Abstract: The effects of elevated CO$_2$ (700 ppm) and O$_3$ (80 ppb) alone and in combination on the photosynthetic efficiency of canola and wheat plants were investigated in open-top chambers (OTCs). The plants were fumigated for four weeks under well-watered and water-stressed (water deficit) conditions. The fast chlorophyll $a$ fluorescence transients were measured after 2 and 4 weeks of fumigation, as well as in control plants, and analyzed by the JIP-test, which is a non-destructive, non-invasive, informative, very fast and inexpensive technique used to evaluate the changes in photosynthetic efficiency. Biomass measurements were taken only after 4 weeks of fumigation. The performance index (PI$_{\text{total}}$), an overall parameter calculated from the JIP-test formulae, was reduced by elevated CO$_2$ and O$_3$ under well-watered conditions. In the absence of any other treatment, water stress caused a decrease of the PI$_{\text{total}}$, and it was partly eliminated by fumigation with elevated CO$_2$ and CO$_2$ + O$_3$. This finding was also supported by the biomass results, which revealed a higher biomass under elevated CO$_2$ and CO$_2$ + O$_3$. The decrease in biomass induced by elevated O$_3$ was likely caused by the decline of photosynthetic efficiency. Our findings suggest that elevated CO$_2$ reduces the drought effect both in the absence and presence of O$_3$ in canola and wheat plants. The study also indicates that elevated O$_3$ would pose a threat in future to agricultural crops.

1. Introduction

The concentrations of carbon dioxide (CO$_2$) and ozone (O$_3$) are increasing at a steady rate in the atmosphere [1,2]. The increasing CO$_2$ trend is mostly caused by the use of fossil fuels for combustion [2]. It is projected that CO$_2$ concentration will rise to about 550 ppm by 2050 [3]. Elevated CO$_2$ stimulates plant growth and development but elevated O$_3$ often has the opposite effect [4,5]. Ozone causes considerable damage in agricultural crops, which includes visible injury, reduced photosynthetic capacity, modifications to carbon allocation and reduced yield quantity and quality [6,7]. Prolonged exposure to O$_3$ levels above 40 ppb decreases crop yields due to reduced photosynthesis and disruption of metabolism [8]. These findings suggest that agricultural crops in southern Africa may be at risk because of elevated O$_3$ levels [9]. The seasonal variation of O$_3$ indicates the highest O$_3$ concentrations in spring and winter and the lowest in summer [10]. The maximum O$_3$ concentrations in this region are between 40–60 ppb and can rise to more than 90 ppb in the spring season [11]. What is of concern is how these changes will interact with one another and influence plant growth, as well as the interaction of these gasses with other factors of climate change, such as droughts.
Climate change will have effects on agriculture and food security [12]. Agriculture plays a vital role in the economy of developing countries. Subsistence farmers in the southern Africa region depend on staple crops for income generation. Commercial farmers will also be affected by climate change, which could affect food security on a local and global scale. The effect of elevated CO₂ and O₃ on important crops (and vegetation) has received a lot of attention in Europe and North America. To be specific, studies that relate to the effect of elevated CO₂ in combination with O₃ and droughts are very limited in southern Africa. As a result, the findings of developed countries have been extrapolated in developing countries [7], but given differences in climatic conditions, these results may not represent the local conditions. Plants grown under elevated CO₂ have been shown to alleviate the effects of drought stress [13,14], due to CO₂-induced increases in stomatal resistance. Moreover, elevated CO₂ is understood to alleviate the harmful effects of O₃ by reducing stomatal conductance and thus reducing O₃ uptake and the potential for oxidant damage [15]. The combined effects of O₃ with elevated CO₂ and droughts are important but not well understood. In fact, there has been little consideration on how the different components of global climate change, such as O₃, CO₂, temperature and weather extremes, might combine and interact to influence the agricultural sector [7].

