Abstract
We compare two approaches for modelling imperfect information in infinite games by using finite-state automata. The first, more standard approach views information as the result of an observation process driven by a sequential Mealy machine. In contrast, the second approach features indistinguishability relations described by synchronous two-tape automata. The indistinguishability-relation model turns out to be strictly more expressive than the one based on observations. We present a characterisation of the indistinguishability relations that admit a representation as a finite-state observation function. We show that the characterisation is decidable, and give a procedure to construct a corresponding Mealy machine whenever one exists.

1 Introduction

Uncertainty is a main concern in strategic interaction. Decisions of agents are based on their knowledge about the system state, and that is often limited. The challenge grows in dynamical systems, where the state changes over time, and it becomes severe, when the dynamics unravels over infinitely many stages. In this context, one fundamental question is how to model knowledge and the way it changes as information is acquired along the stages of the system run.
Finite-state automata offer a solid framework for the analysis of systems with infinite runs. They allow to reason about infinite state spaces in terms of finite ones — of course, with a certain loss. The connection has proved to be extraordinarily successful in the study of infinite games on finite graphs, in the particular setting of perfect information assuming that players are informed about every move in the play history, which determines the actual state of the system. One key insight is that winning strategies, in this setting, can be synthesised effectively [7, 24]: for every game described by finite automata, one can describe the set of winning strategies by an automaton (over infinite trees) and, moreover, construct an automaton (a finite-state Moore machine) that implements a winning strategy.

In this paper, we discuss two approaches for modelling imperfect information, where, in contrast to the perfect-information setting, it is no longer assumed that the decision maker is informed about the moves that occurred previously in the play history.

The first, more standard approach corresponds to viewing information as a result of an observation process that may be imperfect in the sense that different moves can yield the same observation in a stage of the game. Here, we propose a second approach, which corresponds to representing information as a state of knowledge, by describing which histories are indistinguishable to the decision maker.

Concretely, we assume a setting of synchronous games with perfect recall in a partitional information model. Plays proceed in infinitely many stages, each of which results in one move from a finite range. Histories and plays are thus determined as finite or infinite sequences of moves, respectively.

To represent information partitions, we consider two models based on finite-state automata. In the observation-based model, which corresponds to the standard approach in computing science and non-cooperative game theory, the automaton is a sequential Mealy machine that inputs moves and outputs observations from a finite alphabet. The machine thus describes an observation function, which maps any history of moves to a sequence of observations that represents its information set. In the indistinguishability-based model, we use two-tape automata to describe which pairs of histories belong to the same information set.

As an immediate insight, we point out that, in the finite-state setting, the standard model based on observation functions is less expressive than the one based on indistinguishability relations. Intuitively, this is because observation functions can only yield a bounded amount of information in each round — limited by the size of the observation alphabet, whereas indistinguishability relations can describe situations where the amount of information received per round grows unboundedly as the play proceeds.

We investigate the question whether an information partition represented as (an indistinguishability relation given by) a two-tape automaton admits a representation as (an observation function given by) a Mealy machine. We show that this question is decidable, using results from the theory of word-automatic structures. We also present a procedure for constructing a Mealy machine that represents a given indistinguishability relation as an observation function, whenever this is possible.
2 Basic Notions

2.1 Finite Automata

To represent components of infinite games as finite objects, finite-state automata offer a versatile framework (see [14], for a survey). Here, we use automata of two different types, which we introduce following the notation of [23, Chapter 2].

As a common underlying model, a semi-automaton is a tuple \( A = (Q, \Gamma, q_\varepsilon, \delta) \) consisting of a finite set \( Q \) of states, a finite input alphabet \( \Gamma \), a designated initial state \( q_\varepsilon \in Q \), and a transition function \( \delta : Q \times \Gamma \rightarrow Q \). We define the size \( |A| \) of \( A \) to be the number of its transitions, that is \( |Q| \cdot |\Gamma| \). To describe the internal behaviour of the semi-automaton we extend the transition function from letters to input words: the extended transition function \( \delta : Q \times \Gamma^* \rightarrow Q \) is defined by setting, for every state \( q \in Q \),

\[
\begin{align*}
\delta(q, \varepsilon) & := q \\
\delta(q, \tau c) & := \delta(\delta(q, \tau), c)
\end{align*}
\]

for the empty word \( \varepsilon \), and any word obtained by the concatenation of a word \( \tau \in \Gamma^* \) and a letter \( c \in \Gamma \).

On the one hand, we use automata as acceptors of finite words. A deterministic finite automaton (for short, DFA) is a tuple \( A = (Q, \Gamma, q_\varepsilon, \delta, F) \) expanding a semi-automaton by a designated subset \( F \subseteq Q \) of accepting states. We say that a finite input word \( \tau \in \Gamma^* \) is accepted by \( A \) from a state \( q \) if \( \delta(q, \tau) \in F \). The set of words in \( \Gamma^* \) that are accepted by \( A \) from the initial state \( q_\varepsilon \) forms its language, denoted \( L(A) \subseteq \Gamma^* \).

Thus, a DFA recognises a set of words. By considering input alphabets over pairs of letters from a basis alphabet \( \Gamma \), the model can be used to recognise synchronous relations over \( \Gamma \), that is, relations between words of the same length. We refer to a DFA over an input alphabet \( \Gamma \times \Gamma \) as a two-tape DFA. The relation recognised by such an automaton consists of all pairs of words \( c_1c_2\ldots c_\ell, c'_1c'_2\ldots c'_\ell \in \Gamma^* \) such that \( (c_1, c'_1)(c_2, c'_2)\ldots(c_\ell, c'_\ell) \in L(A) \). With a slight abuse of notation, we also denote this relation by \( L(A) \). We say that a synchronous relation is regular if it is recognised by a DFA.

On the other hand, we consider automata with output. A Mealy automaton is a tuple \( (Q, \Gamma, \Sigma, q_\varepsilon, \delta, \lambda) \) where \( (Q, \Gamma, q_\varepsilon, \delta) \) is a semi-automaton, \( \Sigma \) is a finite output alphabet, and \( \lambda : Q \times \Gamma \rightarrow \Sigma \) is an output function. To describe the external behaviour of such an automaton, we define the extended output function \( \lambda : \Gamma^* \times \Gamma \rightarrow \Sigma \) by setting \( \lambda(\tau, c) := \lambda(\delta(q_\varepsilon, \tau), c) \) for every word \( \tau \in \Gamma^* \) and every letter \( c \in \Gamma \). Thus, the external behaviour of a Mealy automaton defines a function from the set \( \Gamma^+ := \Gamma^* \setminus \{\varepsilon\} \) of nonempty words to \( \Sigma \). We say that a function on \( \Gamma^+ \) is regular, if there exists a Mealy automaton that defines it.

2.2 Repeated Games with Imperfect Information

In our general setup, we consider games played in an infinite sequence of stages. In each stage, every player chooses an action from a given set of alternatives, independently and simultaneously. As a consequence, this determines a move that is recorded...
in the play history. Then, the game proceeds to the next stage. The outcome of the play is thus an infinite sequence of moves.

Decisions of a player are based on the available information, which we model by a partition of the set of play histories into information sets: at the beginning of each stage game, the player is informed of the information set to which the actual play history belongs (in the partition associated to the player). Accordingly, a strategy for a player is a function from information sets to actions. Every strategy profile (that is, a collection of strategies, one for each player) determines a play.

Basic questions in this setup concern strategies of an individual player to enforce an outcome in a designated set of winning plays or to maximise the value of a given payoff function, regardless of the strategy of other players. More advanced issues target joint strategies of coalitions among players towards coordinating on a common objective, or equilibrium profiles. Scenarios where the available actions depend on the history, or where the play might end after finitely many stages, can be captured by adjusting the information partition together with the payoff or winning condition.

For our formal treatment of information structures, we use the model of abstract infinite games as introduced by Thomas in his seminal paper on strategy synthesis [27]; the relevant questions for more elaborate settings, such as infinite games on finite graphs or concurrent game structures can be reduced easily to this abstraction. The underlying model is consistent with the classical definition of extensive games with information partitions and perfect recall due to von Neumann and Morgenstern [29], in the formulation of Kuhn [16]. For a more detailed account on partitional information, we refer to Bacharach [1] and Geanakoplos [12].

