Abstract

**Background:** The filarial parasites *Loa loa* and *Mansonella perstans* are endemic in the central and western African forest block. *Loa loa* is pathogenic and represents a major obstacle to the control of co-endemic filariae because its treatment can cause fatal complications such as encephalitis.

**Methodology/Principal Findings:** 4392 individuals aged over 15 years were studied both by direct examination and a concentration technique. The overall prevalence rates were 22.4% for *Loa loa* microfilaremia, 10.2% for *M. perstans* microfilaremia, and 3.2% for mixed infection. The prevalence of both filariae was higher in the forest ecosystem than in savannah and lakeland (p<0.0001). The intensity of microfilariae (mf) was also higher in the forest ecosystem for both parasites. The prevalence and intensity of microfilaria were both influenced by age and gender. Correlations were found between the prevalence and intensity of *Loa loa* microfilariae (r = 0.215; p = 0.036), and between the prevalence of *Loa loa* and the prevalence of individuals with microfilaria >8000 mf/ml (r = 0.624; p = 0.001) and microfilariae >30 000 mf/ml (r = 0.319; p = 0.002). In contrast, the prevalence of pruritis and Calabar swellings correlated negatively with the prevalence of *Loa loa* microfilariae (r = −0.219; p = 0.032; r = −0.220; p = 0.031, respectively). Pruritis, Calabar swellings and eye worm were not associated with *L. loa* mf intensity (r = −0.144, p = 0.162; r = 0.061, p = 0.356; and r = 0.051, p = 0.624, respectively), or with the prevalence or intensity of *M. perstans* microfilariae.

**Conclusions/Significance:** This map of the distribution of filariae in Gabon should prove helpful for control programs. Our findings confirm the spatial uniformity of the relationship between parasitological indices. Clinical manifestations point to a relationship between filariae and allergy.

Introduction

*Loa loa* and *Mansonella perstans* are endemic filarial parasites in the central and western African rainforest. *Loa loa* infects 2 to 3 million people [1]. *M. perstans* is considered non pathogenic [2–3], although some clinical manifestations have been associated with *M. perstans* microfilaria [4,5,6] including ocular disorders [7,8]. Interest in loiasis has grown during the last 30 years, for several reasons. First, in endemic areas loiasis is the second reason for medical visits, after malaria [1,9]. Second, this infection mainly affects active young individuals, who contribute to agricultural productivity [10], and their health is often aggravated by co-infection by other parasites. Two-thirds of infected individuals are amicrofilaricmic, despite subconjunctival migration of adults worms, suggesting immunological elimination of microfilariae [1,11]. Severe adverse events can occur during treatment with diethylcarbamazine (DEC) and ivermectin in individuals with high-level microfilaremia, requiring close treatment monitoring and hindering mass administration of antifilarial drugs aimed at controlling other filariae in areas where *Loa loa* is co-endemic. This is not the case with *M. perstans* [12].

Many epidemiological studies of loiasis and Mansonellosis have been carried out throughout the western and central African forest block. These studies mainly focused on the distribution of loiasis and on the possible relationship between the prevalence and intensity of microfilaremia, in order to estimate the risk of adverse events during mass chemotherapy.

The prevalence of *L. loa* microfilaremia varies from country to country [13], as well as within a given country and even a given geographic area [14]. The highest prevalence is observed in forest areas and the lowest in savannah areas of both Gabon [15,16] and Cameroon [17,18], for example. Differences within a given...
Loa loa and Mansonella perstans are blood filarial parasites, endemic in the central and western African forest block, and transmitted by chrysops and culicoides flies, respectively. Loa loa is pathogenic and represents a major obstacle to the control of co-endemic filariae. Treatment of individuals with >8000 Loa loa microfilariae/ml can result in severe adverse reactions. M. perstans is prevalent in the tropics, with undefined clinical symptoms. We screened 4392 individuals for these infections in 212 Gabonese villages. The overall prevalence rates were 22.4% for Loa loa microfilariae, 10.2% for M. perstans, and 3.2% for mixed infection. These rates varied across the different ecosystems: forest, savannah, Lakeland, river (Ogouée), and equator. A correlation was found between the prevalence and intensity of microfilariae, while a negative relationship was found between clinical symptoms (pruritis, Calabar swelling) and the prevalence of Loa loa microfilaraemia. This study confirms the spatial uniformity of the relationship between parasitological indices, and provides a map and baseline data for implementation of mass chemotherapy for these infections.

geographic zone are directly linked to the biocological specificity of a microzone [19]. These observations were recently used to create a predictive geographical model of loiasis endemicity based on satellite, vector habitat, prevalence, vegetation, temperature, relief, pluviometry and topography data [20]. However, when compared to field data, this model showed certain limitations [21].