Photosynthesis is regarded as a reliable measure of the overall performance in plants [16]. It is one of the important processes to be affected by abiotic stress, such as elevated O₃ and droughts, which cause a decline in CO₂ diffusion to the chloroplast and metabolic constraints [17]. Drought stress gradually decreases CO₂ assimilation rates because of reduced stomatal conductance [18]. Stomatal closure is the initial response to droughts and the main limitation of photosynthesis at mild to moderate drought stress [19]. At a time of severe drought, the inhibition of metabolic process induces reduction in the contents of ribulose bisphosphate, which becomes the main limitation and thus inhibits photosynthetic CO₂ assimilation [19]. In addition, drought stress enhances the generation of active oxygen species and antioxidant defenses [18]. In a meta-analysis of photosynthesis and drought, Pinheiro and Chaves [20] indicated the interaction of sugars, reactive oxygen species and hormones with photosynthetic responses to droughts. Furthermore, Zivcak et al. [21] showed that under drought stress conditions there is a complex interconnected and regulated photoprotective response.

In order to study the effects of elevated CO₂ and O₃ on the photosynthetic apparatus of canola and wheat plants, the chlorophyll (Chl) a fluorescence transients OJIP (a non-destructive, simple and rapid technique for sensing stress) was applied. Analysis of the OJIP transients by the JIP-test provides significant information about the structure and function of the photosynthetic apparatus [22–24]. The parameters calculated by the JIP-test and the shape of the transients have been found to be very sensitive to stress caused by environmental conditions, such as light intensity, temperature, drought, flooding, atmospheric CO₂ or elevated O₃ and chemical influences [25–29]. Therefore, it was hypothesized that elevated CO₂ reduces the water stress (water deficit) effect both in the absence and presence of O₃ in canola and wheat crops. The hypothesis was tested by exposing canola and wheat plants to elevated levels of CO₂, O₃ and the combination of these two gases in open-top chambers (OTCs) under well-watered and water-stressed (water deficit) conditions to quantify the biophysical and physiological responses. The objective was to understand how locally cultivated canola and wheat plants respond to elevated CO₂ and O₃ and if these environmental factors will interact with each other under well-watered and water-stressed conditions.

2. Results

2.1. Photosynthetic Responses of Canola to Elevated Levels of CO₂ and O₃

The averages of the raw fluorescence transients of canola leaves were plotted on a logarithmic time scale from 20 μs to 1 s and the values are expressed as F₀/F₀ (Figure 1). The steps O, J, I and P are indicated. In order to reveal hidden differences, the fluorescence data were normalized between O (20 μs) and K (300 μs) steps, as V_OK = (F₀ – F₀)/(F_K – F₀), and plotted as difference kinetics ΔV_OK = V_OK(treatment) – V_OK(control). Also, fluorescence data were normalized between the steps O
and J (2 ms), as $\Delta V_{OJ} = (F_t - F_0)/(F_I - F_0)$, and plotted as difference kinetics $\Delta V_{OJ} = V_{OJ(\text{treatment})} - V_{OJ(\text{control})}$. These allowed the visualization of the positive $\Delta L$ (0.15 ms) and $\Delta K$-band (0.3 ms) in the $O_3$ treatment (Figure 2). The appearance of $\Delta L$ and $\Delta K$-band is regarded as a good indicator to detect the physiological disturbances of plants caused by environmental conditions [30].

**Figure 1.** Average (of all weeks) chlorophyll (Chl) a fluorescence transients of canola leaves exposed to elevated CO$_2$, O$_3$ and CO$_2$ + O$_3$ under well-watered (A) and water-stressed conditions (B).

