Some of the exciting phenomena uncovered in strongly correlated systems in recent years – for instance quantum topological order, deconfined quantum criticality and emergent gauge symmetries – appear in systems where the Hilbert space is effectively projected at low energies in a way that imposes local constraints on the original degrees of freedom. Cases in point include spin liquids, valence bond systems, dimer and vertex models. In this work, we use a slave boson description coupled to a large-$S$ path integral formulation to devise a generalised route to obtain effective field theories for such systems. We demonstrate the validity and capability of our approach by studying quantum dimer models and by comparing our results with the existing literature. Field theoretic approaches to date are limited to bipartite lattices, they depend on a gauge-symmetric understanding of the constraint, and lack generic quantitative predictive power for the coefficients of the terms that appear in the Lagrangians of these systems. Our method overcomes all these shortcomings and we show how the results up to quadratic order compare with the known height description of the square lattice quantum dimer model, as well as with the numerical estimate of the speed of light of the photon excitations on the diamond lattice. Finally, instanton considerations allow us to infer properties of the finite temperature behaviour in two dimensions.

I. INTRODUCTION

Low energy descriptions of strongly correlated many-body systems sometimes require the introduction of projected Hilbert spaces where the degrees of freedom are subject to local constraints. Notable examples include valence bond systems, quantum dimer and vertex models. The action of the system Hamiltonian within the restricted Hilbert space often gives rise to exotic and unexpected behavior, from emergent gauge symmetries and deconfined quantum criticality to quantum topological order, which have been the subject of much attention in recent years.

Field theoretic descriptions of these systems have proven to be a powerful tool to study their properties, in particular to understand the nature of their correlations and critical points. However, conventional routes to construct such field theories often do not apply, and instead ad hoc methods have been devised throughout the years. Such methods largely hinge on a physical understanding of the constraint and how to best represent it in a (free) field theory language. While on the one hand such approaches have provided great insight into the relevant systems, they cannot be easily generalized. A systematic way to arrive at a field theoretic description of quantum systems with local constraints is currently lacking.

In this paper, we propose a generalized route to obtain field theoretic actions from microscopic Hamiltonians based on a slave boson representation of the relevant degrees of freedom and their constraints, combined with a large-$S$ path integral formulation. We demonstrate the validity and capability of our approach by deploying it to study quantum dimer models (QDMs), recovering known and obtaining new results on bipartite lattices, and showing that it can be used straightforwardly on hitherto inaccessible non-bipartite lattices.

QDMs were introduced to describe a magnetically disordered (resonating valence bond) phase in high-temperature superconducting materials [1]. They can also arise in Bose–Mott insulators, electronic Mott insulators at fractional fillings [2] and in mixed valence systems on frustrated lattices [3]. For a review of these models, we refer the reader to Ref. [4].

When QDMs are defined on bipartite lattices, they are amenable to a height mapping description in 2D, which generalizes to quantum electrodynamics (QED) in 3D [4–7]. The height mapping is built upon a gauge-symmetric understanding of the constraint [8] and has great predictive power for bipartite quantum dimer models, enabling one to answer detailed questions pertaining to their long wavelength properties. All its good features notwithstanding, the height mapping has one essential drawback: a quantitative derivation of its action from the microscopic lattice Hamiltonian is currently not available. The state-of-the-art derivation of the height mapping has been so far phenomenological [4, 9], and the coefficients (including their signs) are a posteriori determined by theoretical considerations (e.g., using the knowledge of the exact ground state at fine-tuned critical points) combined with comparisons to numerical results [4, 7, 9, 10]. Furthermore, the approach cannot be applied to non-bipartite lattices, which remain comparatively unexplored from a field theoretic perspective.

Using our generalized route, we show that one can systematically derive the height Lagrangian for bipartite QDMs in 2D and 3D, from the corresponding microscopic Hamiltonians. We compare our results against the exist-
The paper is organized as follows. In Section II we introduce our approach by studying in detail the introductory and well-known case of the QDM on the square lattice. In Section III, we study the cubic lattice and obtain the dispersion of its photon excitations in the gapless phase. We then briefly consider the case of the non-bipartite triangular lattice in Sec. IV, which is shown to be curiously similar in its analytical form to the cubic lattice—a similarity that we plan to explore further in future work.

The constraint that each site of the lattice has one and exactly one dimer attached to it can be expressed in the boson language as

$$\Pi_r \equiv \sum_{l \in v_r} b_l^\dagger b_l - 1 = 0. \quad (2.1)$$

Here, for convenience of notation, $\ell \in v_r$ labels the four links $r^\prime, \eta$ that are attached to the vertex $r$. We note that the constraint in Eq. (2.1) implies that the bosons are hardcore: $n_{r,\eta} \equiv b_{r,\eta}^\dagger b_{r,\eta} = 0, 1$.

Any dimer Hamiltonian has a bosonic representation; in particular, the RK Hamiltonian can be written as:

$$H_D = \sum_r \left\{-J b_{r,1}^\dagger b_{r+e_{x1},1} b_{r,2} b_{r+e_{x1},2} + (1 \leftrightarrow 2) + V b_{r,1}^\dagger b_{r,1} b_{r+e_{x2},2} b_{r+e_{x2},1} + (1 \leftrightarrow 2)\right\}. \quad (2.2)$$

To generalize this construction to a large-$S$ formulation, we keep the same Hilbert space as before and replace Eq. (2.1) with the constraint

$$\Pi_r \equiv \sum_{l \in v_r} b_l^\dagger b_l - S = 0 \quad (2.3)$$

without changing the Hamiltonian (2.2).

## B. Path integral formulation and Gaussian approximation

In what follows, it is convenient to use the radial gauge for the bosonic fields in the path integral formulation of the model:

$$b_{r,\eta} = \sqrt{\rho_\eta(r + e_\eta/2)} \exp\left[i\Phi_\eta(r + e_\eta/2)\right] \quad (2.4)$$

$$\equiv \sqrt{\frac{S}{z}} + \delta \rho_\eta(r + e_\eta/2) \exp\left[i\Phi_\eta(r + e_\eta/2)\right],$$

where $z$ is the lattice coordination number; for the square lattice, $z = 4$. For later convenience, we think of $\rho_\eta(r + e_\eta/2)$ and $\Phi_\eta(r + e_\eta/2)$ as functions defined on bond midpoints. The RK Hamiltonian is then given by...
and the constraint in Eq. (2.3) can be written as
\[ \sum_{\eta} [\delta \rho_{\eta}(r + e_{\eta}/2) + \delta \rho_{\eta}(r - e_{\eta}/2)] = 0. \] (2.6)

We now introduce the Fourier decomposition
\[ \delta \rho_{\eta}(r + e_{\eta}/2) = \frac{1}{\sqrt{N}} \sum_{k} \delta \rho_{\eta}(k) \exp[-ik(r + e_{\eta}/2)], \] (2.7)
\[ \Phi_{\eta}(r + e_{\eta}/2) = \frac{1}{\sqrt{N}} \sum_{k} \Phi_{\eta}(k) \exp[-ik(r + e_{\eta}/2)], \] (2.8)
where \( k(r + e_{\eta}/2) \equiv \vec{k} \cdot (\vec{r} + e_{\eta}/2) \) for brevity and \( N \) is the number of lattice sites. In these terms, the constraint can be written as
\[ \sum_{\eta} \cos(ke_{\eta}/2) \delta \rho_{\eta}(k) = 0. \] (2.9)

It will be useful in the following to introduce the shorthand notation \( e_{\eta} = \cos(ke_{\eta}/2) \) and correspondingly \( s_{\eta} = \sin(ke_{\eta}/2) \).

The constraint clearly imposes a relation between the two field variables \( \delta \rho_{1}(k) \) and \( \delta \rho_{2}(k) \). The same conclusion can be readily drawn about the fields \( \Phi_{\mu} \) once we notice that the Hamiltonian depends only on the specific combination of them that appears in the argument of the cosine term in Eq. (2.5):
\[ \tilde{\phi}(r) \equiv \Phi_{1}(r + e_{1}/2) - \Phi_{2}(r + e_{1}/2) + \Phi_{1}(r + e_{2}/2) - \Phi_{2}(r + e_{2}/2). \] (2.10)

After a few lines of algebra, its Fourier transform gives
\[ \tilde{\phi}(k) \equiv e^{-ik(e_{1}+e_{2})/2} [c_{2} \Phi_{1}(k) - c_{1} \Phi_{2}(k)]. \] (2.11)

Note that the cosine function depends only on powers of \( \phi(r)^{2} \) and therefore phase factors in \( \phi(k) \) are immaterial, and we define for convenience
\[ \phi(k) \equiv e^{ik(e_{1}+e_{2})/2} \tilde{\phi}(k) = 2 [c_{2} \Phi_{1}(k) - c_{1} \Phi_{2}(k)] \equiv \mathcal{Z}_{\eta} \Phi_{\eta}, \] (2.12)
where \( \mathcal{Z}_{\eta} = (2c_{2}, -2c_{1}) \). In real space, this amounts to introducing a \( \phi(r) \) living on the centres of the plaquettes rather than a corner.

Notice that the constraints on \( \delta \rho_{\eta} \) and on \( \Phi_{\eta} \) are in fact two sides of the same coin – indeed, conjugate variables come in pairs, so their numbers have to be the same. In our case, one can easily verify that imposing one of them implies the other. This is a consequence of how the RK Hamiltonian is designed: the plaquette-flipping term inherently preserves the number of dimers at each vertex; and vice versa, if one imposes the hard core dimer constraint, then any kinetic contribution in the Hamiltonian is projected onto a combination of loop updates, of which the plaquette-flipping term is an example.