A linear relationship between the prevalence and intensity of loiasis has been established. A high prevalence is indicative of intense L. loa infection and therefore a high risk of adverse events [22,23]. The 20% threshold prevalence of microfilaraemia at the community level corresponds to about 5% of high microfilaraemia loads (>8000 mf/ml) and 2% of very high microfilaraemia loads (>30000 mf/ml), the latter being the cut-off point above which there is a risk of severe adverse events during ivermectin treatment [24]. Owing to the difficulties of drawing regional maps based on microscopic analysis, a rapid method for evaluating the prevalence and intensity of Loa loa infection at the community level has been developed (RAPLOA: Rapid Assessment of Prevalence of Loa loa) [25]. RAPLOA is based on interviews assisted by photographs of adult worms in the eye, to detect subconjunctival migration of adult worms (which lasts 1 to 7 days), as reported by interviewees. A 40% prevalence of a history of eye worm corresponds to a 20% threshold prevalence of microfilaraemia at the community level, 5% of high microfilaraemia loads (>8000 mf/ml) and 2% of very high microfilaraemia loads (>30000 mf/ml) [25]. Another clinical manifestation, Calabar swellings, was used to evaluate the risk of adverse events. This sign has shown to correlate with the prevalence of highly microfilaraemic individuals [25].

The use of eye worm and Calabar edema to assess the risk of fatal side effects in patients with loiasis suggests a relationship between clinical symptoms and parasitological indices.

Most of these latter studies were performed in Cameroon, Nigeria, Republic of Congo and Democratic Republic of Congo (17–25), only a few concerning Gabon.

In Gabon, epidemiological surveys have identified five filarial species (L. loa, M. perstans, O. volvulus, M. streptocerca, and M. rodhaini), and yielded a preliminary map [12–16,26–28]. L. loa is the predominant species and co-exists with M. perstans. The prevalence of microfilaraemia varies across provinces and even within a given province, being higher in mountain forest than in savannah.

The aim of the present study was to obtain a fuller picture of the distribution of blood-borne filariae in Gabon, using both the wet blood film and concentration techniques, and to detect a linear relationship between the prevalence and intensity of loiasis and between clinical symptoms and parasitological indices. We therefore conducted a large survey, including all the country’s ecological niches and recording the main clinical manifestations of Loa loa infection.

Materials and Methods

Area of study

We surveyed rural Gabonese populations. The country is 800 km long and 20 to 300 km wide, consists of 80% rain forest, and is bordered to the west by the Atlantic Ocean. The forest zone extends from west to east, from the coastal basin with the grassland forest to the interior and north-eastern forest plates band, through a wide mountainous forest band from 60 to 100 km parallel to the coast. The south and southeast contain isolated areas of savannah and steppe. A coastal and continental marine ecosystem named lakeland is located around the mouth of River Ogoué (Figure 1) [29]. The population is about 1.5 million and there are 2048 villages located in 9 provinces. Rural populations are located along roads and rivers, and few villages have more than 300 inhabitants.

Study population

This survey was conducted during nine-month field missions between June 2005 and September 2008. For this survey, a stratified random sampling method was used, based on the 9 provinces. Twenty to 30 villages per province were randomly selected. The required sample size was calculated on the basis of an estimated prevalence of 5 to 10% (using n = e^2 [p (1−p)]/e^2; with e = 1.96 [alpha risk = 5%], c [precision] = 2% and p = expected prevalence; with n varying from 188 to 864). Within each village, individuals over 16 years of age having lived for at least one year in their village and who accepted blood sampling were included in the study. A free medical examination was offered and basic medicines were provided to all participants and non participants, if appropriate. All the villages were georeferenced (Figure 1).