**Figure 2.** Effect of elevated CO$_2$, O$_3$ and the combination of CO$_2$ and O$_3$ on differential plots of relative chlorophyll a fluorescence ($\Delta V_i$) under well-watered (B,D) and water-stressed conditions (A,C) in leaves of canola. The data represent the average of all weeks. (A,B), $\Delta V_{OK} = V_{OK(\text{treatment})} - V_{OK(\text{control})}$; (C,D), $\Delta V_{OJ} = V_{OJ(\text{treatment})} - V_{OJ(\text{control})}$. 

\[ V_{OK} = \frac{(F_t - F_0)}{(F_I - F_0)} \]
Canola plants fumigated with elevated CO₂ and O₃ caused the decline of the PIₜotal when subjected to well-watered conditions (Figure 3). However, in water-stressed plants, no significant difference was found when compared with the control. The combination of elevated CO₂ and O₃ had higher PIₜotal values under both water regimes (Figure 3).

![Figure 3. Average (of all weeks) PIₜotal of canola plants exposed to CO₂, O₃ and CO₂ + O₃ under well-watered and water-stressed conditions for four weeks. For the same water treatment, different letters show statistically significant differences (p < 0.05).](image)

The PIₜotal is an overall parameter calculated from the JIP-test that combines biophysical parameters. The parameters are the density of reaction centers (RC/ABS); the parameter (ψₚ₀ / (1 − ψₚ₀)), where ψₚ₀ represents the maximum quantum yield of primary photochemistry; the parameter (ψₑₒ / (1 − ψₑₒ)), where ψₑₒ represents the efficiency with which an electron moves into the electron transport chain further than QA; the parameter (δᵣₒ / (1 − δᵣₒ)), where δᵣₒ represents the efficiency with which an electron from the intersystem electron carriers is transferred to reduce end electron acceptors at the PSI (Photosystem I) acceptor side. The statistical analysis of the effect of elevated CO₂, O₃ and CO₂ + O₃ on the components of the PIₜotal in canola leaves is shown in Table 1.

Plants in the O₃ treatment enhanced the parameter ψₑₒ / (1 − ψₑₒ) under both water regimes, while the parameter δᵣₒ / (1 − δᵣₒ) was reduced. The combination of CO₂ and O₃ improved the parameter δᵣₒ / (1 − δᵣₒ) when subjected to well-watered and water-stressed conditions (Table 1).

Elevated CO₂ and the combination of CO₂ and O₃ had no significant effect on the above ground biomass of well-watered plants. However, canola plants exposed to O₃ (80 ppb) caused a significant reduction in biomass under well-watered conditions (Figure 4). In water-stressed plants, none of the
treatments had a significant effect on biomass production, but based on average values, elevated CO$_2$ and the combination of CO$_2$ and O$_3$ led to a higher biomass than the control (Figure 4).

Figure 4. Biomass of canola exposed to CO$_2$, O$_3$ and CO$_2$ + O$_3$ under well-watered and water-stressed conditions after four weeks. For the same treatment, different letters show statistically significant differences ($p < 0.05$).

The radar plot indicates that the decline of PI$_{total}$ in well-watered canola plants exposed to elevated O$_3$ was caused by the parameter $\delta_{Ro}/(1 - \delta_{Ro})$ (Figure 5). This drop was linked to the decrease of biomass accumulation. The higher PI$_{total}$ in canola plants fumigated with a combination of CO$_2$ and O$_3$ was sustained by the parameter, $\delta_{Ro}/(1 - \delta_{Ro})$.

Figure 5. Radar plot of selected biophysical parameters (PI$_{total}$, RC/ABS, $\varphi_{Po}/(1 - \varphi_{Po})$, $\psi_{Eo}/(1 - \psi_{Eo})$, $\delta_{Ro}/(1 - \delta_{Ro})$) and biomass for canola. Values were normalized on those of the control, which is presented by the regular hexagon for well-watered (A) and water-stressed (B) plants.
2.2. Photosynthetic Responses of Wheat to Elevated Levels of CO\(_2\) and O\(_3\)