Our formalisation captures the information structures of repeated games with imperfect monitoring as studied in non-cooperative game theory (see the survey of Gossner and Tomala [13]), and of infinite games with partial observation on finite-state systems as studied in computing science (see Reif [26], Lin and Wonham [19], van der Meyden and Wilke [28], Chatterjee et al. [8], Berwanger et al. [4]). For background on the modelling of knowledge, and the notion of synchronous perfect recall we refer to Chapter 8 in the book of Fagin et al. [10].

2.2.1 Move and Information Structure

As a basic object for describing a game, we fix a finite set $\Gamma$ of moves. A play is an infinite sequence of moves $\pi = c_1c_2\ldots \in \Gamma^\omega$. A history (of length $\ell$) is a finite prefix $\tau = c_1c_2\ldots c_\ell \in \Gamma^*$ of a play; the empty history $\varepsilon$ has length zero. The move structure of the game is the set $\Gamma^*$ of histories equipped with the successor relation, which consists of all pairs $(\tau, \tau c)$ for $\tau \in \Gamma^*$ and $c \in \Gamma$. For convenience, we denote the move structure of a game on $\Gamma$ simply by $\Gamma^*$ omitting the (implicitly defined) successor relation.

The information available to a player is modelled abstractly by a partition $\mathcal{U}$ of the set $\Gamma^*$ of histories; the parts of $\mathcal{U}$ are called information sets (of the player). The intended meaning is that if the actual history belongs to an information set $U$, then the player considers every history in $U$ possible. The particular case where all information sets in the partition are singletons characterises the setting of perfect information.
The information structure (of the player) is the quotient $\Gamma^*/U$ of the move structure by the information partition. That is, the first-order structure on the domain consisting of the information sets, with a binary relation connecting two information sets $(U, U')$ whenever there exists a history $\tau \in U$ with a successor history $\tau c \in U'$. Throughout this article, we assume the perspective of just one player, so we simply refer to the information structure of the game.

Our information model is synchronous, which means, intuitively, that the player always knows how many stages have been played. Formally, this amounts to asserting that all histories in an information set have the same length; in particular the empty history forms a singleton information set. Further, we assume that the player has perfect recall — he never forgets what he knew previously. Formally, if an information set contains nonempty histories $\tau c$ and $\tau' c'$, then the predecessor history $\tau$ is in the same information set as $\tau'$. In different terms, an information partition satisfies synchronous perfect recall if, whenever a pair of histories $c_1 \ldots c_\ell$ and $c'_1 \ldots c'_\ell$ belongs to an information set, then for every stage $t \leq \ell$, the prefix histories $c_1 \ldots c_t$ and $c'_1 \ldots c'_t$ belong to the same information set. As a direct consequence, the information structures that arise from such partitions are indeed trees.

**Lemma 2.1** For every information partition $U$ of perfect synchronous recall, the information structure $\Gamma^*/U$ is a directed tree.

We will use the term information tree when referring to the information structure associated with an information partition with synchronous perfect recall.

In the following, we discuss two alternative representations of information partitions.

### 2.2.2 Observation

The first alternative consists in describing the information received by the player in each stage. To do so, we specify a set $\Sigma$ of observation symbols and an observation function $\beta : \Gamma^+ \rightarrow \Sigma$. Intuitively, the player observes at every nonempty history $\tau$ the symbol $\beta(\tau)$; under the assumption of perfect recall, the information available to the player at history $\tau = c_1 c_2 \ldots c_\ell$ is thus represented by the sequence of observations $\beta(c_1) \beta(c_1 c_2) \ldots \beta(c_1 \ldots c_\ell)$, which we call observation history (at $\tau$); let us denote by $\hat{\beta} : \Gamma^* \rightarrow \Sigma^*$ the function that returns, for each play history, the corresponding observation history.

The information partition $U_\beta$ represented by an observation function $\beta$ is the collection of sets $U_\eta := \{\tau \in \Gamma^* \mid \hat{\beta}(\tau) = \eta\}$ indexed by observation histories $\eta \in \hat{\beta}(\Gamma^*)$. Clearly, information partitions described in this way verify the conditions of synchronous perfect recall: each information set $U_\eta$ consists of histories of the same length (as $\eta$), and for every pair $(\tau, \tau')$ of histories with different observations $\hat{\beta}(\tau) \neq \hat{\beta}(\tau')$, and every pair of moves $c, c' \in \Gamma$, the observation history of the successors $\tau c$ and $\tau' c'$ will also differ $\hat{\beta}(\tau c) \neq \hat{\beta}(\tau' c')$.

To describe observation functions by a finite-state automaton, we fix a finite set $\Sigma$ of observations and specify a Mealy automaton $M = (Q, \Gamma, \Sigma, q_\epsilon, \delta, \lambda)$, with moves
from $\Gamma$ as input and observations from $\Sigma$ as output. Then, we consider the extended output function of $\mathcal{M}$ as an observation function $\beta_{\mathcal{M}}: \Gamma^+ \rightarrow \Sigma$.

To illustrate, Fig. 1a shows a Mealy automaton defining an observation function. The input alphabet is the set $\Gamma = \{a, b\}$ of moves, and the output alphabet is the set $\{1, 2\}$ of observations. For example, the histories $abb$ and $bba$ map to the same observation sequence, namely $111$, thus they belong to the same information set; the information partition on histories of length 2 is $\{aa, ab, bb\}, \{ba\}$.

This formalism captures the standard approach for describing information in finite-state systems (see, e.g., Reif [26], Lin and Wonham [19], Kupferman and Vardi [17], van der Meyden and Wilke [28]).

### 2.2.3 Indistinguishability

As a second alternative, we represent information partitions as equivalence relations between histories, such that the equivalence classes correspond to information sets. Intuitively, a player cannot distinguish between equivalent histories.

We say that an equivalence relation is an *indistinguishability* relation if the represented information partition satisfies the conditions of synchronous perfect recall. The following characterisation simply rephrases the relevant conditions for partitions in terms of equivalence relations.

**Lemma 2.2** An equivalence relation $R \subseteq \Gamma^* \times \Gamma^*$ is an indistinguishability relation if, and only if, it satisfies the following properties:

1. For every pair $(\tau, \tau') \in R$, the histories $\tau, \tau'$ are of the same length.

---

**Fig. 1** A Mealy automaton and a two-tape DFA over alphabet $\Gamma = \{a, b\}$ describing the same information partition (the symbol $\ast$ stands for $\{a, b\}$).
For every pair \((\tau, \tau') \in R\) of histories of length \(\ell\), every pair \((\rho, \rho')\) of histories of length \(t \leq \ell\) that occur as prefixes of \(\tau, \tau'\), respectively, is also related by \((\rho, \rho') \in R\).

As a finite-state representation, we will consider indistinguishability relations recognised by two-tape automata. To illustrate, Fig. 1b shows a two-tape automaton that defines the same information partition as the Mealy automaton of Fig. 1a. Here and throughout the paper, the state \(q_{\text{rej}}\) represents a rejecting sink state. For example, the pair \((\tau_1, \tau_2)\) of words \(\tau_1 = abb\) and \(\tau_2 = bba\) is accepted by the automaton (reaching the accepting state \(q_1\)), meaning that the two words are indistinguishable.

Given a two-tape automaton \(A = (Q, \Gamma \times \Gamma, q_\varepsilon, \delta, F)\), the recognised relation \(L(A)\) is, by definition, synchronous and hence satisfies condition (2.2) of Lemma 2.2. To decide whether \(A\) indeed represents an indistinguishability relation, we can use standard automata-theoretic techniques to verify that \(L(A)\) is an equivalence relation, and that it satisfies the perfect-recall condition (2.2) of Lemma 2.2.

