Effect of Feeding Rate on Survival, Zootechnical Performance of Tilapia Oreochromis niloticus (Linnaeus, 1758) Brazil Strain Larvae Fed on 17-α-methyltestosterone Treated Feed

Issa Nahoua Ouattara, Claver Zea Bi Ue, Siaka Berte, and Bakagnan Kamagate

ABSTRACT

This study was conducted to evaluate the feeding levels on survival, growth performance and feed utilization in the Brazil strain of Nile tilapia Oreochromis niloticus. Four (4) batches of larvae with mean initial weight 0.012±0.005 g and mean initial total length 9±0.003 mm were formed in triplicate, three per feeding rate. The rationing rates according to fry biomass applied in this trial were: batch 1: 50, 40, 30 and 25%, batch 2: 40, 30, 25 and 20%, batch 3: 30, 25, 20 and 18% and batch 4: 25, 20, 18 and 15% of biomass. The different feeding rates were tested during the 1st, 2nd, 3rd and 4th week of larval rearing respectively. The fish were all fed a commercial feed (48% protein) distributed manually at a frequency of 5 meals per day. After 28 days of rearing, the results show that apart from the survival rate, the other parameters such as final average weight, daily growth and food consumption index were affected by the different rationing rates tested. The larvae of batch 2 rationed at 40, 30, 25 and 20 % of their biomass during the 1st, 2nd, 3rd and 4th week of rearing respectively recorded significantly higher growth parameters (MWF: 1.092±0.027 g and DG: 0.038±0.000 g) and a more interesting food conversion ratio (0.88) than the other batches of fry. From this study, it is concluded that an optimal feeding rate of 40, 30, 25 and 20% of the larval biomass during the 1st, 2nd, 3rd and 4th week of rearing, respectively, should be applied in order to avoid either wastage or underfeeding of the subjects during hormone treatment with 17 α-methyltestosterone.

Keywords: feeding rate, hormone treatment, Nile tilapia, strain.

I. INTRODUCTION

Aquaculture is considered one of the fastest growing activities in animal production. Freshwater fish accounts for the major part of aquaculture production. Tilapia farming follows the same evolutionary trend worldwide [1]. This evolution owes its success to the different processes of sexual inversion. Indeed, although the process of tilapia sex determination is under genetic control [2], sexual differentiation can be influenced by environmental conditions [3]. This influence can be related to the physicochemical parameter of the water [4] or to the controlled administration of steroid hormones [5]. The most common practice is the incorporation of androgens (30 to 70 mg of 17 α-methyltestosterone/kg) in the feed during the larval rearing phase [6]. Several countries in Africa are already using this approach for good tilapia fry production [7]. However, this method is still in its infancy in Ivory Cost. Yet, according to [8], sex reversal is one of the most important phases in the rational rearing of Nile tilapia. Furthermore, the popularization of this method of sex reversal by hormone requires a certain knowledge of the technical follow-up of the fry, among which the rationing rate. This factor can influence the survival and growth of fry [9]. Indeed, according to [10], the rationing rate plays an important role in the regulation of food intake, faecal discharges as well as the growth of the fish. Moreover, an optimal feed intake not only promotes better zootechnical performance but also reduces the cost of production [11]. According to [12], the feed ration can vary according to several factors such as the size of the fish, its protein requirements and digestion capacity, the quality of the feed and the physicochemical conditions of the environment. Thus, daily rations according to tilapia fry size have been recommended by [13]. However, to our knowledge, no recommendation of daily ration in larval rearing of O.
niloticus during hormonal treatment has been indicated. Furthermore, [14] point out that very few studies report on the zootecchnical performance of *O. niloticus* specimens with an average initial weight of less than 2 g. Thus, this study focused on the determination of optimal feeding rations in fry rearing was carried out in order to fill this scientific gap.

II. MATERIALS AND METHODS

A. Experimental Protocol

The experiments were carried out in a private fish farm, located between latitude 5°40' N and longitude 4°6' W in the sub-prefecture of Azaguie, 25 km from Abidjan (Ivory Cost). For reproduction, 168 broodstock of the Brazilian strain of Nile tilapia, *Oreochromis niloticus* were used. A sex ratio of 2:1 with 56 males (252±16.81 g) for 112 females (114.5±8.58 g) were used in a breeding happa (6×4.7×1 m) set up with Chinese bamboo in a 350 m² pond. The happas are cages made with small mesh polyethylene nets (1 mm empty mesh).