Questionnaire

The rationale of the study was explained and a one-page questionnaire was administered to all participants. We collected demographic data (age, sex and occupation), geographic data (name of the village, length of residence, department and province) and the medical history (eye worm, Calabar swellings, chronic arthralgia, pruritis, etc.) (Figure S1).

Ethical considerations

The study protocol was approved by the Ministry of Health. The Health Director, the governor of each province and the chiefs of each village received written information. Individual written consent was required before blood sampling. The results of the study were transmitted to the Ministry of Health.

Blood collection

Field laboratory facilities were set up in regional hospitals. Blood samples were collected, usually in the villages’ healthcare centers, on a daily basis, into two 7-ml Vacutainer tubes containing EDTA (VWR International, France). The tubes were stored in the dark at +4°C before transportation to the field laboratory.
Parasitological analyses

Due to the variability of microfilarial load, the analysis started systematically by direct examination of a wet blood film, followed by a concentration technique. Two experienced technicians read the slides separately, and the results were controlled by a parasitologist. Briefly, microfilariae were counted directly in a 10-μl wet blood film between microscope slide and coverslip, using an optical microscope equipped with a 10× objective. Parasitemia was expressed in microfilariae per milliliter (mf/ml) of blood. A modified Knott’s concentration technique [30] was applied routinely to each sample, as follows: 1 ml blood was diluted with 9 ml PBS in a conical tube and 200 μl of saponin (2% w/v) was added to lyse red cells. The tubes were centrifuged (10 min, 500 g) and the supernatants discarded. The entire pellet was then examined under the microscope (10× objective) and microfilariae were counted. Parasite species were identified by their size and motility, and by the absence or presence of a sheath.

Data analysis

*Loa loa* prevalence rates were estimated nationwide. As mentioned above, the 20% threshold prevalence of microfilaremia is the cut-off above which serious adverse events are likely to occur, and corresponds to 5% of high microfilaremia loads (>8000 mf/ml) and 2% of very high microfilaremia loads (>30000 mf/ml). Thus, prevalence rates were calculated in each province, village and ecosystem as prevalence rates for microfilaremia loads. Parasite species were identified by their size and motility, and by the absence or presence of a sheath.

Table 1. Sociodemographic and clinical characteristics of the study population.
were considered statistically significant. A backwards stepwise elimination procedure. P values below 0.05 were respectively 22.4% (95%CI: 21.2–23.7) (up to 57% in some microfilaremic subjects while the concentration technique detected microfilaremia below 100/ml, for both species concentration had microfilaremia below 100/ml, for both species L. loa (Table 3).

Comparison of microfilariae counts with and without concentration The wet blood smear identified 790 L. loa and 116 M. perstans microfilaremic subjects while the concentration technique detected 984 L. loa and 447 M. perstans microfilaremic subjects (difference of 19.7% for L. loa and 74% for M. perstans) (Table 2).

Most of these individuals who were positive only after concentration had microfilaremia below 100/ml, for both species (Table 3).

Geographic distribution of L. loa and M. perstans microfilaria The overall prevalence rates of L. loa and M. perstans microfilaria were respectively 22.4% (95%CI: 21.2–23.7) (up to 57% in some villages), and 10.2% (95%CI: 9.3–11.1) (up to 67% in some villages), while 3.2% of subjects were coinfected (95%CI: 2.7–3.8) (Table 4, Table S1). The highest prevalence was found in the North Equator region (Figure 2A) for L. loa (>10–20%) and along the Ogooué river for M. perstans (Figure 2B).

In the administrative regions, Estuaire province had the highest prevalence of L. loa (33.4%), M. perstans (22.9%) and co-infection (9.5%), while Ogooué maritime province had the lowest prevalence rates (respectively 12.1%, 1.4% and 0.5%) (Table 4).

In the ecological regions, the L. loa prevalence rate (Table 5, Figure 3A) was significantly higher (p<0.0001) in the forest (24.1%) than in the lake (17%) and savannah (14.8%). No difference (p = 0.4) was observed between lake and savannah. Moreover, within the forest ecosystem, the prevalence was significantly higher in grassland (28.9%) than in the mountain (20.5%), interior (24.3%) and north eastern (20.6%) forest regions (p<0.0002). In the same way, the M. perstans prevalence rate (Table 5) was significantly higher (p<0.0001) in the forest region (11.3%) than in lake (4.2%) and savannah (7.4%), and no difference (p = 0.053) was observed between lake and savannah. Within the forest ecosystem, the prevalence in the north-eastern forest (5.2%) was significantly lower (p<0.0001) than in the grassland (14.6%), mountain (14.9%) and interior forest (11.9%) (Table 5). Finally, most villages with high L. loa prevalence rates were located in the forest area (Table S1, Figure 3B).