The average Chl \(a\) fluorescence transient of dark-adapted wheat leaves for the four treatments under well-watered (Figure 6A) and water-stressed (Figure 6B) conditions were plotted on a logarithmic time scale, 20 µs to 1 s and expressed as \(F_t/F_0\) for clarity. The four transients showed a typical OJIP shape, with small differences between them. In order to show the hidden differences, the fluorescence data were normalized between O (20 µs) and K (300 µs) steps, as \(V_{OK} = (F_1 - F_0)/(F_K - F_0)\), and plotted as difference kinetics \(\Delta V_{OK} = V_{OK(treatment)} - V_{OK(control)}\), which revealed the \(\Delta L\)-band. A positive \(\Delta L\)-band indicates lower energetic connectivity while a negative \(\Delta L\)-band indicates higher energetic connectivity [31]. Furthermore, the fluorescence data were normalized between the steps O and J (2 ms), as \(V_{OJ} = (F_1 - F_0)/(F_J - F_0)\), and plotted as difference kinetics \(\Delta V_{OJ} = V_{OJ(treatment)} - V_{OJ(control)}\) revealing the \(\Delta K\)-band.

![Figure 6. Average (of all weeks) Chl \(a\) fluorescence transients of dark-adapted wheat leaves exposed to elevated CO\(_2\), O\(_3\) and CO\(_2\)+O\(_3\) under well-watered (A) and water-stressed (B) conditions.](image)

A positive \(\Delta K\)-band shows an increased reduction rate of quinone (Q\(_A\)), from Q\(_A\) to Q\(_A^-\), which suggests that the oxygen evolving complex (OEC) may have become leaky and offers access to non-water electron donors [32]. Positive \(\Delta L\)- and \(\Delta K\)-bands in the O\(_3\) treatment were revealed clearly under both water regimes (Figure 7).

Elevated CO\(_2\) resulted in a significant decrease of the total performance index (PI\(_{total}\)) in wheat plants subjected to well-watered conditions (Figure 6). However, no significant difference was found in water-stressed plants exposed to elevated CO\(_2\). Ozone fumigation led to a significant decline in PI\(_{total}\) under both water regimes. The combination of elevated CO\(_2\) and O\(_3\) did not affect the photosynthetic performance (based on the PI\(_{total}\)) of well-watered wheat plants. However, in water-stressed wheat plants, the PI\(_{total}\) increased significantly by 9%, compared with the non-fumigated plants (Figure 8).
Figure 7. The effect of elevated CO2, O3 and CO2 +O3 on differential plots of relative Chl a fluorescence ($\Delta V_t$) under well-watered (A,C) and water-stressed conditions (B,D) in leaves of wheat. The data represent the average of all weeks. (A,B), $\Delta V_{OK} = V_{OK\ (treatment)} - V_{OK\ (control)}$; (C,D), $\Delta V_{Oj} = V_{Oj\ (treatment)} - V_{Oj\ (control)}$.

Figure 8. Average (of all weeks) PI total of wheat plants exposed to CO2, O3 and CO2+O3 under well-watered and water-stressed conditions for four weeks. For the same water treatment, the different letters show statistically significant differences ($p < 0.05$).
The statistical analysis of the effect of elevated CO\textsubscript{2}, O\textsubscript{3} and CO\textsubscript{2} + O\textsubscript{3} on these parameters under well-watered and water-stressed conditions is presented in Table 2. We note that fumigation on wheat plants had a significant effect on the components of the PI\textsubscript{total} with the exception of the parameter (\(\psi_{E0}/(1 - \psi_{E0})\)) in well-watered plants. Elevated CO\textsubscript{2} and O\textsubscript{3} caused a significant decline in the density of reaction centers and the parameter \(\delta_{Ro}/(1 - \delta_{Ro})\) (Table 2). The combination of CO\textsubscript{2} and O\textsubscript{3} enhanced the density of reaction centers under both water regimes.

**Table 2.** The effect of elevated CO\textsubscript{2}, O\textsubscript{3} and CO\textsubscript{2} + O\textsubscript{3} on the components of the PI\textsubscript{total} in wheat plants under well-watered and water-stressed conditions. Values are means of weeks and SE. Different letters in the same row indicate statistically significant differences between the treatments (\(p < 0.05\)).