To verify that \(A\) defines a reflexive relation, it suffices to check that no state in \(Q \setminus F\) is reachable by using only transitions in \(A\) on letters \((c, c)\) for \(c \in \Gamma\). To verify that \(A\) defines a symmetric relation, we construct an automaton over alphabet \(\Gamma \times \Gamma\) consisting of two copies of the state space of \(A\) where the transition from \((q_1, q_2)\) on letter \((c_1, c_2)\) leads to \((q'_1, q'_2)\) with \(q'_1 = \delta(q_1, (c_1, c_2))\) and \(q'_2 = \delta(q_2, (c_2, c_1))\), and we check that no state \((q_1, q_2)\) with either \(q_1 \not\in F\) and \(q_2 \not\in F\), or \(q_1 \not\in F\) and \(q_2 \in F\) is reachable from \((q_\varepsilon, q_\varepsilon)\). To verify that \(A\) defines a transitive relation, we construct an automaton over alphabet \(\Gamma \times \Gamma \times \Gamma\) consisting of three copies of the state space of \(A\) where the transition from \((q_1, q_2, q_3)\) on letter \((c_1, c_2, c_3)\) leads to \((q'_1, q'_2, q'_3)\) with \(q'_1 = \delta(q_1, (c_1, c_2))\), \(q'_2 = \delta(q_2, (c_2, c_3))\), and \(q'_3 = \delta(q_3, (c_1, c_3))\), and we check that no state \((q_1, q_2, q_3)\) with \(q_1 \in F\) and \(q_2 \not\in F\) is reachable from \((q_\varepsilon, q_\varepsilon, q_\varepsilon)\). Finally, to verify condition (2.2) of Lemma 2.2 we can check that there is no transition in \(A\) from a reachable non-accepting state to an accepting state.

**Lemma 2.3** The question whether a given two-tape automaton recognises an indistinguishability relation with perfect recall is decidable in polynomial (actually, cubic) time.

The idea of using finite-state automata to describe information constraints of players in infinite games has been advanced in a series of work by Maubert and different coauthors [6, 9, 21, 22], with the aim of extending the classical framework of temporal logic and automata for perfect-information games to more expressive structures. In the general setup, the formalism features binary relations between histories that can be asynchronous and may not satisfy perfect recall. The setting of synchronous perfect recall is addressed as a particular case described by a one-state automaton that compares observation sequences rather than move histories. This allows to capture indistinguishability relations that actually correspond to regular observation functions in our setup.

Another approach of relating game histories via automata has been proposed recently by Fournier and Lhote [11]. The authors extend our framework to arbitrary
synchronous relations, which are not necessarily prefix closed—and thus do not satisfy perfect recall.

2.2.4 Equivalent Representations

In general, any partition of a set $X$ can be represented either as an equivalence relation on $X$—equating the elements of each part—or as a (complete) invariant function, that is a function $f : X \rightarrow Z$ such that $f(x) = f(y)$ if, and only if, $x, y$ belong to the same part. Thus equivalence relations and invariant functions represent different faces of the same mathematical object. The correspondence is witnessed by the following canonical maps.

For every function $f : X \rightarrow Z$, the kernel relation

\[\ker f := \{(x, y) \in X \times X \mid f(x) = f(y)\}\]

is an equivalence. Given an equivalence relation $\sim \subseteq X \times X$, the quotient map $[\cdot]_\sim : X \rightarrow 2^X$, which sends each element $x \in X$ to its equivalence class $[x]_\sim := \{y \in X \mid y \sim x\}$, is a complete invariant function for $\sim$. Notice that the kernel of the quotient map is just $\sim$.

For the case of information partitions with synchronous perfect recall, the above correspondence relates indistinguishability relations and observation-history functions.

Lemma 2.4 If $\beta : \Gamma^* \rightarrow \Sigma$ is an observation function, then $\ker \hat{\beta}$ is an indistinguishability relation that describes the same information partition. Conversely, if $\sim$ is an indistinguishability relation, then the quotient map is an observation function that describes the same information partition.

Accordingly, every information partition given by an indistinguishability relation can be alternatively represented by an observation function, and vice versa. However, if we restrict to finite-state representations, the correspondence might not be preserved. In particular, as the quotient map of any indistinguishability relation on $\Gamma^*$ has infinite range (histories of different length are always distinguishable), it is not definable by a Mealy automaton, which has finite output alphabet.

3 Observation is Weaker than Distinction

Firstly, we shall see that, for every regular observation function, the corresponding indistinguishability relation is also regular.

Proposition 3.1 For every observation function $\beta$ given by a Mealy automaton of size $m$, we can construct a two-tape DFA of size $O(m^2)$ that defines the corresponding indistinguishability relation $\ker \beta$. 
Proof To construct such a two-tape automaton, we run the given Mealy automaton on the two input tapes simultaneously, and send it into a rejecting sink state whenever the observation output on the first tape differs from the output on the second tape. Accordingly, the automaton accepts a pair \((\tau, \tau') \in (\Gamma \times \Gamma)^*\) of histories, if and only if, their observation histories are equal \(\hat{\beta}(\tau) = \hat{\beta}(\tau')\).

The statement of Proposition 3.1 is illustrated in Fig. 1 where the structure of the two-tape DFA of Fig. 1b is obtained as a parallel product of two copies of the Mealy automaton in Fig. 1a, where \(q_1 = (p_1, p_1)\), \(q_2 = (p_2, p_2)\), \(q_3 = (p_1, p_2)\), and \(q_4 = (p_2, p_1)\).

For the converse direction, however, the model of imperfect information described by regular indistinguishability relations is strictly more expressive than the one based on regular observation functions.

Lemma 3.2 There exists a regular indistinguishability relation that does not correspond to any regular observation function.

Proof As an example, consider a move alphabet with three letters \(\Gamma := \{a, b, c\}\), and let \(\sim \in \Gamma^* \times \Gamma^*\) relate two histories \(\tau, \tau'\) whenever they are equal or none of them contains the letter \(c\). This is an indistinguishability relation, and it is recognised by the two-tape automaton of Fig. 2.

We argue that the induced information tree has unbounded branching degree. All histories of the same length \(n\) that do not contain \(c\) are indistinguishable, hence \(U_n = \{a, b\}^n\) is an information set. However, for every history \(w \in U_n\) the history \(wc\) forms a singleton information set. Therefore \(U_n\) has at least \(2^n\) successors in the information tree, for every \(n\).

Fig. 2 A two-tape DFA defining an indistinguishability relation that does not correspond to any regular observation function (the symbol = stands for \(\{a, b, c\}\), the symbol \(\neq\) stands for \(\{y \in \Gamma \times \Gamma \mid x \neq y\}\), and the symbol * stands for \(\{a, b, c\}\))
However, for any observation function, the degree of the induced information tree is bounded by the size of the observation alphabet. Hence, the information partition described by \( \sim \) cannot be represented by an observation function of finite range and so, a fortiori, not by any regular observation function.

4 Which Distinctions Correspond to Observations

We have just seen, as a necessary condition for an indistinguishability relation to be representable by a regular observation function, that the information tree needs to have bounded branching degree. That is, there exists a finite number \( n \) such that every tree node has outdegree at most \( n \). In the following, we show that this condition is actually sufficient.

**Theorem 4.1** Let \( \Gamma \) be a finite set of moves. A regular indistinguishability relation \( \sim \) admits a representation as a regular observation function if, and only if, the information tree \( \Gamma^*/\sim \) has bounded branching degree.

**Proof** The only-if-direction is immediate. If for an indistinguishability relation \( \sim \), there exists an observation function \( \beta : \Gamma^+ \to \Sigma \) with finite range (not necessarily regular) such that \( \sim = \ker \hat{\beta} \), then the maximal degree of the information tree \( \Gamma^*/\sim \) is at most \( |\Sigma| \). Indeed, the observation-history function \( \hat{\beta} \) is a strong homomorphism from the move tree \( \Gamma^* \) to the tree of observation histories \( \hat{\beta}(\Gamma^*) \subseteq \Sigma^* \): it maps every pair \( (\tau, \tau_c) \) of successive move histories to the pair of successive observation histories \( (\hat{\beta}(\tau), \hat{\beta}(\tau)\hat{\beta}(\tau_c)) \), and conversely, for every pair of successive observation histories, there exists a pair of successive move histories that map to it. By the Homomorphism Theorem (in the general formulation of Mal’cev [20]), it follows that the information tree \( \Gamma^*/\sim = \Gamma^*/\ker \hat{\beta} \) is isomorphic to the image \( \hat{\beta}(\Gamma^*) \), which, as a subtree \( \Sigma^* \), has degree at most \( |\Sigma| \).