Larvae were harvested every 14 days. Harvesting consisted in narrowing the surface of the breeding happa, in order to group all the larvae produced. The larvae, thus, concentrated on the surface of the water were taken, using a net of 1 mm of mesh with vacuum. Before the recharging of the breeding happa, the females were examined individually, in order to spit out those that still have eggs. The average weight of a larva was determined using samples of three batches of 200 larvae counted with small plastic spoons in plastic bowls. Each batch of larvae was then weighed using a YP 3002 scale with a capacity of 300g and a precision of 0.01g. The biomasses obtained allowed us to determine the average weight of a larva. From this average weight (0.012 g) a biomass of 17 g corresponding to 1500 larvae per happa was established. Thus, four batches of larvae were constituted in triplicate, at a rate of 3 per ration rate. Each batch was put in a happa of 1 m², that is to say 12 happas in total. Each lot corresponds to a density of 1500 larvae / m². All 12 happas were installed in a 300 m² pond. A total of 18,000 larvae with an average initial weight of 0.012±0.005 mg and a total initial length of 9±0.033 mm were used.

B. Rationing Rate and Feeding of Experimental Batches

The trial lasted 28 days and consisted in testing 4 rationing rates according to the biomass of the fry. The different batches constituted according to the rationing are as follows:

- Batch 1: 50, 40, 30 and 25% of biomass, Batch 2: 40, 30, 25 and 20 % of the biomass, Batch 3: 30, 25, 20 and 18% of the biomass, Batch 4: 25, 20, 18 and 15% of biomass.

The different rationing rates were tested during the 1st, 2nd, 3rd and 4th week of rearing, respectively. Each treatment batch was conducted in triplicate. A density of 1500 fry/m² was applied for all treatments. Rations were fed six times per day at the following times 8:00 a.m., 10:00 a.m., 12:00 p.m., 2:00 p.m., 3:00 p.m., and 4:00 p.m. [15] with Raanan feed presented as a 48% protein flour with a diameter of 0.3 to 0.5 mm. The feed was mixed with the hormone at 60 mg 17α-methyltestosterone/kg feed [16].

C. Monitoring of Physico-chemical Parameters of the Rearing Environment

During the experimentation, the physico-chemical parameters were measured in situ three times a week and twice a day, between 6:30 a.m. and 7:00 a.m. and between 3:30 p.m. and 4:00 p.m. in each happa, using a Handy Polaris model OXYGUAR oximeter for dissolved oxygen and temperature, a WTW model pH 330 pH meter for pH, and a Secchi disk of 30 cm diameter for transparency.

D. Calculation and Evaluation of Zootecchnical Parameters

Weekly weight growth checks were conducted on 10 % of the reared population. These controls allowed to adapt the feeding rate to the new biomass obtained. At the end of the 28 days of rearing for each treatment, the biomass of fish from each happa was determined. Then, 30 randomly selected individuals from each treatment were measured for total length and individually weighed to the nearest gram [17].

From the collected data, survival rate (SR), mean weight final (MWF), daily growth (DG), condition factor (K) and Food conversion ratio (FCR) were determined with the following mathematical formulas:

\[
SR(\%) = \frac{\text{Number of fish harvested}}{\text{Number of fish stocked}} \times 100
\]

\[
MWF (g) = \frac{\text{Weight of all fish (g)}}{\text{Number of fish}}
\]

\[
DG (g) = \frac{\text{Average final weight (g) − Average initial weight (g)}}{\text{Rearing time (d)}}
\]

\[
K = \frac{\text{Final weight (g)}}{\text{(Final length)3(cm)}} \times 100
\]

\[
FCR = \frac{\text{Feed intake (g)}}{\text{Fish weight gain (g)}}
\]

E. Statistical Analysis

The results are presented as mean ± standard deviation. The zootecchnical parameters (final weight, average daily gain, specific growth rate, nutrient quotient and condition factor) were subjected to the one-criteria analysis of variance (ANOVA 1). This test was followed by Tukey's multiple comparison test for parameters with a significant difference (p-value < 0.05) in order to identify specific differences between batches taken in pairs. Survival rate was subjected to contingency table analysis. These analyses were performed using STATISTICA 7.1 software.

III. RESULTS

A. Physico-chemical Parameters of the Rearing Environment

The mean values of temperature, pH, dissolved oxygen and transparency are respectively 29.99±0.41 °C; 7.09±0.30; 4.07±0.60 mg/l and 41.51±3.14 cm. The physico-chemical parameters recorded, show that the environments are not significantly (Anova; p-value > 0.05) different.
B. Study of the Rationing Rate of *O. niloticus* larvae during the Treatment Period with 17-a-methyltestosterone (MT)

After 28 days of rearing Nile tilapia *Oreochromis niloticus* fry subjected to different food treatments, the following results were recorded.