Ozone fumigation caused a reduction in biomass of wheat plants when subjected to well-watered and water-stressed conditions. Compared with the control, biomass was reduced by about 40% under well-watered and 22% under water-stressed conditions (Figure 9). In water-stressed plants, fumigation did not have any significant effect on biomass. However, based on average values the plants exposed to elevated CO\textsubscript{2} and CO\textsubscript{2} + O\textsubscript{3}, treatments had a higher biomass compared with the control (Figure 9).

![Figure 9. Biomass of wheat exposed to CO\textsubscript{2}, O\textsubscript{3} and CO\textsubscript{2}+O\textsubscript{3} under well-watered and water-stressed conditions after four weeks. For the same water treatment, the different letters show statistically significant differences (\(p < 0.05\)).](image)

The radar plot of the PI\textsubscript{total} and its components and biomass is presented in Figure 10. As shown, the reduction in biomass of ozone-treated plants is related to the decrease of the PI\textsubscript{total}. On the other hand, the biomass enhancement in water-stressed wheat plants exposed to the combined effect of elevated CO\textsubscript{2} and O\textsubscript{3} is well associated with the increase in PI\textsubscript{total}. We noted that the PI\textsubscript{total} was generally influenced by the density of reaction centers and efficiency, with which an electron from the
intersystem electron carriers is transferred to reduce end electron acceptors at the PSI acceptor side (Figure 10).

3. Discussion

Elevated CO$_2$ increases the photosynthetic performance of plants, which in turn results in higher biomass production [33,34], but often declines with time when plants are subjected to elevated CO$_2$ over extended periods [33]. Prolonged exposure of plants to elevated CO$_2$ reduces the initial stimulation of photosynthesis [35] and as a result suppresses photosynthesis, which reduces growth responses [36]. It has been suggested that crop plants subjected to reduced water will respond positively to elevated CO$_2$ in comparison to crop plants under sufficient water supply, as CO$_2$ causes an increase in stomatal resistance [5]. We found that plants fumigated with elevated CO$_2$ resulted in a decline of the photosynthetic performance (as revealed by the $P_{\text{Itotal}}$) under well-watered conditions for more than four weeks. The decrease in the $P_{\text{Itotal}}$ under well-watered conditions was mainly influenced by the density of reaction centers and efficiency with which an electron from the intersystem electron carriers is transferred to reduce end electron acceptors at the PSI acceptor side ($\delta R_0$). A low I-P amplitude may indicate a low capacity of electron transport through PSI. It was shown that the activity of PSI can limit photosynthetic electron transport through PSI, and that PSI can be limiting for CO$_2$ assimilation [37,38], which can be especially important under elevated CO$_2$ [39]. Liu et al. [40] reported that elevated

![Figure 10. The radar plot of selected biophysical parameters ($P_{\text{Itotal}}$, RC/ABS, $\psi_{\text{Pp}}/(1 - \varphi_{\text{Pp}})$, $\psi_{\text{Pp}}/(1 - \varphi_{\text{Pp}})$, $\delta R_0/(1 - \delta R_0)$) and biomass of wheat. Values were normalized on those of the control, which is shown by the regular hexagon for well-watered (A) and water-stressed (B) plants. For the JIP-test parameters, the data represent the average of all weeks.](image-url)
CO₂ enhanced the photosynthetic performance of cucumber plants under moderate drought stress. We found that none of the water-stressed plants were affected by elevated CO₂, but on average the \( \Phi_{\text{tota}l} \) values were higher than those of the control. The \( \Phi_{\text{tota}l} \) values were well-maintained by an increase of the parameter \( \delta_{\text{Ro}} \), indicating an increased capacity to reduce end acceptors beyond PSI. The increase of the I-P amplitude was shown to be associated also with an increase of capacity in alternative electron transport pathways [41]. In addition, above ground biomass in both crops was not significantly affected by elevated CO₂ when subjected to well-watered and water-stressed conditions. However, previous studies reported that elevated CO₂ significantly increased biomass in canola and wheat plants [42–44]. The difference can be attributed to the decline in the photosynthetic capacity of the plants, as indicated by the \( \Phi_{\text{tota}l} \), and that the response of crops to elevated CO₂ varies between genotypes [5]. Even though there was no significant difference in the water-stressed plants, the CO₂ treatment enhanced the biomass of both crops. The biomass stimulation caused by elevated CO₂ can also result from reduced water loss and water stress, and/or from decreased respiration [45]. The greater biomass in dry conditions in response to elevated CO₂ has been discussed by Fitzgerald et al. [46]. It should be noted that the beneficial effect of elevated CO₂ in plants subjected to water-stress not only increases biomass production, but also translates into higher crop yield [14,47]. Elevated CO₂ stimulated yield of water-stressed wheat plants (data not shown). Our results suggest that elevated CO₂ concentrations may counteract the negative effect of droughts on canola and wheat. Therefore, it appears that canola and wheat crops grown in limited water availability will benefit more from elevated CO₂.