Analysis of risk factors

In univariate analysis, males had a significantly higher risk of L. loa infection than females (OR: 2.38, 95%CI: 2.05–2.75, p<0.0001), and the prevalence of L. loa parasitemia increased linearly with age (p<0.0001) (Table 6). The prevalence of L. loa microfilaria was higher in hunters than in farmers and other occupational groups (p<0.04), and higher in individuals with eye worm (p<0.001) and those without Calabar swellings (p<0.014) (Table 6). Only gender was a risk factor for M. perstans microfilaria, males having a significantly higher prevalence than females (OR: 1.89, 95%CI: 1.54–2.31, p<0.0001) (Table 7). In multivariate analysis, only age and sex remained significantly associated with L. loa parasitemia, throughout the country and within the forest ecosystem (Table 8 and 9).
For clinical symptoms, only eye worm and Calabar swellings remained significantly associated with *Loa loa* parasitemia, both throughout the country and within the forest ecosystem (Table 8 and 9).

**Intensity of microfilaremia**

Microfilaremia in *Loa loa*-positive individuals ranged from 1 to 500,000 mf/ml (arithmetic mean: 5441 mf/ml; median: 900 mf/ml), while *M. perstans* microfilaremia ranged from 1 to 12,000 mf/ml (mean: 189 mf/ml; median: 18 mf/ml) overall. Mean *L. loa* microfilaremia was significantly higher in the forest ecosystem than in the savannah (median values: 3469 vs 1357; p = 0.048) and similar to that in the lakeland (3469 vs 3140; p = 0.18) (Table 10). There was no difference between lakeland and savannah (3140 vs 1357; p = 0.8) (Table 10).

Likewise, mean *M. perstans* microfilaremia was significantly higher in the forest ecosystem than in the savannah (44 vs 4; p = 0.010) and lakeland (44 vs 0; p = 0.014) (Table 10).

The intensity of *Loa loa* microfilaremia did not vary with age countrywide (r = 0.249, p = 0.634), while it correlated with age in males (r = 0.915 p = 0.011) but not in females (r = 0.684 p = 0.134) (Figure 4). At the district level, the intensity of *Loa loa* microfilaremia did not vary significantly with age and sex.

**Relationship between the prevalence and intensity of *Loa loa* microfilaremia**

The intensity of *Loa loa* microfilaremia (Figure 5A) correlated with the prevalence of microfilaremia nationwide (r = 0.215 p = 0.036) but not at the regional level (r = 0.163, p = 0.675). The intensity of microfilaremia also correlated with the prevalence of microfilaremia in males (r = 0.915 p = 0.011).

### Table 4. Prevalence of *Loa loa* and *Mansonella perstans* microfilaremia in the nine administrative regions of Gabon.

| Provinces      | Sampling period | Number of villages surveyed | *Loa loa* | *Mansonella perstans* | Co-infection |

**Figure 2. Distribution of *Loa loa* (A) and *Mansonella perstans* (B) in Gabon according to the geographic region.**

doi:10.1371/journal.pntd.0001329.g002
>8000 mf/ml (Figure 5B) and >30 000 mf/ml (Figure 5C) (respectively $r = 0.624$, $p = 0.0001$ and $r = 0.319$, $p = 0.002$).

Furthermore, in the subpopulation of individuals with microfilaraemia >8000 mf/ml, this relationship was observed in lakeland ($r = 0.839$, $p = 0.001$), savannah ($r = 0.625$, $p = 0.027$) and forest ($r = 0.575$, $p = 0.0001$), while in individuals with microfilaraemia >30 000 mf/ml this relationship was only observed in the forest ($r = 0.328$, $p = 0.005$).