To verify the if-direction, consider an indistinguishability relation \( \sim \) over \( \Gamma^* \), given by a DFA \( \mathcal{R} \), such that the information tree \( \Gamma^*/\sim \) has branching degree at most \( n \in \mathbb{N} \).

Let us fix an arbitrary linear ordering \( \preceq \) of \( \Gamma \). First, we pick as a representative for each information set, its least element with respect to the lexicographical order \( <_{\text{lex}} \) induced by \( \preceq \). Then, we order the information sets in \( \Gamma^*/\sim \) according to the lexicographical order of their representatives. Next, we define the rank of any nonempty history \( \tau_c \in \Gamma^* \) to be the index of its information set \([\tau_c]_\sim \) in this order, restricted to successors of \([\tau]_\sim \) — this index is bounded by \( n \). Let us consider the observation function \( \hat{\beta} \) that associates to every history its rank. We claim that (1) it describes the same information partition as \( \sim \) and (2) it is a regular function.

To prove the first claim, we show that whenever two histories are indistinguishable \( \tau \sim \tau' \), they yield the same observation sequence \( \hat{\beta}(\tau) = \hat{\beta}(\tau') \). The rank of a history is determined by its information set. Since \( \tau \sim \tau' \), every pair \((\rho, \rho')\) of prefix histories of the same length are also indistinguishable, and therefore yield the same rank \( \beta(\rho) = \beta(\rho') \). By definition of \( \hat{\beta} \), it follows that \( \hat{\beta}(\tau) = \hat{\beta}(\tau') \).
Conversely, to verify that $\hat{\beta}(\tau) = \hat{\beta}(\tau')$ implies $\tau \sim \tau'$, we proceed by induction on the length of histories. The basis concerns only the empty history and thus holds trivially. For the induction step, suppose $\hat{\beta}(\tau c) = \hat{\beta}(\tau' c')$. By definition of $\hat{\beta}$, we have in particular $\hat{\beta}(\tau) = \hat{\beta}(\tau'')$, which by induction hypothesis implies $\tau \sim \tau''$. Hence, the information sets of the continuations $\tau c$ and $\tau' c'$ are successors of the same information set $[\tau]_\sim = [\tau'']_\sim$ in the information tree $\Gamma^*/\sim$. As we assumed that the histories $\tau c$ and $\tau' c'$ have the same rank, it follows that they indeed belong to the same information set, that is $\tau c \sim \tau' c'$.

To verify the second claim on the regularity of the observation function $\beta$, we first notice that the following languages are regular:

- the (synchronous) lexicographical order $\{(\tau, \tau') \in (\Gamma \times \Gamma)^* \mid \tau \leq_{\text{lex}} \tau'\}$,
- the set of representatives $\{\tau \in \Gamma^* \mid \tau \leq_{\text{lex}} \tau' \text{ for all } \tau' \sim \tau\}$, and
- the representation relation $\{(\tau, \tau') \in \sim \mid \tau' \text{ is a representative}\}$.

Given automata recognising these languages, we can then construct, for each $k \leq n$, an automaton $A_k$ that recognises the set of histories of rank at least $k$: together with the representative of the input history, guess the $k - 1$ representatives that are below in the lexicographical order. Finally, we take the synchronous product of the automata $A_1 \ldots A_k$ and equip it with an output function as follows: for every transition in the product automaton all components of the target state, up to some index $k$, are accepting — we define the output of the transition to be just this index $k$. This yields a Mealy automaton that outputs the rank of the input history, as desired.

For further use, we estimate the size of the Mealy automaton defining the rank function as outlined in the proof. Suppose that an indistinguishability relation $\sim \subseteq (\Gamma \times \Gamma)^*$ given by a two-tape DFA $R$ of size $m$ gives rise to an information tree $\Gamma^*/L(R)$ of maximal degree $n$. The lexicographical order is recognisable by a two-tape DFA of size $O(|\Gamma|^2)$, bounded by $O(m)$; to recognise the set of representatives we take the synchronous product of this automaton with $R$, and apply a projection and a complementation, obtaining a DFA of size bounded by $2^{O(m^2)}$; for the representation relation, we take a synchronous product of this automaton with $R$ and obtain a two-tape DFA of size still bounded by $2^{O(m^2)}$. For every index $k \leq n$, the automaton $A_k$ can be constructed via projection from a synchronous product of $n$ such automata, hence its size is bounded by $2^{2^{O(mn^2)}}$. The Mealy automaton for defining the rank runs all these $n$ automata synchronously, so it is of the same order of magnitude $2^{2^{O(mn^2)}}$.

To decide whether the information tree represented by a regular indistinguishability relation has bounded degree, we use a result from the theory of word-automatic structures [5, 15]. For the purpose of our presentation, we define an automatic presentation of a tree $T = (V, E)$ as a triple $(A_V, A_w, A_E)$ of automata with input alphabet $\Gamma$, together with a surjective naming map $h : L \to V$ defined on a set of words $L \subseteq \Gamma^*$ such that

- $L(A_V) = L$,
- $L(A_w) = \ker h$, and
- $L(A_E) = \{(u, v) \in L \times L \mid (h(u), h(v)) \in E\}$. 

 Springer
In this case, $h$ is an isomorphism between $T = (V, E)$ and the quotient $(L, L(A_E))/L(A_{\sim})$. The size of such an automatic presentation is the added size of the three component automata. A tree is automatic if it has an automatic presentation.

For an information partition given by an indistinguishability relation $\sim$ defined by a two-tape-DFA $R$ on a move alphabet $\Gamma$, the information tree $\Gamma^*/\sim$ admits an automatic presentation with the naming map that sends every history $\tau$ to its information set $[\tau]_\sim$, and

- as domain automaton $A_V$, the one-state automaton accepting all of $\Gamma^*$ (of size $|\Gamma|$);
- as the equality automaton $A_\sim$, the two-tape DFA $R$, and
- for the edge relation, a two-tape DFA $A_E$ that recognises the relation

$$\{(\tau, \tau'c) \in \Gamma^* \times \Gamma^* \mid (\tau, \tau') \in L(R)\}.$$

The latter automaton is obtained from $R$ by adding transitions from each accepting state, with any move symbol on the first tape and the padding symbol on the second tape, to a unique fresh accepting state from which all outgoing transitions lead to the rejecting sink $q_{\text{rej}}$. Overall, the size of the presentation will thus be bounded by $O(|R|)$.

Now, we can apply the following result of Kuske and Lohrey.

**Proposition 4.2** ([18, Propositions 2.14–2.15]) The question whether an automatic structure has bounded degree is decidable in exponential time. If the degree of an automatic structure is bounded, then it is bounded by $2^{2mO(1)}$ in the size $m$ of the presentation.

This allows to conclude that the criterion of Theorem 4.1 characterising regular indistinguishability relations that are representable by regular observation functions is effectively decidable. By following the construction for the rank function outlined in the proof of the theorem, we obtain a fourfold exponential upper bound for the size of a Mealy automaton defining an observation function.

**Theorem 4.3** (i) The question whether an indistinguishability relation given as a two-tape DFA admits a representation as a regular observation function is decidable in exponential time (with respect to the size of the DFA).

(ii) Whenever this is the case, we can construct a Mealy automaton of fourfold-exponential size and with at most doubly exponentially many output symbols that defines a corresponding observation function.

## 5 Improving the Construction of Observation Automata

Theorem 4.3 establishes only a crude upper bound on the size of a Mealy automaton corresponding to a given indistinguishability DFA. In this section, we present a more detailed analysis that allows to improve the construction by one exponential.
Firstly, let us point out that an exponential blowup is generally unavoidable, for the size of the automaton and for its observation alphabet.