The appearance of the positive \( \Delta L \) and \( \Delta K \)-bands indicates that both crops are more sensitive to elevated O₃ with reference to lower energetic connectivity and inactivation of the OEC, respectively [26,31,48]. Similar findings were reported by Desotgiu et al. [49] in poplar plants subjected to O₃ and water stress. The amplitude of the \( \Delta K \)-band was higher in the well-watered plants when compared with the water-stressed plants. This suggests that limited water availability can reduce inactivation of the OEC. The OEC represents one of the sensitive components of the PSII (Photosystem II) [50,51]. Furthermore, the appearance of the K-band revealed that elevated O₃ upset the functioning of OEC in the PSII [52]. The transients were further analyzed with the JIP-test equations, which led to the calculation of several photosynthetic parameters and the \( \Phi_{\text{tota}l} \). In the present experiment, both crop species—canola and wheat—showed a tendency to reduce the \( \Phi_{\text{tota}l} \) in the O₃ treatment (80 ppb) particularly under well-watered conditions. Under drought conditions, the decrease was significant only in wheat plants. This indicates that the effect of O₃ was minor under drought conditions in canola plants [53]. The reduction of the \( \Phi_{\text{tota}l} \) was caused by the efficiency with which an electron from the intersystem electron carriers was transferred to reduce end electron acceptors at the PSI acceptor side, as well as the decline of the density of reaction centers, which, taking into account that \( \delta_{\text{Ro}} \) remained nearly unchanged, represented an increase of the functional PSII antenna size [26]. The efficiency that an electron moves further than \( Q_{A} \) is relatively less affected by elevated O₃ in both plants. Although a temporarily enhanced \( \psi_{\text{Eo}} \) was detected in canola plants, it did not influence the \( \Phi_{\text{tota}l} \). The increased efficiency was linked to the activating of repair processes, but when it was linked to a reduced end acceptor capacity in combination with a reduced Calvin cycle, energy demand led to over-excitation of the photosynthetic apparatus [27]. These results support the findings obtained from other studies that the I-P region (as revealed by the relevant parameters) is sensitive to stress caused by O₃ [27,54]. The biomass was significantly affected by O₃ fumigation in both crop plants under well-watered conditions. There was no significant difference under water-stressed treatment, but based on average values, the biomass was reduced in O₃ treatment. In the experiment, where fumigation with 60 ppb of O₃ was applied in canola, the biomass was barely affected [43], and similar findings were reported in a study using four canola cultivars [44]. On the contrary, Feng et al. [55] found that elevated O₃ decreased above ground biomass by 18%. The response to O₃ achieved in the present study can be interpreted by the higher than 60 ppb concentration applied, and to cultivar differences [56]. Similarly, only two out of five wheat cultivars showed a decrease in above ground...
biomass when subjected to O$_3$ [57]. Based on the radar, it was suggested that the drop in biomass production was associated with the decline of the PI$_{\text{total}}$ [58,59].