In order to make further progress in the path integral formulation, we shall expand the action to quadratic order in \( \phi(r, \tau) \approx 2\pi n, n \in \mathbb{Z} \), and \( \delta \rho_{\eta, \mu} \ll 1 \). Firstly, it is convenient to re-write \( \cos(\phi) = 1 - [1 - \cos(\phi)] \) and notice that the term in square brackets contains only quadratic and higher order contributions. Therefore, the square root in the second term of
\[ \sqrt{p_{\mu}p_{\nu}} \cos(\phi) = \sqrt{p_{\mu}p_{\nu}} - \sqrt{p_{\mu}p_{\nu}} [1 - \cos(\phi)], \] (2.13)
needs to be expanded only to leading order in \( S \): \( \sqrt{p_{\mu}p_{\nu}} \approx S^{2}/16 \). Upon expanding the first term, one obtains both linear and quadratic terms in \( \delta \rho_{\eta}(r + e_{\eta}/2) \). However, one can readily convince oneself that the linear terms vanish upon summing over \( r \) because of the dimer constraint in Eq. (2.6). The same is true for the linear contributions due to the terms multiplying \( V \) in Eq. (2.5), leading to the following contributions to quadratic order:

\[ H_{D} = \sum_{r} \left\{ -2J \sqrt{\rho_{1}(r + e_{1}/2)\rho_{2}(r + e_{1}/2)\rho_{1}(r + e_{2}/2)\rho_{2}(r + e_{2}/2)} \right. \]
\[ \times \cos[\Phi_{1}(r + e_{1}/2) - \Phi_{2}(r + e_{1}/2) + \Phi_{1}(r + e_{2}/2) - \Phi_{2}(r + e_{2}/2)] \]
\[ + V \rho_{1}(r + e_{1}/2)\rho_{1}(r + e_{2}/2) + V \rho_{2}(r + e_{1}/2)\rho_{2}(r + e_{2}/2) \right\}, \] (2.5)
\[ \rho\rho + \rho\rho = \frac{S^2}{8} + \delta\rho_1(r + e_1/2)\delta\rho_1(r + e_2 + e_1/2) + \delta\rho_2(r + e_2/2)\delta\rho_2(r + e_1 + e_2/2). \]  

Writing the sum of these terms in Fourier space, we get (for the quadratic contributions only):

\[- J_{c_1c_2} \left[ \delta\rho_1(k)\delta\rho_2(-k) + \delta\rho_2(k)\delta\rho_1(-k) \right]
+ \left[ (2V - J)c_2^2 + (J - V) \right] \delta\rho_1(k)\delta\rho_1(-k)
+ \left[ (2V - J)c_1^2 + (J - V) \right] \delta\rho_2(k)\delta\rho_2(-k). \]  

Adding the relevant Berry phase, we obtain the action

\[ S = \int d\tau \sum_{k,\mu} i\delta\rho_\mu(k,\tau)\partial_\tau\Phi_\mu(-k,\tau) \]
+ \left[ \frac{J S^2}{8} \left[ 1 - \cos(\phi(r,\tau)) \right] \right] 
+ \int d\tau \sum_{k,\mu,\nu} \frac{D_{\mu\nu}(k)}{2} \delta\rho_\mu(k,\tau)\delta\rho_\nu(-k,\tau), \]  

where

\[ D_{\mu\nu} = 2 \begin{pmatrix} J - V + (2V - J)c_2^2 & -J_{c_1c_2} \\ J_{c_1c_2} & J - V + (2V - J)c_1^2 \end{pmatrix}. \]

To proceed further, we can either resolve the constraint explicitly, or keep it implicit. The former allows to relate directly with the customary height field representation for the QDM on the square lattice; the latter is more concise and will be useful to reduce the algebra and obtain analytic results for three-dimensional models in Secs. \[\text{III}\] and \[\text{VI}\]. For this reason, we present them both in the following sections.

C. Implicit constraint

Let us consider a given cosine minimum at first, and assume \( \phi(r,\tau) \ll 1 \). (We shall discuss the effect of instantons later in Sec. \[\text{IVD 2}\].) The middle term in Eq. \[\text{2.17}\] then reduces to

\[ \int d^2\tau \frac{JS^2}{16} \phi^2(r,\tau) = \sum_k \frac{JS^2}{16} Z_\mu Z_\nu \Phi_\mu(k,\tau)\Phi_\nu(-k,\tau). \]  

After integrating the first term in Eq. \[\text{2.17}\] by parts in \( \tau \), one can integrate the fields \( \Phi_\mu \) out and obtain an action only in terms of the fields \( \delta\rho_\mu \):

\[ S = \frac{1}{2} \int d\tau \sum_k \left[ (M^{-1})_{\mu\nu} \partial_\tau\delta\rho_\mu(k,\tau)\partial_\tau\delta\rho_\nu(-k,\tau) \right. \]
+ \left. D_{\mu\nu}(k) \delta\rho_\mu(k,\tau)\delta\rho_\nu(-k,\tau) \right], \]  

where we define \( M = JS^2 ZZ^T/8 \) for convenience. One can now readily obtain the dispersion by computing the eigenvalues of the matrix \( M \).

D. Explicit constraint

The implicit approach in Sec. \[\text{IIIC}\] allows us to arrive at the dispersion of the system with minimal algebra, but does not produce an action in terms of the physical degree of freedom only. In order to achieve this, we need

\[ \omega^2 = JS^2 \left\{ (2V - J)(c_1^2 + c_2^2) + (J - V)(c_1^2 + c_2^2) \right\} + 2Jc_1^2c_2^2 \]  

This dispersion is plotted for three values of \( V/J \) in Fig. \[\text{2}\]. It is interesting to note that the dispersion vanishes at \( (\pi,\pi) \) and symmetry related points for all values of \( J \) and \( V \). An instability develops for \( V > J \) when the dispersion becomes negative near the \( (\pi,\pi) \) point (not shown). As we lower the value of \( V \), secondary minima appear at \( (\pi,0) \) and related points in the Brillouin zone, and they drive the system through an instability for \( V < 0 \) which leads to (plaquette) dimer ordering at these wave vectors.

![Photon dispersion relation of the large-S QDM on the square lattice.](image)
to resolve the constraint explicitly. A convenient way to do so is to look for a conjugate field $h(k)$ such that the Berry phase in the path integral can be written as

$$h(k)\partial_\tau \phi(-k) = \sum_\eta \delta\rho_\eta(k) \partial_\tau \Phi_\eta(-k).$$  \hspace{1cm} (2.21)

Substituting the expression for $\phi(k)$, Eq. (2.12), into the equation above, we obtain

$$\delta\rho_1(k) = 2c_2 h(k)$$
$$\delta\rho_2(k) = -2c_1 h(k).$$  \hspace{1cm} (2.22)

One can then straightforwardly verify that introducing the field $h(k)$ automatically resolves the constraint:

$$\sum_\eta c_\eta \delta\rho_\eta = 2(c_1 c_2 - c_2 c_1)h(k) = 0.$$  \hspace{1cm} (2.23)

Once again, this result should not come as a surprise. It is a reflection, at field theoretic level, of the fact that the plaquette terms in the Hamiltonian respect the dimer constraint. Therefore, if the field theory is built from plaquette kinetic terms only, then the constraint is implied.

We are thus in the position to write the full large-$S$ action for the system, including both the Berry phase and Hamiltonian contributions, in terms of the fields $h(k)$ and $\phi(k)$ only. Adding more complicated ring exchange type terms to the RK Hamiltonian does not invalidate this conclusion, as the phase in each ring exchange term may be written as a sum of phases over single plaquettes. Substituting the expressions of $\delta\rho_\eta(k)$ in terms of $h(k)$, and ignoring trivial constants, we obtain the action:

$$S = \int d\tau \sum_r \left\{ i\hbar(r, \tau) \partial_\tau \phi(r, \tau) + \frac{JS^2}{8} [1 - \cos(\phi(r, \tau))] \right\}$$
$$+ \int d\tau \sum_k \frac{D_0(k)}{2} h(k, \tau) h(-k, \tau)$$  \hspace{1cm} (2.24)

where

$$D_0(k) = 8 \left\{ (2V - J)(c_1^4 + c_2^4) \right\} + (J - V)(c_1^2 c_2^2) + 2Jc_1^2 c_2^2 \right\}.$$  \hspace{1cm} (2.25)

1. Action without instantons

Ignoring for the time being the contribution to the action due to instantons between different minima of the cosine term, we can expand about one given minimum and integrate over $\phi$ to arrive at

$$S = \frac{1}{2} \int d\tau \sum_k \left\{ \frac{8}{JS^2} \partial_\tau h(k, \tau) \partial_\tau h(-k, \tau) \right\}$$
$$+ D_0(k) h(k, \tau) h(-k, \tau).$$  \hspace{1cm} (2.26)

One can easily see that the dispersion is indeed the same as in Eq. (2.20). Expanding $D_0$ about its minimum at $(\pi, \pi)$,

$$D_0[(\pi, \pi) + (k_x, k_y)] \approx 2(J - V)(k_x^2 + k_y^2)$$
$$+ \left\{ \frac{7V}{6} - \frac{2J}{3} \right\} (k_x^4 + k_y^4) + Jk_x^2 k_y^2,$$

we obtain the action

$$S = \frac{1}{2} \int d\tau d^2 r \left\{ \frac{8}{JS^2} (\partial_\tau h)^2 + 2(J - V)(\nabla h)^2 \right\}$$
$$+ \frac{7V}{6} - \frac{2J}{3} \right\} (\partial_x^2 + \partial_y^2) h + Jh (\partial_x^2 \partial_y^2) h \right\} + \ldots$$  \hspace{1cm} (2.27)

At the RK point, the $(\nabla h)^2$ term vanishes and the terms with quartic derivatives add up to

$$\frac{J}{2} (\nabla^2 h)^2,$$  \hspace{1cm} (2.28)

yielding the spectrum $\omega = k^2/2m$ with $m = 2/JS$. We note that the known value at the RK point for $S = 1$ (and $J = V = 1$) in this normalization is $m = 9/\pi$ (corresponding to $K = 7/8$ in Refs. [4] and [11], which can be obtained exactly from the ground state wavefunction of the QDM, available only at the RK point). This shows that, expanding to quadratic order, our estimate is within 40% accuracy. We note that such discrepancy at quadratic order in a large-$S$ expansion is consistent for instance with similar results obtained in Ref. [15] for quantum spin ice.

Our results can be improved by going to higher orders, and more importantly with respect to earlier work on field theories for quantum dimer models – their validity is not limited to the fine tuned RK point.

2. Instantons

We will now incorporate the instanton effects which, as we shall demonstrate, always generate a mass for the photons for $V < J$, as it generally happens in compact electrodynamics. To this end, we are going to integrate out the field $\phi(r, \tau)$ taking into account the fact that the action is periodic in it.