**Example 5.1** Figure 3a shows a two-tape DFA that compares histories over a move alphabet \(\{a, b\}\) with an embargo period of length \(k\). Every pair of histories of length less than \(k\) is accepted, whereas history pairs of length \(k\) and onwards are rejected if, and only if, they are different (the picture illustrates the case for \(k = 3\)). A Mealy automaton that describes this indistinguishability relation needs to produce, for every different prefix of length \(k\), a different observation symbol. To do so, it has to store the first \(k\) symbols, which requires \(2^k\) states and \(2^k\) observation symbols (see Fig. 3b).

We first identify some structural properties of indistinguishability relations and their DFA, and then present the concrete construction.

### 5.1 Structural Properties of Regular Indistinguishability Relations

For the following, let us fix a move alphabet \(\Gamma\) and a two-tape DFA \(\mathcal{R} = (Q, \Gamma \times \Gamma, q_\varepsilon, \delta, F)\) defining an indistinguishability relation \(L(\mathcal{R}) = \sim\). For convenience, we will usually write \(\delta(q, (\tau, \tau'))\) for \(\delta(q, (\tau, \tau'))\).

We assume that the automaton \(\mathcal{R}\) is minimal, in the usual sense that all states are reachable from the initial state, and the languages accepted from two different states are different. Note that, due to synchronous perfect recall (whenever two histories are distinguishable, their continuations are also distinguishable), minimality also implies...

---

**Fig. 3** A synchronous two-tape automaton with \(2^k\) states (here \(k = 3\)) for which an equivalent observation Mealy automaton requires exponential number of states \((2^k)\)
that all states of $\mathcal{R}$ are accepting, except for the single sink state $q_{\text{rej}}$, that is, $F = Q \setminus \{q_{\text{rej}}\}$.

First, we classify the states according to the behaviour of the automaton when reading the same input words on both tapes. On the one hand, we consider the states reachable from the initial state on such inputs, which we call \textit{reflexive} states:

$$\text{Ref} = \{q \in Q \mid \exists \tau \in \Gamma^* : \delta(q_\varepsilon, \tau) = q\}.$$ 

On the other hand, we consider the states from which it is possible to reach the rejecting sink by reading the same input word on both tapes, which we call \textit{ambiguous} states:

$$\text{Amb} = \{q \in Q \mid \exists \tau \in \Gamma^* : \delta(q, \tau) = q_{\text{rej}}\}.$$ 

For instance, in the running example of Fig. 1, the reflexive states are $\text{Ref} = \{q_1, q_2\}$ and the ambiguous states are $\text{Amb} = \{q_3, q_4, q_{\text{rej}}\}$.

Since indistinguishability relations are reflexive, all reflexive states are accepting and by reading any pair of identical words from a reflexive state, we always reach an accepting state. Therefore, a reflexive state cannot be ambiguous. Perhaps less obviously, the converse also holds: a non-reflexive state must be ambiguous.

\textbf{Lemma 5.2 (Partition Lemma)} \quad Q \setminus \text{Ref} = \text{Amb}.

\textbf{Proof} The inclusion $\text{Amb} \subseteq Q \setminus \text{Ref}$ (or, equivalently, that $\text{Amb}$ and $\text{Ref}$ are disjoint) follows from the definitions and the fact that $\sim$ is a reflexive relation, and thus $\delta(q_\varepsilon, \tau)$ for all histories $\tau$.

To show that $Q \setminus \text{Ref} \subseteq \text{Amb}$, let us consider an arbitrary state $q \in Q \setminus \text{Ref}$. By minimality of $\mathcal{R}$, the state $q$ is reachable from $q_\varepsilon$; there exist histories $\tau, \tau'$ such that $\delta(q_\varepsilon, \tau') = q$. Let $q_\tau = \delta(q_\varepsilon, \tau)$ be the state reached after reading $\tau$ (see figure). Thus, $q_\tau \in \text{Ref}$ and in particular $q_\tau \neq q$. Again by minimality of $\mathcal{R}$, the languages accepted from $q$ and $q_\tau$ are different. Hence, there exist histories $\pi, \pi'$ such that $\pi'$ is accepted from $q$ and rejected from $q_\tau$, or the other way round. In the former case, we have that $\tau \pi \sim \tau' \pi'$ and $\tau \pi \not\sim \tau \pi'$, which by transitivity of $\sim$, implies $\tau \pi' \not\sim \tau' \pi'$. This means that from state $q$ reading $\pi'$, leads to $q_{\text{rej}}$, showing that $q \in \text{Amb}$, which we wanted to prove. In the latter case, the argument is analogous.

\hfill $\square$

We say that a pair of histories accepted by $\mathcal{R}$ is \textit{ambiguous}, if, upon reading them, the automaton $\mathcal{R}$ reaches an ambiguous state other than $q_{\text{rej}}$. Histories $\tau, \tau'$ that form an ambiguous pair are thus indistinguishable, so they must map to the same observation. However, there exists a suffix $\pi$ such that the extensions $\tau \cdot \pi$ and $\tau' \cdot \pi$ become distinguishable. Therefore, any observation automaton for $\mathcal{R}$ has to reach two
different states after reading \( \tau \) and \( \tau' \) since otherwise, the extensions by the suffix \( \pi \) would produce the same observation sequence, making \( \tau \cdot \pi \) and \( \tau' \cdot \pi \) wrongly indistinguishable. The argument generalises immediately to collections of more than two histories. We call a set of histories that are pairwise ambiguous an \textit{ambiguous clique}.

We shall see later, in the proof of Lemma 5.10, that whenever the size of ambiguous cliques is unbounded, the information tree \( \Gamma^*/L(R) \) has unbounded branching degree, and therefore there exists no Mealy automaton corresponding to \( R \). Now, we show conversely that whenever the size of the ambiguous cliques is bounded, we can construct such a Mealy automaton.

We say that two histories \( \tau, \tau' \in \Gamma^* \) of the same length are \textit{interchangeable} and write \( \tau \approx \tau' \), if for all \( \pi \in \Gamma^* \). Note that \( \approx \) is an equivalence relation and that \( \tau \approx \tau' \) implies \( \delta(q_\varepsilon, \tau') = \delta(q_\varepsilon, \tau \cdot \pi) \). The converse also holds.

\textbf{Lemma 5.3} \textit{For all histories} \( \tau, \tau' \in \Gamma^* \), \textit{we have} \( \delta(q_\varepsilon, \tau') \in \Ref \) \textit{if, and only if,} \( \tau \approx \tau' \).

\textit{Proof} \ One direction, that \( \tau \approx \tau' \) implies \( \delta(q_\varepsilon, \tau') \in \Ref \), follows immediately from the definitions (take \( \pi = \tau' \) in the definition of interchangeable histories).

For the reverse direction, let us suppose that \( \delta(q_\varepsilon, \tau') \in \Ref \). We will show that, for all histories \( \tau'' \), the states \( \delta(q_\varepsilon, \tau') \in \Ref \) and \( q_1 = \delta(q_\varepsilon, \tau'') \) accept the same language. Towards this, let \( \pi_1, \pi_2 \) be an arbitrary pair of histories such that \( q_2 = \delta(q_\varepsilon, \pi_2) \) is accepted from \( q_1 \). Then,

- \( \tau \pi_1 \sim \tau' \pi_1 \), because \( \pi_1 \approx \pi_2 \), from a reflexive state reading \( \delta(q_\varepsilon, \tau') \in \Ref \) does not lead to \( q_{\text{rej}} \) (by Lemma 5.2).
- \( \tau \pi_1 \sim \tau'' \pi_2 \), because \( \pi_1 \approx \pi_2 \) and \( \delta(q_\varepsilon, \pi_2) = q_1 \) is accepted from \( q_1 \).

By transitivity of \( \sim \), it follows that \( \tau' \pi_1 \sim \tau'' \pi_2 \), hence \( \pi_2 \) is accepted from \( \pi_2 \).

