(Received 3 November 2020; accepted 2 December 2020; published online 6 January 2021)

We performed calculations of the electronic band structure and the Fermi surface, measured the longitudinal resistivity $\rho_x(T, H)$, Hall resistivity $\rho_y(T, H)$, and magnetic susceptibility as a function of temperature at various magnetic fields for $VAs_2$ with a monoclinic crystal structure. The band structure calculations show that $VAs_2$ is a nodal-line semimetal when spin-orbit coupling is ignored. The emergence of a minimum at around 11 K in $\rho_x(T)$ measured at $H = 0$ demonstrates that some additional magnetic impurities ($V^{4+}$, $S = 1/2$) exist in $VAs_2$ single crystals, inducing Kondo scattering, evidenced by both the fitting of $\rho_x(T)$ data and the susceptibility measurements. It is found that a large positive magnetoresistance (MR) reaching 649% at 10 K and 9 T, its nearly quadratic field dependence, and a field-induced up-turn behavior of $\rho_x(T)$ also emerge in $VAs_2$, although MR is not so large due to the existence of additional scattering compared with other topological nontrivial/trivial semimetals. The observed properties are attributed to a perfect charge-carrier compensation, which is evidenced by both the calculations relying on the Fermi surface and the Hall resistivity measurements. These results indicate that the compounds containing V $(3d^4s^2)$ element can be as a platform for studying the influence of magnetic impurities to the topological properties.

DOI: 10.1088/0256-307X/38/1/017202

Since the discovery of quantum Hall effect in two-dimensional electron gas in the 1980s,[1] it has been recognized that the topologies of band structures in solid materials play an important role in classification of matter and understanding of physical properties. Then, many topological materials, such as topological insulators,[2–4] Dirac semimetals,[5,6] Weyl semimetals,[7–9] and nodal-line semimetals[10–13] have been proposed theoretically and confirmed experimentally. Most of them are free of strong correlation effects. In the presence of strong electron interactions, very fruitful topological phases can be expected, such as the topological Mott[14] or Kondo insulators,[15–17] topological superconductors,[18] and fractional topological insulators.[19–21] In order to pursue these exotic phases, searching for suitable compounds which are strongly correlated (usually in $d$ and $f$ orbital systems) and topologically nontrivial attracts much attention. For instance, SmB$_6$, as a typical rare-earth mixed valence compound, has been proposed theoretically as a topological Kondo insulator[15–17] and recently has been confirmed by the transport,[22–25] photoemission[26–28] and scanning tunneling microscopy (STM)[29] experiments. At sufficiently low temperature, the hybridization between 4$f$ orbitals and highly dispersive 5$d$ bands results in the formation of “heavy fermion” bands. Thus, SmB$_6$ is a correlated $Z_2$ topological insulator. Recently, a number of groups[30–33] predicted thousands of candidate topological materials by performing systematic high-throughput computational screening across the databases of known materials. Following these predictions, it is possible to search topological materials in the known compounds containing 3$d$ elements based on the calculations of band structure, and the measurements of physical properties.

$VAs_2$ crystalizes in a monoclinic structure with space group $C_{12/m1}$ (No. 12), as shown in Fig. 1(a), i.e., an isostructure to the transition metal dipnictides XPn$_2$ ($X = Nb$, Ta; Pn = P, As, Sb)[34–40] which have been widely studied theoretically and experimentally as a class of topological materials. For example, Wang et al.[41] identified the presence of rotational-symmetry-protected topological crystalline insulator (TCI) states in these compounds based on first-principles calculations combined with a symmetry analysis. It was found that all these compounds exhibit high mobilities and extremely large positive
magnetoresistance (MR). Interestingly, a negative longitudinal MR when the applied field is parallel to the current direction was observed in both TaSb$_2$ and TaAs$_2$. Similar to those observed in the known Weyl semimetals TaAs family,\cite{7-9,42-47} Compared to the 4d/5d electrons in NbAs$_2$/TaAs$_2$, the more localization of the 3d electrons in VAs$_2$ may lead to a stronger electronic correlation, or introduce an additional magnetic scattering to the carriers (Kondo effect).