Firstly, we proceed by the standard Villain approach and replace

$$1 - \cos \phi \rightarrow \frac{1}{2} [\phi - 2\pi \sum_j q_j \theta(\tau - \tau_j)]^2,$$  \hspace{1cm} (2.29)

where the $q_j = q(r_j, \tau_j)$ are integers representing instanton events, and $\theta(\tau)$ is the Heaviside step function. By integrating over $\phi$ and $h$, we obtain the following action:

$$S = \frac{(2\pi)^2}{2} \sum_{j,k} q(r_j, \tau_j) G_{qq}(r_j - r_k; \tau_j - \tau_k) q(r_k, \tau_k)$$
$$G_{qq}(k, \omega) = \left[ \omega^2/2M + (\rho_2 k^2 + \rho_4 k^4) \right]^{-1},$$  \hspace{1cm} (2.30)
where \( M = J S^2 / 8 \) and we introduced the symbolic terms \( \rho_2 k^2 \) and \( \rho_4 k^4 \) to represent the quadratic and quartic derivative terms in the action: \( D_0(q) \approx \rho_2 k^2 + \rho_4 k^4 + \ldots \). The resulting partition function is that of a Coulomb gas of charges \( q = \pm 1, \pm 2, \ldots \), where the fugacity of charge \( q \) is given by \( I = \exp(-q^2 S_0) \) and \( S_0 \) is the contribution to the action from a single instanton with \( q = 1 \):

\[
S_0 = \frac{1}{4\pi} \int \frac{d\omega \, d^2k}{\omega^2 / M + (\rho_2 k^2 + \rho_4 k^4)}
\approx \frac{\pi S}{8} \sqrt{\frac{J}{2\rho_4}} \ln(\rho_4 / \rho_2),
\]

and hence

\[
I = (\rho_2 / \rho_4)^q \pi S / 8,
\]

where we performed the calculations with the RRK form of the quartic term and substituted \( \rho_4 = J/2 \) for simplicity.

Since \( I \) is a fast decaying function of the instanton charge, we can restrict our consideration to the gas of charges \( q = \pm 1 \). Following Polyakov [16], we approximate the partition function of the Coulomb gas as the one of the sine-Gordon model with action \( I / \rho_2 \) augmented by the term

\[
\delta S = -2\mu I \int d\tau \sum_q \cos(2\pi h),
\]

where \( \mu \) is the preexponential part of the instanton measure (see Appendix [A]); at the RK point, \( 2\mu = 2S^{3/2} \sqrt{\pi/2} \). The presence of this term makes the excitations massive:

\[
\omega^2 = \beta^2 k^2 + m^2, \quad m^2 = 8\pi^2 M \mu I.
\]

As we see from (2.32), this mass vanishes at the RK point. At finite temperatures, instantons interact logarithmically:

\[
E = -\frac{2\pi T^2}{\rho_2} \sum_{j<k} q_j q_k \ln \left( \frac{|r_j - r_k|}{\rho_0} \right),
\]

where \( \rho_0^2 = \rho_4 / \rho_2 \). The corresponding contribution to the free energy density

\[
\delta F \propto q^2 I_q \int \frac{d^2 r}{r^d}, \quad d_q = 2\pi q^2 T / \rho_2,
\]

diverges at small \( T \). The contribution of the static fluctuations of \( h \) is encoded in the free energy functional

\[
F = \int d^2 x \left[ \frac{\rho_2}{2} (\nabla h)^2 + \frac{\rho_4}{2} (\nabla^2 h)^2 - 2\mu I \cos(2\pi h) \right].
\]

The scaling dimension \( d_1 \) of the cosine term is given by (2.39). The critical temperature above which the cosine term is irrelevant is determined by the condition \( d_1 = 2 \):

\[
T_c = \rho_2 / \pi.
\]

Above \( T_c \), we have a critical phase; below it, the correlation length of the \( h \) field is finite:

\[
\xi \sim r_0 (\mu I / T_c)^{-1/2 - d_1}
\]

This corresponds to melting the valence bond crystal. As it is typical for 2D crystals, it melts via a Berezinskii–Kosterlitz–Thouless transition.

We finally take a moment to comment on the difference between our result and the one obtained in Ref. [17], which in fact addresses a somewhat different problem. In Ref. [17], the authors considered equal time correlations at the RK point. The remarkable property of this point is that the ground state wave function can be represented as a path integral with a Gaussian action. It was argued that the periodicity of the height field generates the irrelevant perturbation \( \cos(2\pi h) \). Here, we obtained a formally equivalent perturbation (2.33) also away from the RK point; however, the prefactor of the cosine term in our case vanishes precisely at the RK point.

### E. Large-\( S \) phase diagram

As \( S \to \infty \), zero point fluctuations of any soft modes are negligible, and \( \rho \) and \( \Phi \) can be treated as commuting, classical variables. The ground state energy of the system in this limit is therefore given by classical minimisation of the Hamiltonian (2.3). Since \( \sqrt{\rho_2 \rho_4} \geq 0 \) always, the \( \Phi \) in such an optimal state satisfy \( \cos(\Phi_1 - \Phi_2 + \Phi_3 - \Phi_4) = 1 \) which is achieved, for instance, by setting \( \Phi = 0 \).

Finding the optimal values of \( \rho \) in full generality is more difficult. However, one can always compare the ground state energies of phases suggested in the literature, or develop a variational ansatz that captures several such phases. In the case of the square lattice, we
considered states in which \( \rho \) is constant within each set of bonds populated in the four columnar ordered states. Such an ansatz can capture columnar and plaquette ordered states as well as the RVB liquid phase.

Comparing the ground state energies of these phases yields the \( S \to \infty \) phase diagram shown in Fig. 3. As expected, the ground state is staggered for \( V > J \) and columnar at \( V \to -\infty \). At intermediate \( V/J \), we see a plaquette ordered phase as well as an extended \( U(1) \) RVB liquid, with phase boundaries corresponding to the instabilities shown in Fig. 2. The latter is unstable at finite \( S \) due to instanton effects, as discussed above. The fate of the plaquette phase is, however, less clear: since it is due to instanton effects, as discussed above. The calculation for other lattices is straightforward but for brevity, we omit the details of the calculation and only present the final result at the end of this section. The Hamiltonian is made of three terms equivalent to the square lattice Eq. (2.5), upon replacing \( (12) \leftrightarrow (13) \leftrightarrow (23) \).

As we did for the square lattice QDM, we derive here the resulting field theory to quadratic order. The calculation is similar to the one carried out in Section IIIC keeping the constraints implicit. It is also possible to explicitly resolve the constraints and obtain an action in terms of two independent real scalar fields, as in Sec. IIID but for brevity, we omit the details of the calculation and only present the final result at the end of this section.

The terms in the cubic Hamiltonian are equivalent to combining the square lattice terms for the (12), (13) and (23) components, see Eqs. (2.13), (2.14), and (2.15), up to a factor 4/9 due to the fraction \( S/6 \) replacing \( S/4 \) in Eq. (2.4).

### III. CUBIC LATTICE

The calculations for other lattices are straightforward generalizations of the square lattice case, with minimal but informative modifications. We begin with the cubic lattice, where we have the three lattice vectors \( e_\eta = x, y, z \). The corresponding RK Hamiltonian can be written as:

\[
H_D = \sum_r \left\{ -J b_{r,1} \gamma_1 b_{r+e_2,2} + (1 \leftrightarrow 2) + V b_{r,1} \gamma_1 b_{r+e_2,2} + (1 \leftrightarrow 2) \right\}
\]

subject to the equivalent large-\( S \) constraint

\[
\Pi_r = \sum_{\eta} b_{r,\eta} b_{-r,\eta} - S = 0.
\]

Using the radial gauge expression (2.4) for the bosonic field with \( z = 6 \), this constraint can be written as in (2.6), which in Fourier space reduces to

\[
\sum_{\eta} \phi_\eta(k) = 0.
\]

Contrary to the case of the square lattice, we have now three fields \( \phi_\eta \) and one constraint, leaving therefore two independent field variables. The Hamiltonian is made of three terms equivalent to the square lattice Eq. (2.5), upon replacing \( (12) \leftrightarrow (13) \leftrightarrow (23) \).

\[
S = \int d\tau \left\{ \sum_{k,\mu} \delta \phi_\mu(k) \Phi_\nu(-k) + \frac{JS^2}{18} \sum_{r,\mu} \left[ 1 - \cos(\phi_\mu(r, \tau)) \right] + \sum_{k,\mu,\nu} \frac{D_{\mu\nu}}{2} \delta \phi_\mu(k) \delta \phi_\nu(-k) \right\},
\]

where

\[
D = 2 \left( \begin{array}{ccc} 2(J-V) + (2V-J)(c_1^2 + c_2^2) & -Jc_1c_2 & -Jc_1c_3 \\ -Jc_1c_2 & 2(J-V) + (2V-J)(c_2^2 + c_3^2) & -Jc_2c_3 \\ -Jc_1c_3 & -Jc_2c_3 & 2(J-V) + (2V-J)(c_1^2 + c_2^2) \end{array} \right),
\]

and we labelled \( \phi_\mu \) the argument of the cosine term involving the phase fields \( \Phi_\nu \) with \( \nu \neq \mu \).

### A. Action without instantons

When we expand about one given minimum,

\[
\frac{JS^2}{18} \sum_{\mu=1,2,3} \left[ 1 - \cos(\phi_\mu(r, \tau)) \right] \approx \frac{JS^2}{36} \sum_{\mu=1,2,3} \phi_\mu(r, \tau)^2,
\]

we see that integrating out the fields \( \phi_\mu \) requires some care, since they are not all independent of one another.
Following the same steps as for the square lattice dimer model, it is convenient to introduce in Fourier space the fields

\[ \phi_1(k) \equiv e^{ik(c_1 + e_3)/2} \tilde{\phi}_1(k) = 2[c_3 \Phi_2(k) - c_4 \Phi_3(k)] \]
\[ \phi_2(k) \equiv e^{ik(c_3 + e_1)/2} \tilde{\phi}_2(k) = 2[c_1 \Phi_3(k) - c_3 \Phi_1(k)] \]
\[ \phi_3(k) \equiv e^{ik(e_1 + e_2)/2} \tilde{\phi}_3(k) = 2[c_2 \Phi_1(k) - c_1 \Phi_2(k)] . \]

These are most conveniently expressed as \( \phi_\mu = Z_{\mu \nu} \Phi_\nu \), where \( Z_{\mu \nu} = 2 \varepsilon_{\mu \nu \lambda} \delta_\lambda \) (\( \varepsilon_{\mu \nu \lambda} \) is the fully antisymmetric tensor and summation over \( \lambda \) is implied).