Accordingly, the language accepted from \( q_1 \) is included in the language accepted from \( q_2 \); the converse inclusion holds by a symmetric argument. Since the states \( q_1 \) and \( q_2 \) accept the same language, and because the automaton \( R \) is minimal, it follows that \( q_1 = q_2 \), which means that \( \tau \) and \( \tau' \) are interchangeable. \( \square \)

According to Lemma 5.3 and because \( q_{\text{rej}} \notin \Ref \), all pairs of interchangeable histories are also indistinguishable. In other words, the interchangeability relation \( \approx \) refines the indistinguishability relation \( \sim \), and thus \( [\tau]_\approx \subseteq [\tau]_\sim \) for all histories \( \tau \in \Gamma^* \). In the running example (Fig. 1), the sets \{aa, ab, bb\} and \{ba\} are \( \sim \)-equivalence classes, and the sets \{aa, bb\}, \{ab\}, and \{ba\} are \( \approx \)-equivalence classes.

We have seen that any observation automaton for \( R \) must reach two different states after reading two histories \( \tau, \tau' \) that form an ambiguous pair, which, by Lemma 5.3, is equivalent to saying that \( \tau, \tau' \) are indistinguishable but not interchangeable, \( \tau \sim \tau' \) and \( \tau \neq \tau' \). On the other hand, a crucial property of our
construction is that interchangeable histories will be mapped to the same state of the observation automaton.

5.2 Constructing the Observation Automaton

Intuitively, the observation automaton stores an abstract representation of the information set $[\tau]_\sim$ of the input history $\tau$. The abstract representation of $[\tau]_\sim$ is described as follows. First consider the histories in $[\tau]_\sim$ in lexicographical order: $\tau_1, \ldots, \tau_k$ (where $k$ is the cardinality of $[\tau]_\sim$). Then, consider the complete directed graph on the set of nodes $V = \{1, \ldots, k\}$, where each edge $(i, j) \in V^2$ is labelled by $q_{i,j} = \delta(q_i, \tau_j)$. This graph is finite for every particular history $\tau$, but it may be of unbounded size as the length of the input history grows. It may also contain some redundancy, for example if two histories $\tau_i, \tau_j$ are interchangeable $\tau_i \approx \tau_j$. Then, by definition of interchangeability, the two nodes $i$ and $j$ look alike in the sense that the label $q_{i,k}$ of the edge from $i$ to any node $k \in V$ is equal to the label $q_{j,k}$ of the edge from $j$ to $k$. Our abstract representation of $[\tau]_\sim$ is the (complete) subgraph induced by the $\approx$-representatives of $[\tau]_\sim$, that is the lexicographically smallest elements of each class $[\tau_i]_\approx$ for $i = 1, \ldots, k$. This subgraph corresponds to an ambiguous clique.

Given a history $\tau$, our observation automaton stores such a graph representation of $[\tau]_\sim$ as well as an index $i$ corresponding to the (unique) $\approx$-representative $\tau_i$ such that $\tau \approx \tau_i$.

Note that any two interchangeable histories have the same abstract representation. We show that this representation can be updated upon reading the moves in $\tau$ sequentially, and that it preserves sufficient detail to define an observation function that produces a correct output on each move. We also show that the size of ambiguous cliques, which correspond to the graphs induced by $\approx$-representatives, is bounded (if the branching degree of the information tree $\Gamma^*/L(\mathcal{R})$ is bounded), thus the number of abstract representations is finite and our observation automaton has a finite state space.

To describe the construction formally, let us lift the lexicographical order $\leq_{\text{lex}}$ to sets of histories of the same length by comparing the smallest word of each set: we write $S \leq_{\text{lex}} S'$ if $\min S \leq_{\text{lex}} \min S'$. This allows us to rank the $\approx$-equivalence classes contained in a $\sim$-equivalence class, in increasing order. In the running example, if we consider the $\sim$-equivalence class $\{aa, ab, bb\}$, then $\{aa, bb\}$ gets rank 1, and $\{ab\}$ gets rank 2 because $\{aa, bb\} \leq \{ab\}$. On the other hand, the $\sim$-equivalence class $\{ba\}$, as a singleton, gets rank 1.

Now, we denote by $\tau)$ the rank of the $\approx$-equivalence class containing $\tau$. For example, $(bb) = 1$ and $(ab) = 2$. Further, we denote by $\text{mat}(\tau)$ the square matrix of dimension $n = \max_{i \in [1, \tau]} n(i)$ where we associate to each coordinate $i = 1, \ldots, n$ the $i$-th $\approx$-equivalence class $C_i$ contained in $[\tau]_\sim$. The $(i, j)$-entry of $\text{mat}(\tau)$ is the state $q_{ij} = \delta(q_i, \tau_j)$ where $\tau_i \in C_i$ and $\tau_j \in C_j$. Thanks to interchangeability, the state $q_{ij}$ is well defined being independent of the choice of $\tau_i$ and $\tau_j$. 
Example 5.4 In the running example, we have $a \sim b$ thus $\text{mat}(a) = \text{mat}(b)$:

$$\text{mat}(a) = \text{mat}(b) = \begin{pmatrix} a \\ b \end{pmatrix} \begin{pmatrix} q_1 & q_3 \\ q_4 & q_2 \end{pmatrix}.$$ 

Moreover $[aa] \approx = \{aa, bb\}$, and $[ab] \approx = \{ab\}$, and $[ba] \approx = \{ba\}$, and thus:

$$\text{mat}(aa) = \text{mat}(ab) = \text{mat}(bb) = \begin{pmatrix} q_1 & q_3 \\ q_4 & q_2 \end{pmatrix} \text{ and } \text{mat}(ba) = \begin{pmatrix} q_2 \end{pmatrix}.$$

Notice that, in the matrix $\text{mat}(\tau)$ associated to any history $\tau \in \Gamma^*$, the diagonal entries are reflexive states, by Lemma 5.3. Conversely, non-diagonal entries correspond to pairs of histories that are not $\approx$-equivalent, hence these states are not reflexive (Lemma 5.3), therefore, by Lemma 5.2, they must be ambiguous states.

**Lemma 5.5** For every history $\tau$, the diagonal entries in $\text{mat}(\tau)$ are reflexive states, and the non-diagonal entries in $\text{mat}(\tau)$ are ambiguous states.

Each state of our observation automaton will be formed by a square matrix corresponding to the complete directed graph of $\approx$-representatives of an information set, and by an index corresponding to a node in the graph (or equivalently, to an $\approx$-equivalence class).

Towards describing the transition and output function, let us consider a square matrix $M$ with entries in $Q$ (let $n$ be the dimension of $M$). We define $\text{next}(M)$ to be the $n \times |\Gamma| \times n \times |\Gamma|$ matrix obtained by substituting each entry $q_{ij}$ in $M$ with the $|\Gamma| \times |\Gamma|$ matrix where every $(a, b)$-entry is $q_{ij} = \delta(q_{\epsilon}, \tau_i)$, as illustrated in the following example.

Example 5.6 In the running example, the $|\Gamma| \times |\Gamma|$ matrix associated with state $q_1$ is:

$$q_1 \mapsto \begin{pmatrix} \delta(q_1, q_1) & \delta(q_1, q_3) \\ \delta(q_4, q_1) & \delta(q_4, q_3) \end{pmatrix} = \begin{pmatrix} q_1 & q_3 \\ q_4 & q_2 \end{pmatrix}.$$ 

The matrices associated with the other states are (where we denote the $q_{\text{rej}}$ state by $\times$):

$$q_2 \mapsto \begin{pmatrix} q_2 \times \\ \times q_1 \end{pmatrix}, \quad q_3 \mapsto \begin{pmatrix} \times q_1 \\ \times q_4 \end{pmatrix}, \quad q_4 \mapsto \begin{pmatrix} \times \times \\ q_1 q_3 \end{pmatrix}.$$ 

Hence for $M = \begin{pmatrix} q_1 & q_3 \\ q_4 & q_2 \end{pmatrix}$, we have $\text{next}(M) = \begin{pmatrix} q_1 & q_3 & q_1 \\ q_4 & q_2 & q_1 \\ \times & q_4 & q \times q_2 \times \\ \times & q_3 & q_1 \end{pmatrix}$.