The $\Delta$L-band exhibited differences in energetic connectivity among the PSII units [26]. The energetic connectivity among PSII units improved in the CO$_2$ + O$_3$ treatment under water-stressed conditions. This was demonstrated by the appearance of the negative $\Delta$L-band, which indicated higher energetic connectivity. A higher energetic connectivity resulted in an improved use of the excitation energy and the stability of photosynthetic systems. Furthermore, the appearance of the negative $\Delta$K-band under water stress showed that plants fumigated with elevated CO$_2$ + O$_3$ have either a more active oxygen evolving system or a smaller PSII antenna size [60]. As shown by the PI$_{\text{total}}$, fumigation with elevated CO$_2$ + O$_3$ increased the photosynthetic efficiency of canola plants under both well-watered and water-stressed conditions. In wheat plants, the increase was significant only under water-stressed conditions. The increase in the PI$_{\text{total}}$ was mostly caused by the parameter $\delta_{\text{Ro}}$. The combinations of CO$_2$ and O$_3$ did not reveal any significant reductions in biomass. This suggests that elevated CO$_2$ can ameliorate the detrimental effects of elevated O$_3$ and droughts upon canola and wheat. In addition, the photosynthetic process was not compromised as a result of the combined effects of elevated CO$_2$ and O$_3$. The increase in photosynthetic performance (as revealed by the JIP-test parameters) was associated with the increase in biomass production. This indicates that biomass enhancement was most probably caused by the increase in photosynthetic efficiency of the plants.

4. Materials and Methods

4.1. Experimental Site and Plant Materials

The experiments were conducted in Open-Top Chambers situated at the North-West University, South Africa. The canola and wheat experiments were performed from June to August in 2014 and 2015, respectively. Heyneke et al. [61] has discussed the design and operation of the OTCs system used in the current study. Canola (Brassica napus L. cv. Rainbow) and wheat (Triticum aestivum L. cv. SST875) seeds were sown in pots with a diameter of about 30 cm. The pots were watered manually prior to the start of fumigation with elevated CO$_2$ and O$_3$ to ensure that the seeds germinated successfully. Six-month slow release fertilizer (25 g) was added to each pot comprising 17 nitrogen:11 phosphorus:10 potassium:2 magnesium oxide:TE (Osmocote Pro, The Netherlands). The growth medium was composed of topsoil, river sand and vermiculite (2:1:1). The pots were placed into eight OTCs. Two chambers were used per treatment. The treatments were the control (carbon filtered air, OTC 1 and 2); CO$_2$ (700 ppm, OTC 3 and 4); O$_3$ (80 ppb, OTC 5 and 6) and CO$_2$ + O$_3$ (700 ppm + 80 ppb, OTC 7 and 8). The carbon filtered air was used only for the control treatment, from which O$_3$ and other pollutants were removed.

4.2. Fumigation and Water Treatment

Plants were exposed to elevated CO$_2$ (700 ppm) and O$_3$ (80 ppb) and the combination of these two gases (CO$_2$ + O$_3$) from 08:00am to 17:00pm for 4 weeks. Elevated CO$_2$ levels inside the OTCs were monitored with a CO$_2$ monitor (Model 174687 CO$_2$ temp-relative-humidity monitor, Scientific Associates, Inc., China). Ozone levels were continuously monitored using an O$_3$ monitor (Model 205 Ozone Monitor, 2B Technologies, Inc., USA). The temperatures varied between 23 °C and 17 °C during the fumigation period. The ambient ozone levels were below 35 ppb over the entire fumigation period.

The plants were exposed to two water regimes, namely water-watered and water-stressed (water deficit) conditions. All the plants absorbed water through glass fiber wicks that were projected into water reservoirs. In the well-watered treatment, four wicks were placed at four levels within the pots, while in the water-stressed treatment, one glass fiber wick was positioned at the middle level of each
pot [43]. The pots were positioned into reservoirs that were connected to a drip irrigation system that filled up the water.