**Relationship between clinical symptoms and parasitological indices**

The prevalence of pruritis correlated negatively with the prevalence of *Loa loa* microfilaraemia ($r = -0.219$; $p = 0.032$) (Figure 6A) but not with the intensity of *Loa loa* microfilaria ($r = -0.144$; $p = 0.162$) or with very intense microfilaraemia ($r = 0.000$; $r = -0.117$; $p = 0.255$). Similarly, microfilaraemia >8000 mf/ml correlated negatively with the prevalence of pruritis ($r = -0.22$; $p = 0.027$). Pruritis was associated with Calabar swellings ($r = 0.578$; $p < 0.001$) and eye worm ($r = 0.425$; $p < 0.001$). The prevalence of Calabar swellings (Figure 6B) correlated negatively with the prevalence of *L. loa* microfilaria ($r = -0.220$; $p = 0.031$) but did not correlate with the intensity of microfilaria ($r = -0.061$; $p = 0.550$), microfilaraemia >8000 mf/ml ($r = -0.185$; $p = 0.071$) or microfilaraemia >30 000 ($r = 0.093$; $p = 0.370$); in contrast, it correlated positively with the prevalence of pruritis ($r = 0.578$; $p < 0.001$) and eye worm ($r = 0.335$; $p = 0.001$).

![Figure 3. Distribution of *L. loa* in Gabon in the different ecosystems (A) (Prevalence rates of *Loa loa* are shown within the corresponding ecosystem), and villages (B).](https://www.plosntds.org/6October2011/volume5issue10/e1329)
p < 0.001). The prevalence of eye worm (Figure 6C) did not correlate with the prevalence of microfilaria (r = −0.05; p = 0.624) or with microfilaria intensity (r = −0.137; p = 0.182), microfilaria ≥8000 (r = −0.139; p = 0.178) or microfilaria ≥30 000 (r = −0.090; p = 0.302), while it correlated positively with pruritis (r = 0.425; p < 0.001) and Calabar swellings (r = 0.335; p < 0.001). Interestingly, there was no relationship between these three symptoms and the prevalence of M. perstans microfilaria (r = −0.146; p = 0.155 for pruritis; r = −0.090; p = 0.385 for Calabar swellings; and r = −0.164; p = 0.110 for eye worm) or the intensity of M. perstans microfilaria (pruritis: r = 0.004; p = 0.971; Calabar swelling: r = −0.169; p = 0.100; eye worm: r = 0.182; p = 0.075).

**Discussion**

We conducted a large-scale survey of two blood-borne filarial parasites, using direct examination and a concentration technique, in rural populations of 212 villages in Gabon, in order to map their distribution throughout the country, to characterize the modalities of population exposure and to explore the relationship between prevalence and intensity, and between clinical symptoms and parasitological indices.

DOI: 10.1371/journal.pntd.0001329.t006

DOI: 10.1371/journal.pntd.0001329.t007
The overall prevalence rates were 22.4% for *Loa loa* microfilaremia, 10.2% for *M. perstans*, and 3.2% for mixed infection. These rates varied across the different ecosystems, the Ogooue River, and the equator. A correlation was found between the prevalence and the intensity of microfilaremia, and between clinical symptoms (eye worm, Calabar swelling) and the prevalence of *Loa loa* microfilaremia.

As direct microscopic detection of microfilaria in wet blood films is not very sensitive, we combined two techniques for this survey, namely direct examination of 10 μl of blood (wet film) and prior concentration of 1 ml of blood. If we had used direct examination only, 19.7% *Loa loa* mf carriers and 74% of *M. perstans* carriers would have been missed. Most of these subjects had fewer than 100 ml/ml. Such underestimation may have implications for estimates of the risk of transmission and even for control programmes. Better sensitivity after sample concentration has estimates of the risk of transmission and even for control programmes. Better sensitivity after sample concentration has

doi:10.1371/journal.pntd.0001329.t008

The prevalence of *Loa loa* microfilaremia was 22.4% overall (up to 57% in some villages) while that of *M. perstans* was 10% (up to 67% in some villages). Gabon is thus a highly endemic country and a zone at high risk of fatal treatment complications. These prevalence rates are similar to those reported in southern Cameroon (up to 30% in the district of Elig-Mfomo) and Equatorial Guinea (27%). This contrasts with Central African Republic (CAR) and Chad, where prevalence is lower (11% and 8.4% respectively). In DRC-Congo, Republic of Congo and Nigeria the prevalence rates range from 1.2% to 97% [13]. It should be noted that these prevalence rates are for specific regions of these countries, whereas our survey covered the whole of Gabon. The prevalence of *Loa loa* remains high in Gabon [15,29].

