

In conclusion, we describe the finding of a sporadic p73 NH2-terminal located missense mutation in MCC together with the observation of two previously reported loss of function mutations within the COOH-terminal transactivation region of p73 in neuroblastoma. These mutations provide circumstantial evidence for a role of p73 in these malignancies of neuroectodermal origin. At present, the exact physiological function of p73 in tumour development is unclear. In view of these findings, we propose further investigations of p73 in normal development and tumorigenesis. Further insights in its role in apoptosis (Jost et al, 1997) and possibly other mechanisms such as cell cycle control and cell differentiation may provide additional clues for possible contribution of p73 in tumorigenesis. This report also shows for the first time the occurrence of inactivating TP53 mutations in 19% of the investigated MCCs. The C to T mutations in cell line MCC13 are known to be caused by UVB irradiation and thus provide further evidence for sun-exposure in some Merkel cell carcinomas.

ACKNOWLEDGEMENTS

We thank Drs L Kelly and O Williams for providing tumour material (tumour 13 and tumour 14). Dr HJ Cooke and Dr M Litt for providing us with DNA probes pUC1.77 and pL–p79 respectively. This work was supported by GOA-grant 12051397, the John A Wiebe Children’s Health Care Fund, the Queensland Cancer Fund and the Queensland Radium Institute. Nadine Van Roy is a postdoctoral researcher of the Fund for Scientific Research, Flanders.