Notice that \( Z \) is a nonzero traceless antisymmetric matrix. It has one zero eigenvalue, \( \sum_\nu Z_{\mu \nu} c_\nu = 0 \), and the other two must be non-vanishing and opposite, \( \pm \zeta \):

\[ 2\zeta^2 = \text{tr} Z^2 = -2(c_1^2 + c_2^2 + c_3^2) \]
\[ \zeta = i\sqrt{c_1^2 + c_2^2 + c_3^2} . \]  

(3.6)

The two non-vanishing eigenvectors define the physical space, and the null one is the gauge degree of freedom. One can therefore construct a projector onto the physical space as \( -Z^2/(c_1^2 + c_2^2 + c_3^2) \).

The cosine term in the Hamiltonian reduces to

\[ \frac{JS^2}{36} \sum_\mu \phi_\mu(k) \phi_\mu(-k) = \frac{JS^2}{36} \Phi^T(k) Z(k) Z(-k) \Phi(-k) \]
\[ = \frac{JS^2}{36} \Phi^T(k) Z^T(k) Z(-k) \Phi(-k) \]
\[ = -\sum_\mu \frac{M_{\mu \nu}}{2} \Phi_\mu(k) \Phi_\nu(-k) , \]

where we used the fact that \( Z(-k) = Z(k) \) and \( Z^T = -Z \), and we defined

\[ M = -\frac{JS^2}{18} Z^2 \]
\[ = \frac{2JS^2}{9} \left[ \begin{array}{ccc} c_1^2 + c_2^2 & -c_1 c_2 & -c_1 c_3 \\ -c_1 c_2 & c_2^2 + c_3^2 & -c_2 c_3 \\ -c_1 c_3 & -c_2 c_3 & c_3^2 + c_2^2 \end{array} \right] . \]

(3.7)

Integrating out the fields \( \Phi_\mu \) then gives

\[ \frac{1}{2} \sum_{\mu, \nu} M_{\mu \nu}^{-1} \partial_\tau \delta_{\rho_\mu}(k) \partial_\tau \delta_{\rho_\nu}(-k) , \]

so we can write the full quadratic action without instants as

\[ S = \frac{1}{2} \int d\tau \sum_{k, \mu, \nu} \left\{ M_{\mu \nu}^{-1} \partial_\tau \delta_{\rho_\mu}(k) \partial_\tau \delta_{\rho_\nu}(-k) \right. \]
\[ \left. + D_{\mu \nu} \delta_{\rho_\mu}(k) \delta_{\rho_\nu}(-k) \right\} . \]

(3.9)

The dispersion can be obtained from the eigenvalues of \( \mathcal{M} \mathcal{D} = -2JS^2 Z^2 \mathcal{D}/9 \), after projecting out the non-physical modes that do not satisfy the constraint

\[ \sum_\mu c_\mu \delta_{\rho_\mu} = 0 . \]  

This could be done formally by adding an infinite Lagrange multiplier, but in fact there is no need to do so because the only non-physical mode is trivially the zero mode of \( Z^2 \mathcal{D} \) – as we had previously observed in the square lattice QDM. The two non-vanishing eigenvalues are

\[ \omega^2 = \frac{4JS^2}{9} \left[ J \left[ 2(c_1^2 + c_2^2 + c_3^2) - (c_1^4 + c_2^4 + c_3^4) \right] \right. \]
\[ \left. + 2V \left[ c_1^4 + c_2^4 + c_3^4 - (c_1^2 + c_2^2 + c_3^2)^2 + c_1^2 c_2^2 + c_2^2 c_3^2 + c_3^2 c_1^2 \right] \right] \]
\[ \pm 2|J - V| \sqrt{c_1^4 c_2^4 + c_1^4 c_3^4 + c_2^4 c_3^4 - c_1^2 c_2^2 c_3^2 (c_1^2 + c_2^2 + c_3^2)} \]  

(3.10)

This dispersion is plotted for three values of \( V/J \) in Fig. 4. It is interesting to note that \( \omega^2|_{J=V} \propto (c_1^2 + c_2^2 + c_3^2)^2 \) and the two bands are degenerate at the RK point, with vanishing minima at \((\pi,\pi,\pi)\) and symmetry related points, and quadratic dispersion around them. Expanding in general near such minima, we find

\[ \omega^2 \approx \frac{2S^2}{9} J(J - V) k^2 , \]

where \( k \) is the (small) vector distance from the minimum, giving a speed of light

\[ c = \frac{S}{3} \sqrt{2J(J - V)} . \]

(3.11)

(3.12)

As mentioned earlier, one could have alternatively resolved the constraint explicitly, writing the three fields \( \delta_{\rho_\mu} \) in terms of two independent real scalar fields \( h_\alpha \) and resolving the corresponding inter dependence of the three fields \( \phi_\mu \):

\[ c_1 \phi_1 + c_2 \phi_2 + c_3 \phi_3 = 0 . \]

(3.13)
For instance, one can do so via the relation \( \phi_1 = -(c_2/c_1)\phi_2 - (c_3/c_1)\phi_3 \) and \( \delta \rho_\mu = \sum_a R_{\mu a} h_a \) with
\[
R = 2 \begin{pmatrix} c_2 & -c_3 \\ c_1 & 0 \\ 0 & c_1 \end{pmatrix}.
\] (3.16)

After a few lines of algebra, one arrives at the action
\[
S = \frac{1}{2} \int dt \sum_{k,a,b} \left\{ \tilde{M}^{-1}_{ab} \partial_k h_a(k) \partial_k h_b(-k) + \tilde{D}_{ab} h_a(k) h_b(-k) \right\},
\] (3.17)

where \( \tilde{D} = R^T DR \) and
\[
\tilde{M} = \frac{JS^2}{18c_1^2} \begin{pmatrix} c_1^2 + c_2^2 & c_2c_3 \\ c_2c_3 & c_1^2 + c_3^2 \end{pmatrix}.
\]

One can easily verify that the action (3.17) gives indeed the same dispersion as Eq. (3.12).

**B. Instantons**

The instanton contributions are calculated as for the square lattice case. However, we have to take into account that the fields \( \phi_\mu \) are not independent, see Eq. (3.15). We can use this to eliminate field \( \phi_3 \). The Villain transformation is then performed by replacing \( \phi_{1,2} \) in (3.10) by (2.29) and integrating out over the smooth fields \( \phi_\mu, h_\mu \). The result is the Coulomb gas action for integer charges \( q_{1,2} \).

\[
S = \frac{(2\pi)^2}{2} \sum_{\omega,k} \sum_{\mu,\nu} q_\mu (-\omega, -k) \\
\times \left[ (18\omega^2/JS^2)M^{-1} + D^{-1}_{\mu\nu} q_\nu (\omega, k) \right],
\] (3.18)

with the standard unscreened long ranged Coulomb interaction. In (3+1)-dimensions instantons are irrelevant and can be safely neglected.

**C. Large-\( S \) phase diagram**

Using the method described in Sec. IIE, we can obtain the ground state of the QDM Hamiltonian (3.1) in the limit \( S \to \infty \). The results are summarised in Fig. 5. Similarly to the square lattice case, we observe an extended \( U(1) \) RVB liquid phase: in three dimensions, this phase is anticipated to survive at \( S = 1 \). For \( V > J \), the photon modes become unstable at the \((\pi, \pi, \pi)\) point, leading to staggered order. Likewise, the instability of the \((\pi, 0, 0)\) points for \( V < 0 \) drives a transition into an RVB solid phase with isolated, resonating cubes. For \( V < -J/4 \), this phase gives way to columnar order.

**IV. TRIANGULAR LATTICE**

It is interesting to consider the case of the triangular lattice QDM immediately after the cubic one. It has connectivity 6 and is tripartite, and one can view it as a projected cubic lattice along one of the \([111]\) directions. Following the notation in Fig. 4, the solid dots belong to one cubic sublattice, the open circles to the other, and the dotted circles are sites that belong to both cubic sublattices but get projected onto one another. The rhombic plaquettes of the triangular lattice correspond to the three independent faces of a cube, and therefore one can precisely identify flippable plaquettes and plaquette flipping terms between the two models. This projective view allows to draw a complete correspondence between the two QDMs. Formally, the large-\( S \) path integral approach presented in this paper proceeds identically, down to the numerical prefactors, for the triangular and cubic cases and we end up with the same two-component field theory, with action given (to quadratic order) by Eq. (3.11) and dispersion given by Eq. (3.12). The correspondence holds only so long as we express the positions and wave vectors formally as \( r \) and \( k \), and the basis vectors as \( e_1, e_2 \) and \( e_3 \).
In order to study the triangular lattice QDM one then needs to substitute \( k = (k_x, k_y) \) and a given choice of base vectors, for example \( e_1 = (\sqrt{3}, 1)/2, e_2 = (-\sqrt{3}, 1)/2, \) and \( e_3 = (0, -1) \), illustrated in Fig. 6. This is however beyond the scope of the present paper. For \( S = 1 \) we expect a \( \mathbb{Z}_2 \) liquid phase to be stable around the RK point \([27]\); its fate however is unclear in the large-\( S \) limit. If the description is able to capture it at all, it can only be after accounting for instantons and understanding how their role differs in bipartite and non-bipartite lattices – a task which promises to pose non-trivial challenges.