In this work, we grew successfully VAs$_2$ crystals with a monoclinic structure and measured its longitudinal resistivity $\rho_{xx}(T, H)$, Hall resistivity $\rho_{xy}(T, H)$, and magnetic susceptibility as a function of temperature at various magnetic fields, also calculated its electronic band structure and Fermi surface (FS). The band structure calculations show that VAs$_2$ is also a nodal-line semimetal when spin-orbit coupling (SOC) is ignored. It is found that the $\rho_{xx}(T)$ measured at $H = 0$ exhibits a minimum at around 11 K, which is considered to originate from the magnetic impurities V$^4+$ ($S = 1/2$) scattering (i.e. Kondo effect), evidenced by both the susceptibility measurements and the fitting of $\rho_{xx}(T)$ data at low temperatures. It is further revealed that a nearly quadratic field dependence of MR, reaching 649% at 10 K and 9 T, and a field-induced up-turn behavior of $\rho_{xx}(T)$ also occur in this material, which are attributed to a perfect charge-carrier compensation, evidenced by both the calculations relying on the FS topology and the Hall resistivity measurements.

![Figure 1](image)

**Fig. 1.** (a) Crystal structure of VAs$_2$; (b) photograph of a VAs$_2$ crystal with 4 wires for resistance measurements; (c) single crystal XRD pattern of VAs$_2$; (d) the calculated Fermi surface of VAs$_2$; (e) the Brillouin zone; (f) and (g) band structures calculated without and with considering SOC; (h) and (i) nodal lines in the first Brillouin zone from different perspectives.

VAs$_2$ single crystals were grown by a chemical vapor transport method. High purity V and As powder were mixed in a mole ratio 1:2, then sealed in an evacuated silica tube containing I$_2$ as a transport agent with 10 mg/cm$^3$. The quartz tube was placed in a tube furnace with a temperature gradient of 950–750°C and heated for two weeks. Polyhedral crystals were obtained at the cold end of the tube. A single crystal with a dimension of $2.0 \times 0.73 \times 0.29$ mm$^3$ [see Fig. 1(b)] and a cleavage surface (001) was selected for the transport and magnetic property measurements. The composition was detected to be V:As = 32.7 : 67, using the energy dispersive x-ray spectrometer (EDXS), the crystal structure was determined by the single-crystal x-ray diffraction (XRD), as shown in Fig. 1(c), from which the lattice parameter $c = 7.481(7)$ Å was obtained, consistent with the result in Ref. [48]. The longitudinal resistivity and Hall resistivity measurements were carried out on a physical property measurement system (Quantum Design, PPMS-9T) with a standard four-probe method [see Fig. 1(b)]. The magnetization measurements were carried out on a magnetic property measurement system (Quantum Design, MPMS-7T). The band structure was calculated using the Vienna ab initio simulation package (VASP)\cite{49,50} with a generalized gradient approximation (GGA) of Perdew, Burke and Ernzerhof (PBE)\cite{51} for the exchange correlation potential. A cutoff energy of 520 eV and a $10 \times 10 \times 6$ k-point mesh were used to perform the bulk calculations. The nodal-line search and FS calculations were performed using the open-source software WannierTools\cite{52} that is based on the Wannier tight-binding model (WTBM) constructed using Wannier90.\cite{53}
Firstly, we discuss the results of our electronic structure calculations that extend the initial prediction of the high symmetry line semimetal for VAs$_2$\cite{32}. In order to address the topological character of VAs$_2$, we calculate its band structure and the FS. As shown in Fig. 1(d), there are six different FS sheets: two hole-like surfaces (green) at the L and Y points, and four electron-like (red) surfaces near the L and Z points, the volume of the electron and hole pockets is roughly the same, indicating that VAs$_2$ is nearly an electron-hole compensated semimetal, also evidenced by the Hall resistivity measurements discussed as follows. The bulk band structure of VAs$_2$ without and with SOC is presented in Figs. 1(f) and 1(g), respectively. It can be seen clearly that the bands near the Fermi level mainly arise from the d orbitals of V atoms, and the valence and conduction bands cross along the Y–X$_1$, Z–I$_1$ and L–I high symmetry directions. Without SOC, in the Brillouin zones (BZ), the nodal lines can be found using the open-source software WannierTool,\cite{32} see in Fig. 1(h). There are two types of nodal lines, one includes two nonclosed spiral lines extending across the BZ through point Z, the other contains two nodal loops near the L point. When SOC is included, these nodal lines are gapped [see Fig. 1(g)] and lead to a band inversion along the Y–X$_1$, Z–I$_1$ and L–I high symmetry directions, driving into a TCI, as discussed by Wang et al.\cite{41} for the identical structure transition metal dipnictides RX$_2$ (R = Nb or Ta; X = P, As or Sb). Although the opening of a local band gap between the valence and conduction bands occurs when SOC is included, VAs$_2$ preserves its semimetal character with the presence of electron and hole pockets, similar to that in NbAs$_2$ reported in Ref. \cite{41}.