The matrix $\text{next}(M)$ contains the disjoint union of matrices corresponding to the information sets that are successors (in the information tree) of the information set corresponding to $M$.

Now, for every $n \times n$ matrix $M$ with entries in $Q$, every $i \in \{1, \ldots, n\}$, and every move $c \in \Gamma$, we define an observation $\text{obs}_c(M, i)$ and a successor $\text{succ}_c(M, i) = (N, j)$ by the following construction:
(i) Initialise $N = \text{next}(M)$; consider the $(c, c)$ entry of the $|\Gamma| \times |\Gamma|$ matrix substituting the $(i, i)$-entry of $M$ in $N$, and initialise $j$ to be its position on the diagonal of $N$;

(ii) define $\text{obs}_c(M, i) = \min \{ k \mid \text{the } (k, j)\text{-entry of } N \text{ is not the } q_{\text{rej}} \text{ state} \}$ (note that the $(k, k)$-entry of $N$ is not the $q_{\text{rej}}$ state, thus $\text{obs}_c(M, i)$ is well defined);

(iii) for every $1 \leq k \leq n \cdot |\Gamma|$, if the $(k, j)$-entry of $N$ is the $q_{\text{rej}}$ state, then remove the $k$-th row and $k$-th column (note that the $j$-th row and $j$-th column are never removed) and update the index $j$ accordingly (this amounts to removing histories that are not in the information set of the history pointed by the index);

(iv) if two columns of $N$ are identical, then remove the column and the corresponding row at the larger position. If the removed column is at the position $j$, assign the (smaller) position of the remaining duplicate column to $j$. Repeat this step until no two columns are identical (this amounts to removing histories that are interchangeable with a lexicographically smaller history).

**Example 5.7** Consider $M = \begin{pmatrix} q_1 & q_3 \\ q_4 & q_2 \end{pmatrix}$ and $i = 2$, which are the matrix and index of the history $\tau = b$ in the running example. In figures, the index $i$ is depicted as a vertical arrow pointing to the $i$th column of the matrix. We obtain $\text{succ}_a(M, i)$ (the matrix and index of $\tau' = ba$) and $\text{obs}_a(M, i)$ as follows:

\[
\begin{pmatrix} q_1 & q_3 \\ q_4 & q_2 \end{pmatrix} \xrightarrow{(i)} \begin{pmatrix} q_1 & q_3 \times q_1 \\ q_4 & q_2 \times q_4 \\ \times & q_2 \times \\ q_1 & q_3 \times q_1 \end{pmatrix} \xrightarrow{(iii)} \begin{pmatrix} q_2 \\ q_2 \end{pmatrix} \xrightarrow{(iv)} \begin{pmatrix} q_2 \end{pmatrix} \text{ and } \text{obs}_a(M, i) = 3
\]

and we obtain $\text{succ}_b(M, i)$ (the matrix and index of $\tau' = bb$) and $\text{obs}_b(M, i)$ as follows:

\[
\begin{pmatrix} q_1 & q_3 \\ q_4 & q_2 \end{pmatrix} \xrightarrow{(i)} \begin{pmatrix} q_1 & q_3 \times q_1 \\ q_4 & q_2 \times q_4 \\ \times & q_2 \times \\ q_1 & q_3 \times q_1 \end{pmatrix} \xrightarrow{(iii)} \begin{pmatrix} q_1 & q_3 & q_1 \\ q_4 & q_2 & q_4 \\ q_1 & q_3 & q_1 \end{pmatrix} \xrightarrow{(iv)} \begin{pmatrix} q_1 & q_3 \\ q_4 & q_2 \end{pmatrix} \text{ and } \text{obs}_b(M, i) = 1.
\]

Finally, we define a Mealy automaton $F = (P, \Gamma, \Sigma, p_\epsilon, \delta, \lambda)$ over the input alphabet $\Gamma$ and an output alphabet $\Sigma \subseteq \mathbb{N}$ as follows:

- $P := \{(M, i) \mid M = \text{mat}(\tau) \text{ and } i = \tau\}$ for some history $\tau$,
- $p_\epsilon := (q_\epsilon, 1)s$,
- for every state $(M, i) \in P$ and every move $c \in \Gamma$, let $\delta((M, i), c) := \text{succ}_c(M, i)$, and let $\lambda((M, i), c) := \text{obs}_c(M, i)$.

The Mealy automaton $F$ obtained for the two-tape DFA of Fig. 1b is shown in Fig. 4.
5.3 Correctness of the Construction

First we show that the successor function along moves defined above provides an homomorphic image of $\Gamma^*$ on matrix-index pairs.

**Lemma 5.8** For all histories $\tau \in \Gamma^*$ and moves $c \in \Gamma$, if $(M, i) = (\text{mat}(\tau), \tau)$, then $\text{succ}_c(M, i) = (\text{mat}(\tau c), \tau c))$.

**Proof** The statement is verified along the construction of the transition function:

- In step $(i)$, suppose $M = \text{mat}(\tau)$ is of dimension $n$. We can associate to each coordinate of $M$ an $\approx$-equivalence class contained in $[\tau]_\approx$, say $C_1, C_2, \ldots, C_n$. For an $\approx$-equivalence class $C$ and a move $b \in \Gamma$, consider the class $C b = [wb]_\approx$ for some/every $w \in C$ – the definition is independent of the choice of $w$: it is easy to prove that $w \approx w'$ implies $wb \approx w'b$. Now, we associate to the coordinates of $\text{next}(M)$ the $\approx$-equivalence classes $C_j b$ (for each $1 \leq j \leq n$ and $b \in \Gamma$) in lexicographic order. The stored index is the index of the $\approx$-equivalence class of $\tau c$.

- In step $(iii)$, we remove the coordinates associated with an $\approx$-equivalence class that is not contained in $[\tau c]_\approx$ The stored index (pointing to the $\approx$-equivalence class containing $\tau c$) is updated accordingly.

- In step $(iv)$, we merge identical rows/columns which correspond to identical $\approx$-equivalence classes. Keeping the leftmost class ensures that the lexicographic order between $\approx$-equivalence classes is preserved. At the end, each $\approx$-equivalence class contained in $[\tau c]_\approx$ is indeed associated to some coordinate, and the resulting matrix-index pair corresponds to $\text{mat}(\tau c)$ and $\tau c)$, as desired.

To establish the correctness of the observation function $\text{obs}$, by the assumption of synchronous perfect recall, it suffices to show that the first time two histories become
distinguishable, the observation function returns different outputs (and returns the same output before that).

**Lemma 5.9** For all histories \( \tau, \tau' \in \Gamma^* \), moves \( c, c' \in \Gamma \), with \( (M, i) = (\text{mat}(\tau), \tau) \) and \( (M', i') = (\text{mat}(\tau'), \tau') \), if \( \tau \sim \tau' \), then:

\[
\text{obs}_c(M, i) = \text{obs}_{c'}(M', i') \quad \text{if and only if} \quad \tau c \sim \tau' c'.
\]

**Proof** Since \( \tau \sim \tau' \), we have \( M = M' \) and therefore \( N := \text{next}(M) = \text{next}(M') \). Let \( j \) (resp., \( j' \)) be the position of the \( (c, c) \) entry (resp., the \( (c', c') \) entry) of the \( |\Gamma| \times |\Gamma| \) matrix substituting the \( (i, i) \)-entry (resp., the \( (i', i') \)-entry) of \( M \) in \( N \). The \( (j, j') \)-entry of \( N \) is the \( q_{\text{rej}} \) state if and only if \( \tau c \not\sim \tau' c' \), hence \( \text{obs}_c(M, i) = \text{obs}_{c'}(M', i') \) if and only if \( \tau c \sim \tau' c' \).

Note that the observation function obtained via our procedure is not canonical, different constructions are possible [2, 11]. For instance, considering the matrix \( M \) from Example 5.7, we can reduce the range of observations by using consecutive observations: since the observation value 2 is not used from any state \( (M, \cdot) \), we can set \( \text{obs}_{q}(M, 2) = 2 \) (instead of 3).