V. HONEYCOMB LATTICE

In this section, we consider the QDM on the honeycomb lattice, illustrated in Fig. 7 and we present only the approach where the constraint is resolved explicitly. Contrary to the cases considered so far, the primitive cell of the lattice contains two distinct sites (labelled \( A \) and \( B \) in the figure). With the choice of lattice vectors \( e_1 = (\sqrt{3}, 1)/2, e_2 = (-\sqrt{3}, 1)/2, \) and \( e_3 = (0, -1) \) in Fig. 7 we can write the bosonic representation of the Hamiltonian as

\[
H_D = \sum_{r \in A} \left\{ -J b_r^\dagger r_1 b_{r+r_e_1-e_3,2} b_{r+e_2-e_3,3} + \right. \\
\left. \times b_{r+e_1-e_3,3} b_{r+e_2-e_3,1} b_{r+2} + \text{h.c.} \\
+ V b_r^\dagger r_1 b_{r,1} b_{r+e_1-e_3,2} b_{r+e_2-e_3,1} b_{r+e_2-e_3,3} b_{r+e_2-e_3,3} \\
+ V b_r^\dagger r+e_1-e_3,3 b_{r+e_1-e_3,1} b_{r+e_2-e_3,3} b_{r+e_2-e_3,3} b_{r+1} b_{r,2} \right\}.
\]

One has to write two separate (large-\( S \)) constraints, one for each sublattice:

\[
\sum_{l \in e_{v_{e_{A}}}} b_l^\dagger b_l - S = 0 \\
\sum_{l \in e_{v_{e_{B}}}} b_l^\dagger b_l - S = 0.
\] (5.2)

The rest of the calculation follows rather straightforwardly from the square lattice case, barring some added algebraic difficulties, and is presented for completeness in App. B. The argument of the cosine leads us to introduce the field

\[
\phi(k) = 2i \left[ \Phi_1(k)(s_2 c_3 - s_3 c_2) + \Phi_2(k)(s_3 c_1 - s_1 c_3) \\
+ \Phi_3(k)(s_1 c_2 - s_2 c_1) \right]
\]

and the following convenient resolution of the constraint in terms of a scalar field \( h(k) \):

\[
\delta \rho_1(k) = -2i (s_2 c_3 - s_3 c_2) h(k) \\
\delta \rho_2(k) = -2i (s_3 c_1 - s_1 c_3) h(k) \\
\delta \rho_3(k) = -2i (s_1 c_2 - s_2 c_1) h(k).
\] (5.3)

To quadratic order, one arrives then at the action

\[
S = \int d\tau \sum_k \left\{ i \hbar (r, \tau) \partial_r (r, \tau) + \frac{2JS^3}{27} \left[ 1 - \cos(\phi(r, \tau)) \right] \right\} \\
+ \int d\tau \sum_k \frac{D(k)}{2} h(k, \tau) h(-k, \tau),
\]

where

\[
D(k) = \frac{8JS}{3} \left( s_{12}^4 + s_{23}^4 + s_{31}^4 \right) \\
- \frac{16JS}{3} \left( s_{12}s_{23}c_{12}c_{23} + s_{23}s_{31}c_{23}c_{31} + s_{31}s_{12}c_{31}c_{12} \right) \\
+ \frac{16VS}{3} \left( s_{12}s_{23}(c_{12}c_{23} - s_{12}s_{23}) \\
+ s_{23}s_{31}(c_{23}c_{31} - s_{23}s_{31}) \\
+ s_{31}s_{12}(c_{31}c_{12} - s_{31}s_{12}) \right),
\]

where we introduce for convenience

\[
s_{\mu \nu} = \sin[k(\epsilon_a - \epsilon_a)/2] = s_{\mu} c_{\nu} - s_{\nu} c_{\mu} \\
c_{\mu \nu} = \cos[k(\epsilon_a - \epsilon_a)/2] = c_{\mu} c_{\nu} + s_{\mu} s_{\nu}.
\]

Expanding about one given minimum,

\[
\frac{2JS^3}{27} \left[ 1 - \cos(\phi(r, \tau)) \right] \approx \frac{JS^3}{27} \phi(r, \tau)^2,
\]

and integrating over \( \phi \), we arrive at the action

\[
S = \frac{1}{2} \int d\tau \sum_k \left[ \frac{27}{2JS^3} \partial_r h(k, \tau) \partial_r h(-k, \tau) \\
+ D(k)h(k, \tau)h(-k, \tau) \right],
\]

and the corresponding dispersion \( \omega^2(k) = 2JS^3 D(k)/27 \). This dispersion is plotted for three values of \( V/J \) in Fig. 8. It is gapless at the \( \Gamma \) point for all values of \( J \) and \( V \).

An instability develops for \( V > J \) whereby \( \omega^2 \) becomes negative for small \( k \). For \( V \ll J \), the long-wavelength dispersion is linear:

\[
\omega \approx \sqrt{2J(J-V)} \frac{S^2}{3} k.
\] (5.9)
As the value of $V$ is lowered, secondary minima appear at the $K$ points in the Brillouin zone which drive the system through an instability for $V < - J / 8$.

Expanding $D(k)$ about its minimum at $\Gamma = (0, 0)$,

$$D[(k_x, k_y)] \simeq 3S(J - V)(k_x^2 + k_y^2) + \frac{9S}{16}(7V - J)(k_x^2 + k_y^2 + 2k_x^2k_y^2),$$

we obtain the action:

$$S = \frac{1}{2} \int d\tau d^2r \left\{ \frac{27}{2JS^3} (\partial_x h)^2 + 3S(J - V)(\nabla h)^2 + \frac{9S}{16}(7V - J)(\nabla^2 h)^2 \right\} + \ldots \quad (5.10)$$

Contrary to the square lattice QDM, see Eq. (2.27), we find that rotational symmetry is preserved near the band minimum of the honeycomb lattice QDM for $J \neq V$, at least up to quartic order. This is expected, since the discrete symmetry of the lattice upon $2\pi/3$ rotations implies that the first symmetry breaking term allowed in the action must be of 6-th order in $k$.

The ground state of the $S \to \infty$ model was also obtained as a function of $V/J$ by comparing the energy of several ordered and resonating phases suggested in the literature [29, 28] under the Hamiltonian (5.1). The resulting phase diagram is shown in Fig. [3] together with the $S = 1$ phase diagram obtained in Ref. [29]. As in the previous cases, the large-$S$ phase diagram predicts a columnar ordered, a plaquette ordered, an RVB liquid, and a staggered ordered phase, which are also sketched in Fig. [3]. It is interesting to note that the RVB liquid phase instability for $V < J$ occurs below the RVB-plaquette transition point (cf. Fig. [5] and Fig. [9]; this suggests that the latter may in fact be a first order transition.

At finite $S$, instantons are expected to gap out the $U(1)$ liquid phase in two dimensions, leading to its immediate collapse, see Sec. [ID2]. The other three phases are all observed at $S = 1$ with critical $V/J$ similar to the large-$S$ result.

VI. DIAMOND LATTICE

The diamond lattice is composed of two interpenetrating face centered cubic (fcc) lattices, as shown in Fig. [10]. Sublattice $A$ is connected to sublattice $B$ by the vectors

$$e_1 = \frac{1}{\sqrt{3}} (1, 1, 1) \quad e_2 = \frac{1}{\sqrt{3}} (1, -1, -1) \quad e_3 = \frac{1}{\sqrt{3}} (-1, 1, -1) \quad e_4 = \frac{1}{\sqrt{3}} (-1, -1, 1), \quad (6.1)$$

which we chose to define the unit length in the system. Notice that $\sum_{\mu} e_{\mu} = 0$. The lattice is 4-fold coordinated and the smallest lattice loop over which a dimer move can take place is a hexagon. Each hexagonal plaquette involves lattice bonds of three out of the four types, and
therefore there are four inequivalent plaquette terms, involving respectively $\mu = 1, 2, 3$, $\mu = 1, 2, 4$, $\mu = 1, 3, 4$, and $\mu = 2, 3, 4$.

The QDM Hamiltonian is the sum of four copies of the honeycomb lattice Hamiltonian, Eq. (5.1), and we refrain from writing it here explicitly for convenience (see Sec. V and App. B). Expressing the bosonic operators in the radial gauge (2.4) and expanding to quadratic order, and $\epsilon$ each plaquette. In Fourier space, we have

$$\delta\rho_{\mu}(k, \tau) = \frac{2}{J}\sum_{r, \alpha} \epsilon_{\alpha, \beta, \gamma, \delta} \Phi_{\beta}(r) s_{\gamma} c_{\delta},$$

(6.3)

where $\epsilon_{\alpha, \beta, \gamma, \delta}$ is the totally antisymmetric tensor, $c_{\mu} = \cos(k c_{\mu}/2)$, and $s_{\mu} = \sin(k c_{\mu}/2)$.

Since the two sublattices of the diamond lattice are inequivalent, there are two separate (large-$S$) constraints on $\rho$, one for each sublattice:

$$\sum_{l \in v \in A} b_{l}^{\dagger} b_{l} - S = 0$$

$$\sum_{l \in v \in B} b_{l}^{\dagger} b_{l} - S = 0.$$ (6.4)

In Fourier space, these can be written as

$$\sum_{\mu} c_{\mu} \delta\rho_{\mu}(k) = \sum_{\mu} s_{\mu} \delta\rho_{\mu}(k) = 0;$$ (6.5)

since we have two constraints for the four fields $\delta\rho_{\mu}$, there are two independent fields left. Resolving the constraints explicitly, however, leads to rather intractable algebra; therefore, we only present the implicit approach of Sec. III C

Ignoring instantons (for the same reasons discussed in Sec. III B), the middle term of Eq. (6.2) can be expanded about a given minimum of the cosine. After Fourier transforming and substituting (6.3), we obtain

$$S = \int d\tau \sum_{k, \mu} i\delta\rho_{\mu}(k, \tau) \partial_{\tau} \Phi_{\mu}(-k, \tau)$$

$$+ \int d\tau \sum_{k, \mu, \nu} \frac{M_{\mu\nu}}{2} \Phi_{\mu}(k, \tau) \Phi_{\nu}(-k, \tau)$$

$$+ \int d\tau \sum_{k, \mu, \nu} \frac{D_{\mu\nu}(k)}{2} \delta\rho_{\mu}(k, \tau) \delta\rho_{\nu}(-k, \tau);$$ (6.6)

obtaining the matrices $M$ and $D$ from the QDM Hamiltonian is straightforward but algebraically tedious and is presented in App. C.

As in Sec. II C the fields $\Phi_{\mu}$ can now be integrated out to obtain the action

$$S = \frac{1}{2} \sum_{k, \mu, \nu} \left( (M^{-1})_{\mu\nu} \partial_{\tau} \delta\rho_{\mu}(k, \tau) \partial_{\tau} \delta\rho_{\nu}(k, \tau)$$

$$+ D_{\mu\nu}(k) \delta\rho_{\mu}(k, \tau) \delta\rho_{\nu}(-k, \tau) \right).$$ (6.7)

The dispersion $\omega^2(k)$ is given by the eigenvalues of the matrix $MD$. Two of these eigenvalues are identically zero; these correspond to the unphysical modes ruled out by the constraints (6.5). The remaining two eigenvalues can be worked out by straightforward but rather lengthy algebra; the resulting dispersion is plotted along high-symmetry directions for three values of $V/J$ in Fig. 11.