Secondly, we focus on the Kondo effect emerging in the longitudinal resistivity for VAs$_2$. Figure 2(a) shows the temperature dependence of resistivity, $\rho_{xx}(T)$. With decreasing temperature, the resistivity $\rho_{xx}$ decreases monotonously from $\rho_{xx}(300\,\text{K}) = 78\,\mu\Omega\cdot\text{cm}$, reaches a minimum at around 11K, then increases a little to 6.4\,\mu\Omega\cdot\text{cm} at 2K, thus the residual resistivity ratio (RRR) $\rho_{xx}(300\,\text{K})/\rho_{xx}(2\,\text{K}) \sim 12$, much smaller than that observed in the other transition metal dipnictide crystals, such as NbAs$_2$ ($\sim 75$),\cite{37} TaAs$_2$ ($\sim 100$).\cite{40} As we know, the system, containing magnetic impurities which usually scatter the conduction electrons through the s–d exchange interactions, exhibits a minimum in resistivity at lower temperatures, i.e., termed as the Kondo effect.\cite{54,55} As discussed by Barua et al. for VSe$_2$,\cite{55} considering the correction to the resistivity due to the Ruderman–Kittel–Kasuya–Yosida (RKKY) interactions between the paramagnetic V$^{4+}$ ions, the Kondo resistivity described by the Hamann expression is modified to

$$\rho_{sd} = \frac{\rho_0}{2} \left[1 - \frac{\ln(T_{\text{eff}}/T_K)}{\ln^2(T_{\text{eff}}/T_K) + S(S + 1)\pi^2/6} \right],$$

where $\rho_0$ is the unitarity limit, $T_K$ is the Kondo temperature, and $S$ is the spin of magnetic impurity, the effective temperature $T_{\text{eff}} = (T^2 + T_K^2)^{1/2}$ with $k_B T_K$ representing the effective RKKY interaction strength\cite{54} replaces $T$ in the original expression.\cite{55} The temperature dependence of resistivity, $\rho_{xx}(T)$, is expressed as

$$\rho(T) = \rho_{sd} + bT^2 + cT^5 + \rho_b,$$

where $bT^2$ is the Fermi liquid term, $cT^5$ is the electron-phonon scattering contribution, $\rho_b$ is a temperature-independent resistivity. We used Eq. (2) to fit the resistivity data measured at low temperatures (2–40K), as shown in the inset in Fig. 2(a). It is clear that Eq. (2) can well describe the $\rho(T)$ data below 40K, and the obtained parameters in Eqs. (1) and (2) from the fitting are listed in Table 1. The existence of V$^{4+}$ ($S = 1/2$) impurities in our VAs$_2$ crystal was confirmed by the magnetic susceptibility measurements. The temperature dependence of magnetic susceptibility, $\chi(T)$, measured at 1T with a field-cooling (FC) process is presented in Fig. 2(b). With decreasing temperature, the susceptibility $\chi$ decreases a little, reaches a minimum at around 180K, then increases strikingly below 100K. Now we do not know why the $\chi$ shows a little decrease with decreasing temperature above 180K, any magnetic fluctuation or influence of measuring bar in a superconducting quantum interference device, which is needed to clarify in the future. No magnetic transition was observed in the whole temperature range (2–300K), and the significant increase of $\chi$ in the lower temperatures was considered to originate from the contribution of V$^{4+}$ ($S = 1/2$) impurities existing in crystals as the interstitial ions,
as observed in VSe$_2$ crystals.\cite{56} We used the Curie–Weiss law $\chi = \frac{C}{T + \theta}$ to fit the data below 40 K, as shown in Fig. 2(b), the Curie constant $C = 1.27 \times 10^{-3}$ emu K/mol and the curie temperature $\theta = -2.61 \pm 0.08$ K were obtained. The nearly linear relationship between $1/\chi$ and $T$ below 40 K [see the inset in Fig. 2(b)] demonstrates the reliability of the fitting. The $V^{4+}$ ($S = 1/2$) impurity molar fraction was estimated to be of 0.34(±0.02)%, small amount impurities existing in the crystals.

| $\rho_0$ (μΩ-cm) | $\rho_0$ (μΩ-cm) | $b$ (μΩ-cm/K$^2$) |
|-----------------|-----------------|-------------------|
| 2.33            | 4.7             | $1.3 \times 10^{-3}$ |

Table 1. The obtained parameters by the fitting to $\rho(T)$ data using Eq. (2).