Values preceded by ± signs represent standard deviations of triplicates. Values with the same alphabetical letters on the same row of the table are not significantly different at the 0.05 level.

Batch 1 (50, 40, 30, and 25% of biomass); batch 2 (40, 30, 25, and 20% of biomass); batch 3 (30, 25, 20, and 18% of biomass); and batch 4 (25, 20, 18, and 15% of biomass) of fry on the 1st, 2nd, 3rd, and 4th week of feeding, respectively.

### TABLE I: ZOOTECNICAL PARAMETERS OF BRAZIL STRAIN FINGERLINGS OF NILE TILAPIA *OREOCHROMIS NILOTICUS* UNDERGOING MASCULINIZATION AND SUBJECTED TO DIFFERENT FEEDING RATES FOR 28 DAYS

| Parameters                             | Batch 1          | Batch 2          | Batch 3          | Batch 4          |
|----------------------------------------|------------------|------------------|------------------|------------------|
| Average initial weight (g)             | 12 ± 0.5         | 12 ± 0.5         | 12 ± 0.5         | 12 ± 0.5         |
| Survival rate (%)                      | 94.89±1.65       | 91.39±1.22       | 92.23±1.61       | 91.07±6.46       |
| Average final weight (g)               | 0.879±0.116      | 1.092±0.027      | 0.980±0.041      | 0.823±0.132      |
| Daily growth (g/d)                     | 0.030±0.004      | 0.038±0.000      | 0.034±0.001      | 0.028±0.004      |
| Condition factor                       | 1.53±0.01        | 1.58±0.02        | 1.58±0.01        | 1.56±0.03        |
| Food conversion ratio                  | 1.57±0.22        | 0.88±0.02        | 0.9±0.03         | 1.06±0.29        |

1) **Survival rate**

During this experiment, the survival rate ranged from 91.07 to 94.89% for all treatments (Table I). The value of this parameter was higher for batch 1 and lower for batch 4. The survival rate values obtained showed no significant difference (Contingency Table; *p*-value > 0.05) from one rationing rate to another.

2) **Average final weight and daily growth**

At the end of 28 days of feeding, the final average weight and daily growth recorded in fry during treatment (Table I) is 0.879±0.116 g and 0.030±0.004 g/d; 1.092±0.027 g and 0.038±0.000 g/d; 0.980±0.041 g and 0.034±0.001 g/d and 0.823±0.132 g and 0.028±0.004 g/d for batches 1, 2, 3, and 4 respectively. The highest values (1.092±0.027 g and 0.038±0.000 g/d) of these parameters were recorded in batch 2 fed at 40, 30, 25 and 20% of their biomasses respectively in the 1st, 2nd, 3rd and 4th week of rearing. The lowest values (0.823±0.132 g and 0.028±0.004 g/d) were observed in batch 4 fed at 25, 20, 18 and 15 % of their biomass respectively during the 1st, 2nd, 3rd and 4th week of the trial. Comparison of these parameters reveals a significant difference (Anova; *p*-value < 0.05) from one batch to another. Multiple comparison of means (Tukey's LSD test) shows that the final average weight and daily growth of fry in batch 2 differed significantly (*p*-value < 0.05) from those of the other treatment batches.

The variation in mean weight of fry of Brazil strain of Nile tilapia *Oreochromis niloticus* as a function of the batches tested during 28 days of rearing in happa is shown in Fig 1.

Batch 1 (50, 40, 30 and 25% of biomass); batch 2 (40, 30, 25 and 20% of biomass); batch 3 (30, 25, 20 and 18% of biomass) and batch 4 (25, 20, 18 and 15% of biomass) of fingerlings on the 1st, 2nd, 3rd and 4th week of feeding respectively.

1) **Condition factor**

The condition factor (Table I) ranged from 1.53 to 1.58 for all treatments. This parameter varied slightly from batch to batch. The highest condition factor was observed in the fry of lot 3 fed at 30, 25, 20 and 18 % of their biomass in the 1st, 2nd, 3rd and 4th week of rearing respectively. The lowest value of this parameter is recorded in batch 1 fry during the 1st, 2nd, 3rd and 4th week of feeding at 50, 40, 30 and 25% of biomass respectively. The one-way analysis of variance shows no significant difference (*p*-value > 0.05) between the different values of the condition factor obtained for all treatments.