Away from the RK point, the resulting two photon modes are normally nondegenerate; near $k = 0$, however, they agree to leading order:

$$\omega^2 \approx \frac{J(J - V)}{8} \Omega S^4 \approx \frac{S^4}{6} J(J - V) k^2;$$ (6.8)

giving a speed of light

$$c = S^2 \sqrt{J(J - V)/6}.$$ (6.9)

This can be contrasted to the quantum Monte Carlo result for $S = 1$ in Refs. 12 and 13, namely $c \approx \sqrt{0.6 J(J - V)}$. Once again, we find a discrepancy of approximately 47% at quadratic order.

The ground state of the $S \rightarrow \infty$ model was obtained as a function of $V/J$ by comparing the large-$S$ minimum
energy of ordered and resonating phases suggested in the literature \cite{11, 12, 13}. The resulting phase diagram is shown in Fig. 12 together with the \( S = 1 \) phase diagram obtained in Ref. \cite{13}. Unlike the previous cases, no resonating solid phase is identified in either limit: both phase diagrams consist of staggered ordered, \( U(1) \) liquid and ordered \( R \) phases. The liquid phase is far larger for \( S \to \infty \) than at \( S = 1 \); this is consistent with the intuition that soft dimers (and spins) favour fluctuating phases.

**VII. RELATION TO OTHER FIELD-THEORETIC APPROACHES**

For quantum dimers models on bipartite lattices, field-theoretic approaches were already known in the literature. These include height mappings in two dimensions \cite{7} and \( U(1) \) gauge theory mappings in three dimensions \cite{8}. In this Section, we briefly review them and discuss how they relate to our large-\( S \) representation. For simplicity, we focus on the square and cubic lattices.

**A. Height mapping on the square lattice**

In \( S = 1 \) dimer models, a height mapping can be constructed by assigning a height \( \tilde{h} \) to all plaquettes of the lattice, starting from a reference plaquette with \( \tilde{h} = 0 \). Going clockwise around a vertex in the \( A \) sublattice (see Fig. 1), the height field changes by \(-1/4\) on crossing a bond without a dimer and by \(+3/4\) on crossing one with a dimer. Likewise, going clockwise around a vertex in the \( B \) sublattice, \( \tilde{h} \) changes by \(-3/4\) and \(+1/4\) on bonds with and without dimers, respectively. These numbers are the difference between the occupation of a given bond and the average occupation of all bonds, \( 1/4 \). Therefore, this mapping can be generalised to the large-\( S \) case by requiring that

\[
\Delta \tilde{h} = \pm \delta \rho, \quad (7.1)
\]

where the sign depends on the direction in which the bond is traversed, as described above.

In order to coarse-grain this height description, it is useful to define the so-called magnetic field representation,

\[
\tilde{B}(r) = (B_x, B_y, 0), \quad B_\mu(r) = (-1)^{x+y} \mu \rho_\mu(r), \quad (7.2)
\]

in which the height mapping (7.1) can be expressed as

\[
B_\mu(e_\mu r/2) = \tilde{h}[r+(e_\mu+\epsilon_\mu e_\nu)/2]-\tilde{h}[r+(e_\mu-\epsilon_\mu e_\nu)/2], \quad (7.3)
\]

In reciprocal space, the signs appearing in (7.2) have the effect of shifting the gapless point of the dispersion \( (2.20) \) from \((\pi, \pi)\) to \((0, 0)\), that is, coarse-graining will capture the long-wavelength, low-frequency features of the gapless modes. In particular, (7.3) can be Fourier transformed to give

\[
B_\mu(q) = 2i \epsilon_{\mu\nu} \sin(k_\nu/2) \tilde{h}(k) \quad (7.4)
\]

comparing with (2.22) immediately gives

\[
\tilde{h}(k) = h[k+(\pi, \pi)] \quad (7.5)
\]

\[
\tilde{h}(r) = (-1)^{x+y} h(r), \quad (7.6)
\]

where \( h \) is the single-component height field introduced in Sec. \( \Pi \). This concludes the reconstruction of the height mapping for classical (nondynamical) dimer models.

To recover quantum dynamics, the conjugate variables \( \Phi_\mu \) and \( \phi \) can be reexpressed as

\[
\tilde{\Phi}(r) = (\tilde{\Phi}_x, \tilde{\Phi}_y, 0), \quad \tilde{\Phi}_\mu(r) = (-1)^{x+y} \Phi_\mu(r), \quad (7.7)
\]

\[
\tilde{\phi}(r) = (-1)^{x+y} \phi(r), \quad (7.8)
\]

which leads to Berry phase terms of the form

\[
i \sum_{k,\mu} \delta \rho_\mu(k) \partial_r \Phi_\mu(-k) = i \sum_k \tilde{B}(k) \cdot \partial_r \tilde{\Phi}(-k) \quad (7.9)
\]

\[
i \sum_k h(k) \partial_r \phi(-k) = i \sum_k \tilde{h}(k) \partial_r \tilde{\phi}(-k). \quad (10.10)
\]

Integrating \( \tilde{\phi} \) out and coarse-graining (that is, focusing on small \( k \)) then yields the quadratic action (2.27).

**B. Coulomb gauge theory on the cubic lattice**

The key idea of the mapping discussed above is turning the lattice gauge field and its divergence-free condition (2.3) into a coarse-grained, true vector field with \( \nabla \cdot \tilde{B} = 0 \). Indeed, for small \( k \), (7.4) reduces to

\[
\tilde{B}(k) = ik \times \tilde{h}(k) \iff \tilde{B} = \nabla \times \tilde{h}, \quad (7.11)
\]

where \( \tilde{h} = (0, 0, \tilde{h}) \). Similarly, we now want to construct a divergence-free magnetic field \( \tilde{B} \) on the cubic lattice by coarse-graining \( \delta \rho_\mu \). To achieve this, we express our field in terms of a magnetic vector potential: \( \tilde{B} = \nabla \times \tilde{A} \).
The construction again starts by defining
\[ B_\mu(r) = (-1)^{x+y+z} \delta \rho_d(r); \]  
(7.12)
similarly to the square lattice case, this amounts to shifting the gapless point of the photon dispersion from \((\pi, \pi, \pi)\) to the origin. The reciprocal space constraint \((3.3)\) now becomes
\[ \sum_\mu 2i \sin(k_\mu/2) B_\mu(k) = 0. \]  
(7.13)
This constraint can be resolved similarly to \((7.4)\) by introducing another vector field \( \tilde{A} \):
\[ B_\mu(k) = 2i \epsilon_{\mu\nu\lambda} \sin(k_\nu/2) A_\lambda(k); \]  
(7.14)
at small \( q \), this reduces to \( B = \nabla \times A \), as desired.
We now turn the conjugate variables \( \Phi \) and \( \phi \) into vector fields by writing
\[ \tilde{\Phi}_\mu(r) = (-1)^{x+y+z} \Phi_\mu(r) \]  
(7.15)
\[ \tilde{\phi}_\mu(r) = (-1)^{x+y+z} \phi_\mu(r). \]  
(7.16)
Eq. \((3.6)\) can be written as
\[ \tilde{\phi}_\mu(k) = 2i \epsilon_{\mu\nu\lambda} \sin(k_\nu/2) \tilde{\Phi}_\lambda(k) \]  
(7.17)
and the Berry phase can be integrated by parts to obtain
\[ i \sum_{k,\mu} \delta \rho_d(k) \Phi_\mu(-k) = i \sum_k \tilde{A}(k) \cdot \tilde{\phi}(-k). \]  
(7.18)
Expanding to quadratic order in \( \phi \) around a given minimum of the cosine, we finally obtain the action
\[ S = \int d\tau \sum_k \left[ i \tilde{A}(k) \cdot \tilde{\phi}(-k) + \frac{JS^2}{36} \tilde{\phi}(k) \cdot \tilde{\phi}(-k) \right] \]  
\[ + \frac{D_{\mu\nu}}{2} A_\mu(k) A_\nu(-k), \]  
(7.19)
where \( D \) is given in terms of the matrix \( D \) defined in \((3.4)\)
\[ D_{\mu\nu}(k) = 4 \epsilon_{\mu\kappa\rho} \epsilon_{\nu\lambda\sigma} \sin(k_\kappa/2) \sin(k_\lambda/2) D_{\rho\sigma}[k + (\pi, \pi, \pi)]. \]  
(7.20)
Finally, we integrate out \( \phi \) and expand \( \tilde{A} \) around \( q = 0 \) to obtain a coarse-grained action in terms of \( A \) only. Away from the RK point, the leading order terms give
\[ S \simeq \int d\tau \sum_k \left[ \frac{9}{JS^2} \partial_\tau \tilde{A}(k) \cdot \partial_\tau \tilde{A}(-k) \right] \]  
\[ + 2(J - V) \tilde{B}(k) \cdot \tilde{B}(-k), \]  
(7.21)
Similarly to ordinary quantum electrodynamics, we can identify \( \partial_\tau \tilde{A} \) as the electric field; that is, \((7.21)\) is the action of a linearly dispersing \( U(1) \) gauge theory. The speed of light is given by
\[ c = \frac{S}{3} \sqrt{2(J - V)J}, \]  
(7.22)
in agreement with \((3.14)\). At the RK point, the \( B^2 \) term vanishes; to leading order, the action becomes
\[ S \simeq \int d\tau \sum_k \left\{ \frac{9}{JS^2} \partial_\tau \tilde{A}(k) \cdot \partial_\tau \tilde{A}(-k) \right\} \]  
\[ - \frac{J}{2} [k \times \tilde{B}(k)] \cdot [k \times \tilde{B}(-k) \right\}. \]  
(7.23)

**VIII. CONCLUSIONS**

We proposed a general route to obtain the field theoretic action for microscopic Hamiltonians with hard constraints, based on a slave boson representation of the relevant degrees of freedom and their constraints, combined with a large-\( S \) path integral formulation.

We used it to derive systematically the Lagrangians for bipartite QDMs in 2D and 3D from the corresponding microscopic Hamiltonians. We find good agreement with known results in the literature; namely, calculations up to quadratic order yield a stiffness for the square lattice QDM at the RK point equal to \( 1/4 \) compared to the exact result \( \pi/18 \) \([4,11]\); and give a speed of light in the gapless phase of the diamond lattice QDM \( c = \sqrt{(J - V)/6 S^2} \) compared to the numerical result \( c(S = 1) \approx \sqrt{0.6(J - V)} \) \([12,13]\).