According to Lemma 5.8 the state space \( P \) of \( F \) is the closure of \( \{p_{\varepsilon}\} \) under the \( c \)-successor operation, for all \( c \in \Gamma \). The correctness of the Mealy automaton \( F \) is established in Lemma 5.9. It remains to show that \( P \) is finite. The key is to bound the dimension of the largest matrix in \( P \), which is the size of the largest ambiguous clique.

**Lemma 5.10** If the branching degree of the information tree \( \Gamma^* / L(\mathcal{R}) \) is bounded, then the largest ambiguous clique contains at most a doubly-exponential number of histories (with respect to the size of \( \mathcal{R} \)).

**Proof** First we show, by contradiction, that the size of ambiguous cliques is bounded. Since the number of ambiguous states in \( \mathcal{R} \) is finite, if there exists an arbitrarily large ambiguous clique, then by Ramsey’s theorem [25], there exists an arbitrarily large set \( \{\tau_1, \tau_2, \ldots, \tau_k\} \) of histories and a state \( q \in \text{Amb} \setminus \{q_{\text{rej}}\} \) such that \( \delta(q, \tau_i) = q \) for all \( 1 \leq i < j \leq k \). By definition of \( \text{Amb} \), there exists a nonempty history \( \tau c \) such that \( \delta(q, \tau c) = q_{\text{rej}} \). Consider such a history \( \tau c \) of minimal length. The histories \( \tau_i \tau (i = 1, \ldots, k) \) are in the same \( \sim \)-equivalence class, but the equivalence classes \( [\tau_i \tau c]_{\sim} \) are pairwise distinct, and hence, the class \( [\tau_1 \tau c]_{\sim} \) has at least \( k \) many successors in the information tree. Accordingly, the number of successors of an information set can be arbitrarily large, in contradiction to our assumption that the branching degree of the information tree \( \Gamma^* / L(\mathcal{R}) \) is bounded.

Note that the size of the largest ambiguous clique corresponds to the maximum number of \( \approx \)-equivalence classes contained in an \( \sim \)-equivalence class (Lemma 5.5). We argue that this number is at most doubly-exponential. Similarly to the proof of Theorem 4.1, we notice that the set of \( \approx \)-representatives defined by \( \{\tau \in \Gamma^* \mid \tau \leq_{\text{lex}} \tau' \text{ for all } \tau' \approx \tau\} \) is regular, and therefore the representation relation \( \{(\tau, \tau') \in \sim \mid \)
\( \tau' \) is a \( \approx \)-representative) is also regular. A result of Weber [30, Theorem 2.1] yields a bound on the number of \( \approx \)-representatives of a history that is exponential in the size \( \ell \) of the two-tape DFA recognising the representation relation, namely \( O(\ell)^{\ell} \). Furthermore, \( \ell \) is bounded by \( 2^{O(m^2)} \) by the same argument as in the proof of Theorem 4.1 (where \( m \) is the size of \( R \)). This provides a doubly-exponential bound \( 2^{2^{O(m^2)}} \) on the size of ambiguous cliques.

According to Lemma 5.10, the dimension \( k \) of the largest matrix in \( P \) is at most doubly exponential in \( |R| \). The number of matrices of a fixed dimension \( d \) is at most \( |Q|^{d^2} \). Overall the number of matrices that appear in \( P \) is therefore bounded by \( k \cdot |Q|^{k^2} \), and as the index is at most \( k \), it follows that the number of states in \( P \) is bounded by \( k^2 \cdot |Q|^k \), that is exponential in \( k \) and triply exponential in the size of \( R \).

**Theorem 5.11** For every indistinguishability relation given by a two-tape DFA \( R \) such that the information tree \( \Gamma^* / L(R) \) has bounded branching degree, we can construct a Mealy automaton of triply exponential size (with respect to the size of \( R \)) that defines a corresponding observation function.

### 6 Conclusion

The question of how to model information in infinite games is fundamental to defining their strategy space. As the decisions of each player are based on the available information, strategies are functions from information sets to actions. Accordingly, the information structure of a player in a game defines the support of her strategy space.

The assumption of synchronous perfect recall gives rise to trees as information structures (Lemma 2.1). In the case of observation functions with a finite range \( \Sigma \), these trees are subtrees of the complete \( |\Sigma| \)-branching tree \( \Sigma^* \) — on which \( \omega \)-tree automata can work (see [14, 27] for surveys on such techniques). Concretely, every strategy based on observations can be represented as a labelling of the tree \( \Sigma^* \) with actions; the set of all strategies for a given game forms a regular (that is, automata-recognisable) set of trees. Moreover, when considering winning conditions that are also regular, Rabin’s Theorem [24] allows to conclude that winning strategies also form a regular set. Indeed, we can construct effectively a tree automaton that recognises the set of strategies (for an individual player) that enforce a regular condition and, if this set is non-empty, we can also synthesise a Mealy automaton that defines one of these strategies. In summary, the interpretation of strategies as observation-directed trees allows us to search the set of all strategies systematically for winning ones using tree-automatic methods.

In contrast, when setting out with indistinguishability relations, we obtain more complicated tree structures that do not offer a direct grip to classical tree-automata techniques. As the example of Lemma 3.2 shows, there are cases where the information tree of a game is not regular, and so the set of all strategies is not recognisable by a tree automaton. Accordingly, the automata-theoretic approach to strategy synthesis
via Rabin’s Theorem cannot be applied to solve, for instance, the basic problem of constructing a finite-state strategy for one player to enforce a given regular winning condition.

On the other hand, modelling information with indistinguishability relations allows for significantly more expressiveness than observation functions. This covers notably settings where a player can receive an unbounded amount of information in one round. For instance, models with causal memory where one player may communicate his entire observation history to another player in one round can be captured with regular indistinguishability relation, but not with observation functions of any finite range. Even when an information partition that can be represented by finite-state observation functions, the representation by an indistinguishability relation may be considerably more succinct. For instance, a player that observes the move history perfectly, but with a delay of \(d\) rounds can be described by a two-tape DFA with \(O(d)\) many states, whereas any Mealy automaton would require exponentially more states to define the corresponding observation function.

At the bottom line, as a finite-state model of information, indistinguishability relations are strictly more expressive and can be (at least exponentially) more succinct than observation functions. In exchange, the observation-based model is directly accessible to automata-theoretic methods, whereas the indistinguishability-based model is not. Our result in Theorem 4.3 allows to identify effectively the instances of indistinguishability relations for which this gap can be bridged. That is, we may take advantage of the expressiveness and succinctness of indistinguishability relations to describe a game problem and use the procedure to obtain, whenever possible, a reformulation in terms of observation functions towards solving the initial problem with automata-theoretic methods.

This initial study opens several exciting research directions. One immediate question is whether the fundamental finite-state methods on strategy synthesis for games with imperfect information can be extended from the observation-based model to the one based on indistinguishability relations. Is it decidable, given a game for one player with a regular winning condition against Nature, whether there exists a winning strategy? Can the set of all winning strategies be described by finite-state automata? In case this set is non-empty, does it contain a strategy defined by a finite-state automaton?

Another, more technical, question concerns the automata-theoretic foundations of games. The standard models are laid out for representations of games and strategies as trees of a fixed branching degree. How can these automata models be extended to trees with unbounded branching towards capturing strategies constrained by indistinguishability relations? Likewise, the automatic structures that arise as information quotients of indistinguishability relations form a particular class of trees, where both the successor and the descendant relation (that is, the transitive closure) are regular. On the one hand, this particularity may allow to decide properties about games (viz. their information trees) that are undecidable when considering general automatic trees, notably regarding bisimulation or other forms of game equivalence.

Finally, in a more application-oriented perspective, it will be worthwhile to explore indistinguishability relations as a model for games where players can communicate via messages of arbitrary length. In particular this will allow to extend the framework
of infinite games on finite graphs to systems with causal memory considered in the area of distributed computing.