2) **Food conversion ratio**

The food consumption index (Table I) shows values that vary from 0.88 to 1.57 depending on the treatment. The highest value (1.57) of this parameter was obtained in the fry of batch 1, fed at 50, 40, 30 and 25% of their biomass per day during the 1st, 2nd, 3rd and 4th week of rearing monitoring respectively. The lowest value (0.88) was recorded in individuals of batch 2, rationed at 40, 30, 25 and 20% of their biomass per day during the 1st, 2nd, 3rd and 4th week of rearing respectively. The one-factor analysis of variance showed a significant effect (*p*-value < 0.05) of rationing rate on feed intake index. Multiple comparison of means (Tukey's HSD test) showed that batch 1 differed significantly from the other batches (2, 3 and 4).
IV. DISCUSSION

The average values of physico-chemical parameters (temperature, dissolved oxygen, pH and transparency) determined during this study in hapas are within the recommended ranges for rearing Nile tilapia Oreochromis niloticus [18], [19]. Thus, the variation in growth performance and feed conversion rate of individuals in all batches was not affected by abiotic parameters.

The survival rates obtained in this trial ranged from 91.07 to 94.89% and from 83.78 to 87.64%, respectively. The values of this parameter are high and are not affected by the variations of the feeding rate applied in the present study. The highest values of this parameter were recorded in individuals fed with high ration rates. Similar results were reported by [20]. These authors found an improvement in the survival rate of tilapia Oreochromis mossambicus fry with an increase in the level of feeding rate from 6 to 24% of body weight per day. However, the mortalities recorded during the rearing periods could be the result of manipulations during the weekly control fisheries. Overall, the survival rates observed during the two rearing periods were within the normal range (≥75%) for pond culture of Nile tilapia [21]. Regarding the growth parameters (final average weight, daily growth and specific growth rate), the fry of batch 4 (Pni: 0.012 g) fed at 25; 20; 18 and 15% of their biomass/day show the significantly lower growth performance than those obtained in batch 2 fed with the feed rations of 40; 30; 25 and 20% of their biomass/day during the same feeding period. The results of the present study show that growth parameters improved with increasing feeding rates. These results are in agreement with those reported by [22]. Indeed, this author observed an improvement in the growth of Nile tilapia O. niloticus fingerlings with an increase of up to 30% of the feeding rate. Similar results were also reported by [23]. These authors found improved growth of Nile tilapia fingerlings with an increase in the ration rate to 65% of body weight/day. They obtained an optimal ration of 30-45% of biomass per day for Nile tilapia O. niloticus fry. However, [22] reports that increasing the ration rate beyond 30% does not result in any improvement in fish growth. Indeed, an increase in feeding rate generally results in a significant improvement in growth to a level of stability [24]. In the present study, feed rations of 25, 20, 18 and 15% of biomass fed respectively at 1st, 2nd, 3rd and 4th in batch 4 during the rearing period induced the lowest growth. The low growth observed in the fry of batch 4 could be the result of the amount of feed offered by these different ration rates. These rations probably proved to be insufficient to meet the basic dietary requirements of tilapia Oreochromis niloticus fry. Furthermore, beyond the rationing rate of 40; 30; 25 and 20% of biomass per day during the 1st, 2nd, 3rd and 4th week of feeding respectively, no significant improvement in growth was observed in Nile tilapia fry (0.012 g). Thus, fry (0.012 g) astriented at the highest feeding rates of 50; 40; 30 and 25% of body weight/day during the 1st, 2nd, 3rd and 4th week of feeding respectively recorded a decrease in growth performance. This decrease in growth when the food ration exceeds the maximum value, could be explained by a lack of appetite in an environment oversaturated with food [25]. This phenomenon could also be explained by an imbalance between the optimum feeding rate and the stocking density of the fish in the hapas. Indeed, if the stocking density is lower or higher than the optimal density, there is wastage and underfeeding of fish. This leads to poor feed utilization resulting in low feeding efficiency [26]. The rationing rates established during this rearing period show a variation in growth according to the level of rationing. Indeed, according to [27], the efficiency of the transformation of an artificial feed depends on the quality and quantity of the feed consumed. Thus, the results of this study will allow a rational management of the feed for an optimal growth of the fry. However, for [28], in a profit-oriented economic context, a better knowledge of fish rationing allows minimizing or maximizing their growth.

V. CONCLUSION

At the end of this study, it appears that fry growth improves with increasing feeding rate until an optimal level beyond which no growth is observed. These results show that for an improvement of fry production, an optimal feeding rate of 40, 30, 25 and 20 % of the fry biomass during the 1st, 2nd, 3rd and 4th week of rearing respectively should be applied in order to avoid either wastage or underfeeding of the subjects during hormone treatment.