Thirdly, we discuss the MR occurring in the nodal-line semimetal VAs$_2$, in the presence of Kondo scattering of $V^{4+}$. Figure 3(a) presents the temperature dependence of longitudinal resistivity, $\rho_{xx}(T)$, measured at various magnetic fields $H$, with current $I$ applied in the (001) plane, and $H \perp (001)$ plane. Similar to many other nontrivial and trivial topological semimetals,\cite{57,58,59} VAs$_2$ also exhibits a large MR. As shown in Fig. 3(a), an up-turn in $\rho_{xx}(T)$ curves under applied magnetic field occurs at low temperatures: $\rho_{xx}$ increases with decreasing $T$ and then saturates. Figure 3(b) shows the MR as a function of temperature measured at various magnetic fields, with the conventional definition $MR = \frac{\Delta \rho}{\rho(0)} = \frac{\rho(H) - \rho(0)}{\rho(0)} \times 100\%$. The normalized MR, shown in the inset of Fig. 3(b), has the same temperature dependence for various fields, excluding the suggestion of a field-induced metal-insulator transition\cite{57,58} at low temperatures, as discussed in our works addressing the topological trivial semimetal $\alpha$-WP$_2$,\cite{56} for the nodal-line semimetal MoO$_2$,\cite{14} and the work of Thou iam et al. on the type-II Weyl semimetal WTe$_2$.\cite{60} Figure 3(c) displays $\rho_{xx}(T)$, measured at 0 and 9 T, as well as their difference $\Delta \rho_{xx} = \rho_{xx}(T, 9 \text{ T}) - \rho_{xx}(T, 0 \text{ T})$. It is clear that the resistivity in an applied magnetic field consists of two components, $\rho_0(T)$ and $\Delta \rho_{xx}$, with opposite temperature dependences. As discussed by us for $\alpha$-WP$_2$,\cite{56} MoO$_2$,\cite{14} and by Thouiam et al. for WTe$_2$,\cite{60} the resistivity can be written as

$$\rho_{xx}(T, H) = \rho_0(T)[1 + \alpha(H/\rho_0)^m]. \quad (3)$$

The second term is the magnetic-field-induced resistivity $\Delta \rho_{xx}$, which follows the Kohler rule with two constants $\alpha$ and $m$. $\Delta \rho_{xx}$ is proportional to $1/\rho_0$ when $m = 2$ and competes with the first term upon changing temperature, possibly giving rise to a minimum in $\rho(T)$ curves.

![Fig. 3.](image_url)

Fig. 3. (a) Temperature dependence of resistivity measured at various magnetic fields. (b) The MR vs temperature under various magnetic fields. The inset is normalized MR. (c) Temperature dependence of resistivity at 0 and 9 T and their difference. The red and blue lines are the fitting lines using the Kohler scaling law.

![Fig. 4.](image_url)

Fig. 4. (a) Field dependence of MR at various temperatures. (b) MR plotted as a log scale as a function of $H/\rho_{xx}(0)$.

Figure 4(a) presents the MR as a function of field at various temperatures. The measured MR is large at low temperatures, reaching 649% at 10 K and 9 T, and does not show any of saturation up to the highest field (9 T) in our measurements. As discussed above,
MR can be described by the Kohler scaling law:
\[
MR = \frac{\Delta \rho_{xx}(T, H)}{\rho_0(T)} = \alpha (H/\rho_0)^n.
\] (4)

As shown in Fig. 4(b), all MR data in the temperature range 2–100 K collapse onto a single straight line as plotted in the MR ~ \( H/\rho_0 \) curve, and \( \alpha = 0.038 \) (\( \mu\Omega \cdot \text{cm} \)^{1.76} and \( n = 1.76 \) were obtained by fitting. The nearly quadratic field dependence of MR observed in this nodal-line semimetal VAs\(_2\) is attributed to the electron-hole compensation, evidenced by FS calculations mentioned above, as well as the Hall resistivity measurements discussed in the following, which is a common characteristic for the most topologically nontrivial and trivial semimetals\([35,36,38]\). Figure 5(a) displays the Hall resistivity, \( \rho_{xy}(H) \), measured at various temperatures for a VAs\(_2\) crystal with \( H \parallel c \) axis. The nonlinear field dependence of \( \rho_{xy}(H) \) below 100 K demonstrates its semimetal characteristics, in which both electron and hole carriers coexist. Following the analysis of Ref.\([63]\) for \( \gamma \)-MoO\(_3\)\([64]\) and our result for MoO\(_2\),\([13]\) we analyze the longitudinal and Hall resistivity using the two-carrier model. In this model, the conductivity tensor in its complex representation is given as:
\[
\sigma = \frac{c e n_e \mu_e}{1 + i q_e \mu_e H} + \frac{c e n_h \mu_h}{1 + i q_h \mu_h H},
\] (5)