Our approach applies straightforwardly to the non-bipartite case of the QDM on the triangular lattice, where we observe an intriguing analytical relation to the formalism of the cubic lattice, which will be interesting to explore in future work.

Statement of compliance with the EPSRC policy framework on research data: this publication reports theoretical work that does not require supporting research data.

**Appendix A: Instanton measure on the square lattice**

Instantons appear naturally in the compact gauge theory as stationary trajectories of the action with \( \phi \) changing by \( 2\pi \) on a given site between \( \tau = \pm \infty \). Unlike the...
point-like instantons described in Sec. II D 2 these objects are smooth as a function of time, and thus have a nontrivial instanton core. The action can then be expanded to quadratic order around such solutions, similarly to the case \( h = \phi \equiv 0 \) shown in Sec. II D 1. The resulting fluctuation determinant will appear in the probability of instantons as a preexponential factor.

We thus have to construct such a stationary instanton solution. Using (2.24, 2.29) with a single instanton event at \( r = \tau = 0 \), we get the following quadratic action in terms of Fourier components:

\[
S = \int (d\omega)(d^2k) \left\{ \omega h(k, \omega)\phi(-k, -\omega) + \frac{D_0(k)}{2}h(k, \omega)h(-k, -\omega) + M\left[ \phi(k, \omega) - \frac{2\pi i}{\omega} \right] \times \text{c.c.} \right\},
\]

where we introduce \( M = JS^2/8 \) for brevity and \( i/\omega \) is the Fourier transform of the Heaviside function in \( \tau \). Since the different Fourier components are decoupled in this action, we can minimise with respect to them separately, resulting in the stationary action

\[
h_0(k, \omega) = \frac{2\pi i q M}{\omega^2 + MD_0(k)} \quad \phi_0(k, \omega) = \frac{2\pi i M D_0(k)}{\omega^2 + MD_0(k)}.
\]

In real space, this corresponds to a point-like instanton described in Sec. II D 2 together with a power-law decaying “instanton core”. We should also note that (A2) is not a stationary trajectory under the original action, but it becomes one if the \( M(1 - \cos \phi) \) potential term is replaced with a continued parabolic potential, \( V(\phi) = M \min_\phi (\phi - 2\pi n)^2 \). Indeed, the only point where \( \phi_0 \) reaches \( \pi \) is \( r = \tau = 0 \), where the cusp in the potential is recovered by the external instanton charge. In the following, we will thus use \( V(\phi) \).

The action can now be expanded to quadratic order in \( \delta h \) and \( \delta \phi \) around both the trivial trajectory \( h = \phi = 0 \) and the instanton trajectory (A2). \( \delta h \) can easily be integrated out in both cases, giving the following actions in \( \delta \phi \):

\[
\delta S_0 = \frac{1}{2} \int (d\omega)(d^2k) \left( \frac{\omega}{D_0(k)} + M \right) \delta \phi(k, \omega)\delta \phi(-k, -\omega)
\]

\[
\delta S_1 = \delta S_0 \quad \partial_r \phi_0(r = \tau = 0)\left[ \delta \phi(r = \tau = 0) \right]^2,
\]

where the additional term in (A4) corresponds to the cusp of the continued parabolic potential at \( \phi = \pi \), only reached at \( r = \tau = 0 \). The most important difference between the two actions is that \( \delta S_1 \) has the zero mode \( \psi = \partial_r \phi_0 \), corresponding to the continuous time translation symmetry of the setup. For such modes, the usual contribution to the partition function, \( e^{-S_0}(\det K)^{-1/2} \) is replaced by

\[
d\tau \sqrt{\frac{\langle \psi|\psi \rangle}{2\pi}} e^{-S_1}(\det K)^{-1/2},
\]

where \( S_1 \) is the action due to the stationary instanton, given by (2.31), and \( K \) is the fluctuation kernel of (A4) restricted to the non-zero modes. Assume \( \psi \) proportional to a basis vector (this can always be achieved using a unitary transformation on the kernel \( K \)). Then, \( K \) is the principal minor of \( K \) that excludes the row and column of \( \psi \). \( \det K \) is thus a cofactor of the full kernel, and we have

\[
\det K = \langle \psi|K^{-1}|\psi \rangle \det K
\]

by the cofactor formula for matrix inversion. Note that \( \psi \) is assumed to be normalised (we shall come back to this later).

In a matrix language, \( K \) is the sum of the kernel \( K_0 \) appearing in (A3) and a dyad \( -\lambda v|v \rangle \langle v| \) (where \( v \) corresponds to the \( \delta \)-function at \( r = \tau = 0 \) implied in (A4) in an arbitrary basis). For such a matrix, we have the following:

1. \( \det K = \det K_0(1 - \lambda \langle v|K_0^{-1}|v \rangle) \).
2. If \( 1 - \lambda \langle v|K_0^{-1}|v \rangle = 0 \), \( K_0^{-1}|v \rangle \) is an eigenvector of \( K \) with eigenvalue 0.
3. \( K^{-1} = K_0^{-1} + \lambda K_0^{-1}|v \rangle \langle v|K_0^{-1}/(1 - \lambda \langle v|K_0^{-1}|v \rangle) \).

The first statement can be shown by inserting factors of \( K_0^{1/2}K_0^{-1/2} \) into the definition of \( K \); the other two are straightforward to verify. Now, \( \det K \) follows as

\[
\det K = \langle \psi_0|K_0^{-1} + \lambda K_0^{-1}|v \rangle \langle v|K_0^{-1}|\psi_0 \rangle \times \langle 1 - \lambda \langle v|K_0^{-1}|v \rangle |v \rangle \langle v|K_0^{-1}/(1 - \lambda \langle v|K_0^{-1}|v \rangle) |\psi_0 \rangle \times
\]

\[
(1 - \lambda \langle v|K_0^{-1}|v \rangle) \det K_0 \quad \text{(A7)}
\]

\[
= \langle \psi_0|\lambda K_0^{-1}|v \rangle \langle v|K_0^{-1}|\psi_0 \rangle \det K_0
\]

\[
= \lambda \langle v|K_0^{-2}|v \rangle \det K_0 \quad \text{(A8)}.
\]

In the first line, we substitute statements 1 and 3 into (A6) in the second, we note that \( 1 - \lambda \langle v|K_0^{-1}|v \rangle = 0 \) in our case, so only the second term of \( K^{-1} \) gives any contribution 31. Finally, we use that \( |\psi_0 \rangle \) is the normalised zero mode, so by statement 2, it must be \( K_0^{-1}|v \rangle \sqrt{\langle v|K_0^{-2}|v \rangle} \). Altogether, the measure of the instanton solutions relative to that of the instanton-free solution, \( (\det K_0)^{-1/2} \), is

\[
d\tau \sqrt{\frac{(\langle \psi|\psi \rangle}{2\pi}} \lambda |v|K_0^{-2}|v \rangle e^{-S_0}. \quad \text{(A9)}
\]

In the \( (k, \omega) \) basis, \( K_0 \) is positive definite and diagonal, \( K_0(k, \omega) = \omega^2/D_0(k) + M \), \( \lambda = 2\pi M/|\partial_r \phi_0(0, 0)| \), and \( v(k, \omega) = 1 \) (the Fourier transform of a \( \delta \)-function at the origin). It is easy to verify that \( 1 - \lambda \langle v|K_0^{-1}|v \rangle = 0 \), that
is, $K$ indeed has a zero mode; furthermore, $K_0^{-1}|\nu\rangle \propto \partial_\tau \phi_0$, as expected. Substituting into (A9), then gives that the measure of instanton solutions of a given sign is

$$\mu = \sqrt{\frac{M \pi}{(d^2 k) \omega(k)}} = JS^{3/2} \sqrt{\pi/8}$$  \hspace{1cm} (A10)

at the RK point.

**Appendix B: Details of the calculation for the honeycomb lattice**

Following from Sec. V we express the bosonic operators in the radial gauge in the path integral formulation of the model. For $r \in A$:

$$b_{r,\eta} = \sqrt{\rho_\eta(r + e_\eta/2)} \exp[i \Phi_\eta(r + e_\eta/2)] \equiv \sqrt{\frac{S}{3}} + \delta \rho_\eta(r + e_\eta/2) \exp[i \Phi_\eta(r + e_\eta/2)].$$  \hspace{1cm} (B1)

For $r \in B$, the expressions are equivalent except for a change in sign, $+e_\eta/2 \to -e_\eta/2$. Notice that, by thinking of $\rho_\eta(r + e_\eta/2)$ and $\Phi_\eta(r + e_\eta/2)$ as functions defined on the midpoints of the bonds, there is no ambiguity nor redundancy in the notation.

The constraints in Eq. (B2) can then be written (choosing for concreteness $r \in A$) as

$$\sum_\eta \delta \rho_\eta(r + e_\eta/2) = 0$$  \hspace{1cm} (B2)

and its Fourier transform

$$\tilde{\phi}(k) = \Phi_1(k)e^{-ikr_1/2} - \Phi_3(k)e^{-ikr_3/2} + \Phi_2(k)e^{-ikr_2/2}$$

and its Fourier transform

$$\tilde{\phi}(k) = \Phi_1(k)e^{-ikr_1/2} - \Phi_3(k)e^{-ikr_3/2} + \Phi_2(k)e^{-ikr_2/2}$$

where again we used the shorthand notation $c_\eta = \cos(ke_\eta/2)$ and $s_\eta = \sin(ke_\eta/2)$. With three field variables $\delta \rho_\eta(k)$ and two constraints, we expect only one degree of freedom.

As we did for the square lattice, it is convenient not to attempt to resolve the constraint directly but rather consider first the argument of the cosine term in the Hamiltonian

$$\tilde{\phi}(k) = \Phi_1(k)e^{-ikr_1/2} - \Phi_3(k)e^{-ikr_3/2} + \Phi_2(k)e^{-ikr_2/2}$$

(Notice the importance of the factor of $i$ in preserving the condition of Fourier transform of a real field, $\phi^*(k) = \phi(-k)$ due to the antisymmetric behaviour of the sine function.)