*Loa loa* was highly prevalent in the north Equator (>20%), compared to the south (10–20%). Most areas crossed by the Ogooue River from the south-east (its source) to the north-west (towards the Atlantic Ocean) had an *M. perstans* prevalence of more than 10%, while other areas had a prevalence below 10%.

Among the three major ecosystems, forest had a higher prevalence of both parasites than savannah and lakeland. Differences were also seen among the different types of forest, as previously observed in Cameroon [19]. Geographic factors have been implicated in the prevalence of diseases like arteriosclerosis [31]. Sunlight might have a protective effect on some diseases [32], as ultraviolet B radiation stimulates the synthesis of vitamin D, which plays a role in immunity [33]. Geographic factors may influence filarial distribution by affecting the host immune system or the vector. The environment created by Ogooue River may affect the distribution and transmission of *M. perstans*. Although no soil studies around Ogooue River are available, studies in other ecosystems show that the concentration of microfilariae is higher near the river and the Afrotropical region, which may be due to the effect of ultraviolet B radiation on the vector or host immune system.

doi:10.1371/journal.pntd.0001329.t010
areas have shown that low-pH soil, low organic soil content, salty soil, and wet soil promote Culicoides fly breeding [34,35] while temperature may affect vector competence [36].

The prevalence of Loa loa microfilaremia was influenced by age in both sexes. In some parts of the country the prevalence continued to increase up to 70 years of age, while in others the prevalence appeared to plateau after 60 years. Males tended to be more microfilaremic than females, possibly because men are more exposed to chrysops bites due to their outdoor occupations (hunting, etc.), which become more intense with age, hence the correlation between age and microfilaremia. Genetic factors may also have a role [37]. Furthermore, the negative correlation of the...
intensity of microfilaremia with age in males may be due to concomitant immunity against new incoming infection [38] or natural death of existing microfilariae [39].

In some areas of Cameroon where the general prevalence of microfilaremia exceeds 20%, approximately 5% of individuals have 8000 mf/ml and 2% have more than 30 000 mf/ml [24]. Similarly, in an area with a prevalence of 30%, 9% of carriers had >30 000 mf/ml, while in an area with a prevalence of 40%, approximately 16% of carriers had >8000 mf/ml and 5–6% had >30 000 mf/ml. Therefore, areas with a prevalence of more than 20% are considered to be at a high risk of treatment complications. Such studies have only been conducted in Cameroon [24,25]. In this study, we observed a positive relationship between the prevalence and intensity of microfilaria. This suggests that the relationship between these two parasitological indices is spatially stable.

Clinical symptoms have also been used to predict the risk of side effects during mass chemotherapy. As previously described, eye worm and Calabar swelling have been found to correlate strongly with prevalence [25]. Photographs of ocular passage of the eye worm were used in previous studies [25]. Whether the lack of photographs in the present study influenced the accuracy of the patients’ answers is not known. Yet, in our opinion, the use of photographs would yield a higher prevalence of amicrofilaremic subjects. Another striking observation is the negative correlation of pruritis and Calabar swelling with the prevalence of Loa loa but not M. perstans. Pruritis is a clinical sign of an allergic reaction. The negative relationship suggests that Loa loa filaria may induce desensitization. In Gabon, skin test reactivity against common allergens is low [40], while treatment of helminth infections increases skin test reactivity to mite antigens [41]. Similar observations have been made with M. perstans in Ugandan women [42]. A previous study in Gabon showed a high level of polyclonal IgE and Loa loa-specific IgG4 in permanent residents [27].

Further investigations are needed to elucidate the relation between filaremia and allergy in Gabon.
In conclusion, we provide a map of *Loa loa* and *M. perstans* microfilaremia in Gabon, and describe important relationships between parasitological indices and clinical manifestations. A clear and spatially uniform relationship was found between the prevalence and intensity of parasitism. These data should be useful for planning mass chemotherapy.