where \( n_e (n_h) \) and \( \mu_e (\mu_h) \) denote the carrier concentrations and mobilities of electrons (holes), respectively. To appropriately evaluate the carrier densities and mobilities, we calculated the Hall conductivity \( \sigma_{xy} = -\frac{\rho_{xy}}{\rho_{xx}^2 + \rho_{yy}^2} \) and the longitudinal conductivity \( \sigma_{xx} = \frac{\rho_{xx}}{\rho_{xx}^2 + \rho_{yy}^2} \) using the original experimental \( \rho_{xy}(H) \) and \( \rho_{xx}(H) \) data. Then, we fit both \( \sigma_{xy}(H) \) and \( \sigma_{xx}(H) \) data using the same fitting parameters and the field dependence given by\([64]\): \( \sigma_{xy} = \frac{e (\mu_0 H) n_h \mu_e^2}{1 + \mu_h^2 (\mu_0 H)^2} = \frac{e (\mu_0 H) n_h \mu_e^2}{1 + \mu_e^2 (\mu_0 H)^2} \); \( \sigma_{xx} = \frac{e n_e \mu_e}{1 + \mu_h^2 (\mu_0 H)^2} = \frac{e n_h \mu_h}{1 + \mu_h^2 (\mu_0 H)^2} \). (6) (7)

Figures 5(c) and 5(d) display the fitting of both the \( \sigma_{xy}(H) \) and \( \sigma_{xx}(H) \) measured at \( T = 2–60 \) K, respectively. The excellent agreement between our experimental data and the two-carrier model over a wide range of temperature confirms the coexistence of electrons and holes in VAs\(_2\). Figure 5(b) shows the obtained \( n_e, n_h, \mu_e \) and \( \mu_h \) by fittings as a function of temperature. The almost same values of \( n_e \) and \( n_h \) below 60 K [see the inset Fig. 5(b)], such as \( n_e = 1.77 \times 10^{20} \) cm\(^{-3}\) and \( n_h = 1.69 \times 10^{20} \) cm\(^{-3}\) at 2 K, indicate that VAs\(_2\) is indeed an electron-hole compensated semimetal, consistent with the above results from the calculation FS. Both electron and hole densities are estimated to be \( 10^{20} \) cm\(^{-3}\) in our VAs\(_2\) crystal, significantly higher than those in Dirac semimetals, such as Cd\(_3\)As\(_2\) (~\( 10^{18} \) cm\(^{-3}\)\([66]\)) and Na\(_3\)Bi (~\( 10^{17} \) cm\(^{-3}\)\([67]\)), while comparable to those of nodal-line semimetals ZrS\(_2\) (~\( 10^{20} \) cm\(^{-3}\)\([11]\)) and MoO\(_2\) (~\( 10^{20} \) cm\(^{-3}\)\([11]\)), demonstrating further the nodal-line characteristics of VAs\(_2\). As shown in Fig. 5(b), it is clear that the hole mobility \( \mu_h \) is higher than \( \mu_e \) in the whole temperature range (2–300 K), e.g., at 2 K, \( \mu_h = 4.08 \times 10^3 \) cm\(^2\)/Vs.
$\mu_e = 1.54 \times 10^3 \text{ cm}^2/\text{Vs}$, whereas one order of magnitude smaller than those observed by us in the nodal-line semimetal MoO$_2$ ($\sim 10^4 \text{ cm}^2/\text{Vs}$)\cite{10}, and both $\mu_h$ and $\mu_e$ decrease notably with increasing temperature due to the existence of phonon thermal scattering at higher temperatures. It is worth noting that both $\mu_h$ and $\mu_e$ have a little decrease below 11 K, corresponding to the Kondo scattering from V$^{4+}$ magnetic impurities mentioned above.

In summary, we have calculated the electronic structure, and measured the longitudinal resistivity, Hall resistivity and magnetic susceptibility for V$_2$S$_3$. It is found that V$_2$S$_3$ exhibits many common characteristics of topological nontrivial/trivial semimetals, such as a large MR reaching 649, exhibited up-turn behavior in $\rho_{xx}(T)$, and a field-induced up-turn behavior in $\rho_{xx}(T)$. Both the FS calculations and the Hall resistivity measurements verify the properties that are attributed to a perfect carrier compensation. Interestingly, the Kondo scattering due to the existence of V$^{4+}$ ($S = 1/2$) magnetic impurities in our V$_2$S$_3$ crystals occurs, indicating that V$_2$S$_3$ crystal can be used to study the Kondo effect in the nodal-line semimetal.