Finally, we look for a conjugate field $h(k)$ such that the Berry phase in the path integral can be written as $ih(k)\partial_\tau \phi(-k)$. Namely, we look for $h(k)$ that satisfies

$$h(k)\partial_\tau \phi(-k) = \sum_\eta \delta \rho_\eta(k)\partial_\tau \Phi_\eta(-k).$$  \hspace{1cm} (B12)

Substituting the expression for $\phi(k)$, Eq. (B11), into the
equation above, we obtain
\[\delta \rho_1(k) = -2i(s_2c_3 - s_3c_2) h(k)\]
\[\delta \rho_2(k) = -2i(s_3c_1 - s_1c_3) h(k)\]
\[\delta \rho_3(k) = -2i(s_1c_2 - s_2c_1) h(k).\]  \hspace{1cm} (B13)

One can then straightforwardly verify that the introduction of the field \(h(k)\) automatically resolves the constraints,

\[\sum_{\eta} c_\eta \delta \rho_\eta \propto \left[c_1(s_2c_3 - s_3c_2) + c_2(s_3c_1 - s_1c_3) + c_3(s_1c_2 - s_2c_1)\right] h(k) = 0\]  \hspace{1cm} (B14)

\[\sum_{\eta} s_\eta \delta \rho_\eta \propto \left[s_1(s_2c_3 - s_3c_2) + s_3(s_3c_1 - s_1c_3) + s_3(s_1c_2 - s_2c_1)\right] h(k) = 0.\]  \hspace{1cm} (B15)

We are thus in the position to write the full large-\(S\) action of the system, including both the Berry phase and Hamiltonian contributions, in terms of the fields \(h(k)\) and \(\phi(k)\) only.

In order to obtain the Gaussian field theory for the honeycomb lattice QDM, it is convenient to re-write \(\cos(\phi) = 1 - [1 - \cos(\phi)]\) and notice that the term in square brackets contains only quadratic and higher order contributions. Correspondingly, when can write (symbolically)

\[\sqrt{pppppp} \cos(\phi) = \sqrt{pppppp} - \frac{s^2}{27} [1 - \cos(\phi)],\]  \hspace{1cm} (B16)

and focus on expanding to second order the first term on the right hand side, as well as the \(\rho pp (V)\) terms in the Hamiltonian in Eq. [5.1]. Linear terms in \(\delta \rho_\eta (r + e_\eta)/2\) vanish upon summing over \(r\) because of the dimer constraint. After quite some algebraic manipulations, one arrives at the following contributions to quadratic order:

\[
\frac{JS}{3} \left\{ \delta \rho_1(k) \delta \rho_1(-k) s^2_{23} + \delta \rho_2(k) \delta \rho_2(-k) s^2_{31} + \delta \rho_3(k) \delta \rho_3(-k) s^2_{12} \right\},
\]

\[
- \frac{JS}{3} \left\{ \left[ \delta \rho_1(k) \delta \rho_2(-k) + \delta \rho_2(k) \delta \rho_1(-k) \right] c_{23} c_{31} + \left[ \delta \rho_2(k) \delta \rho_3(-k) + \delta \rho_3(k) \delta \rho_2(-k) \right] c_{31} c_{12} + \left[ \delta \rho_3(k) \delta \rho_1(-k) + \delta \rho_1(k) \delta \rho_3(-k) \right] c_{12} c_{23} \right\},
\]

\[
+ \frac{VS}{3} \left\{ \left[ \delta \rho_1(k) \delta \rho_2(-k) + \delta \rho_2(k) \delta \rho_1(-k) \right] \left( c_{23} c_{31} + s_{23} s_{31} \right) + \left[ \delta \rho_2(k) \delta \rho_3(-k) + \delta \rho_3(k) \delta \rho_2(-k) \right] \left( c_{31} c_{12} + s_{31} s_{12} \right) + \left[ \delta \rho_3(k) \delta \rho_1(-k) + \delta \rho_1(k) \delta \rho_3(-k) \right] \left( c_{12} c_{23} + s_{12} s_{23} \right) \right\},
\]

where we introduced

\[s_{\mu\nu} = \sin[k(e_\mu - e_\nu)/2] = s_\mu c_\nu - s_\nu c_\mu\]

\[c_{\mu\nu} = \cos[k(e_\mu - e_\nu)/2] = c_\mu c_\nu + s_\mu s_\nu\]  \hspace{1cm} (B18)

for convenience. Substituting the expressions \[B13\] of \(\delta \rho_\eta(k)\) in terms of \(h(k)\), and ignoring trivial constants, we obtain the action given in Eq. [5.4] in Sec. \[Y\].

**Appendix C: Details of the calculation for the diamond lattice**

The interaction matrix \(D_{\mu\nu}\) can be obtained in much the same way as for the honeycomb lattice, see App. \[B\]. For plaquettes in the \(\mu = 1, 2, 3\) sublattice, we obtain the contribution

\[
J = \begin{pmatrix}
\frac{1}{2} s_{23}^2 + s_{34}^2 + s_{43}^2 & -(c_{12} c_{23} + c_{14} c_{24}) & -(c_{12} c_{32} + c_{14} c_{34}) & -(c_{12} c_{42} + c_{13} c_{43}) \\
-(c_{23} c_{14} + c_{24} c_{31}) & \frac{1}{2} s_{34}^2 + s_{41}^2 + s_{13}^2 & -(c_{21} c_{31} + c_{24} c_{34}) & -(c_{21} c_{41} + c_{23} c_{43}) \\
-(c_{23} c_{14} + c_{24} c_{31}) & -(c_{31} c_{23} + c_{34} c_{24}) & \frac{1}{2} s_{41}^2 + s_{12}^2 + s_{24}^2 & -(c_{31} c_{41} + c_{32} c_{42}) \\
-(c_{42} c_{12} + c_{43} c_{13}) & -(c_{41} c_{21} + c_{43} c_{23}) & -(c_{41} c_{31} + c_{42} c_{32}) & \frac{1}{2} s_{12}^2 + s_{23}^2 + s_{31}^2
\end{pmatrix}
\]

\[
D = \frac{JS}{2} J + \frac{VS}{2} V
\]

\[
J = \begin{pmatrix}
\frac{1}{2} s_{23}^2 + s_{34}^2 + s_{43}^2 & -(c_{12} c_{23} + c_{14} c_{24}) & -(c_{12} c_{32} + c_{14} c_{34}) & -(c_{12} c_{42} + c_{13} c_{43}) \\
-(c_{23} c_{14} + c_{24} c_{31}) & \frac{1}{2} s_{34}^2 + s_{41}^2 + s_{13}^2 & -(c_{21} c_{31} + c_{24} c_{34}) & -(c_{21} c_{41} + c_{23} c_{43}) \\
-(c_{23} c_{14} + c_{24} c_{31}) & -(c_{31} c_{23} + c_{34} c_{24}) & \frac{1}{2} s_{41}^2 + s_{12}^2 + s_{24}^2 & -(c_{31} c_{41} + c_{32} c_{42}) \\
-(c_{42} c_{12} + c_{43} c_{13}) & -(c_{41} c_{21} + c_{43} c_{23}) & -(c_{41} c_{31} + c_{42} c_{32}) & \frac{1}{2} s_{12}^2 + s_{23}^2 + s_{31}^2
\end{pmatrix}
\]

\[
(C2)
\]

\[
(C3)
\]
We can express the matrices $\mathcal{J}$ and $\mathcal{V}$ more concisely by introducing the matrix $\mathcal{C}$ with entries $c_{\mu\nu}$, the diagonal matrix $\mathcal{R}$ with entries $R_{\mu\nu} = \sum_\mu [k(\epsilon_\mu - \epsilon_\nu)] - 2$, and defining $\Omega = \sum_{\mu<\nu} s_{\mu\nu}^2$:

$$\mathcal{J} = \Omega \mathbb{I} + \mathcal{R} - \mathcal{C}^2 + 2\mathcal{C}$$

$$\mathcal{V} = 2\mathcal{C}^2 - 6\mathcal{C} - \mathcal{R},$$

where $\mathbb{I}$ is the identity matrix.

Ignoring instantons, the middle term of Eq. (C3) can be expanded about a given minimum of the cosine, giving

$$\frac{JS^3}{64} \sum_{\alpha,r} \phi_\alpha^2(r,\tau) = \frac{JS^3}{64} \sum_{\alpha,k} |\phi_\alpha(k,\tau)|^2 =$$

$$\frac{JS^3}{64} \sum_{k,\mu\nu\alpha} Z_{\alpha\mu}(k)Z_{\alpha\nu}(-k)\Phi_\mu(k,\tau)\Phi_\nu(-k,\tau),$$

where $Z_{\mu\nu} = 2i\epsilon_{\mu\lambda\nu\kappa}s_\lambda c_\kappa$, see Eq. (6.3). Defining the matrix

$$\mathcal{M} = \frac{JS^3}{32} Z^T(-k)Z(k) = \frac{JS^3}{32} Z^2,$$

the quadratic action can now be written in the form (6.6).

The dispersion $\omega^2(k)$ is given by the eigenvalues of the matrix $\mathcal{M}D$. It is important to note that $Z_{\mu\nu}c_\nu = Z_{\mu\nu}s_\nu = 0$ by the definition of $Z$. Consequently, $\mathcal{MC} = 0$, which greatly simplifies the form of $\mathcal{M}D$. All in all, one has to diagonalize the matrix

$$\frac{JS^4}{64} [\Omega Z^2 + (J - V)\mathcal{R}Z].$$

It follows from the definition of $Z$ that $c_\mu$ and $s_\mu$ (understood as 4-dimensional vectors) are eigenvectors of this matrix with zero eigenvalue. These correspond to the unphysical modes ruled out by the constraint (6.5).

[26] Curiously, in this case the condition that reduces the three cosine terms to two is the fact that you can decompose a hexagonal cell on the triangular lattice into 6 overlapping plaquettes; the product of the resulting 6 plaquette-flipping operators amounts to the identity. In-
indeed, these 6 plaquettes can be viewed as the 6 faces of a cube projected onto a plane down one of his major diagonals.

[31] Note that, since $1 - \lambda \langle v | K_0^{-1} | v \rangle = 0$ due to the presence of the zero mode, both terms in (A7) are ill-defined. However, both are finite for any other $\lambda$, so we can formally evaluate it elsewhere and take the limit of $\lambda$ going to its physical value. The divergence due to $1 - \lambda \langle v | K_0^{-1} | v \rangle = 0$ cancels, so the correct limit is indeed given by (A8).