4.3. Chlorophyll a Fluorescence

The fast chlorophyll a fluorescence transients were measured with a Handy PEA (Plant Efficiency Analyser) fluorimeter (Hansatech Instruments Ltd, UK) on the leaves of canola and wheat. Before measurements were taken, the leaves were dark-adapted for an hour. The OJIP transients were induced by red light (peak at 650 nm) of 3000 µmol photons m⁻² s⁻¹ provided by an array of three light-emitting diodes and recorded for 1 s with 12 bit resolution. The data acquisition occurred at every 10 µs, from 10 µs to 0.3 ms; every 0.1 ms, from 0.3 to 3 ms; every 1 ms, from 3 to 30 ms; every 10 ms, from 30 to 300 ms and every 100 ms, from 300 ms to 1 s. The OJIP transients were analyzed by the JIP-test [19,50] using the PEA Plus ver. 1.10 Program (Hansatech Instruments Ltd, UK). The following fluorescence data from the original measurements were used by the JIP-test: the minimal intensity at 20 µs (O step); the intensities at 50 and 300 µs (F₃₀₀ and F₅₀) used for calculation of the initial slope (M₀); the intensity at 2 ms (I step); the intensity at 30 ms (I step) and the maximal measured intensity when all PSII reaction centers (RCs) were closed (Fₐ, P step). The following JIP-test parameters were derived from the OJIP transients, all referring to time zero (onset of fluorescence induction): the maximum quantum yield of primary photochemistry, \( \eta_{\text{Po}} = TR_0/\text{ABS} = [1 - (F_0/F_M)] \); the efficiency/probability that an electron moves further than \( Q_A^- \) into the electron transport chain, \( \psi_{E_0} = \text{ET}_0/\text{TR}_0 = (1 - V_I) \); the efficiency/probability with which an electron from the intersystem electron carriers is transferred to reduce end electron acceptors at the PSI acceptor side (RE), \( \delta_{\text{Ro}} = \text{RE}_0/\text{ET}_0 = (1 - V_I)/(1 - V_J) \); the density of reaction centers, \( \text{RC}/\text{ABS} = \gamma_{\text{RC}}/(1 - \gamma_{\text{RC}}) = \eta_{\text{Po}} (V_J/M_0) \) and the total performance index \( (\text{PI}_{\text{total}}) = [\gamma_{\text{RC}}/(1 - \gamma_{\text{RC}}), \eta_{\text{Po}}/(1 - \eta_{\text{Po}}), \psi_{E_0}/(1 - \psi_{E_0}), \delta_{\text{Ro}}/(1 - \delta_{\text{Ro}})] \), an index (potential) for energy conservation from excitons to the reduction of PSI end-electron acceptors.

4.4. Biomass

Plants were harvested after four weeks and the fresh plant material was oven-dried at 60 °C for 72 h and weighed.

4.5. Statistical Analysis

Statistical analysis were carried out with STATISTICA 13 (Stat Soft. Inc., Tulsa, OK, USA).

The data were analyzed using one-way analysis of variance (ANOVA) and significant differences between treatment means were determined by the Tukey’s honest significant difference (HSD) post-hoc test.

5. Conclusions

In conclusion, elevated O₃ led to a decrease in biomass of canola and wheat plants. This reduction was caused by a decline in the photosynthetic efficiency as revealed by the total performance index \( (\text{PI}_{\text{total}}) \). The results of the current study indicate that elevated O₃ would pose a threat in the future to agricultural crops. The decline in the \( \text{PI}_{\text{total}} \) was mostly influenced by the efficiency with which an electron from the intersystem electron carriers was transferred to reduce end electron acceptors at the PSI acceptor side. The present study also suggests that the PSII was damaged and the photosynthetic apparatus was compromised due to elevated O₃. Elevated CO₂ reduces the drought effect both in the absence and presence of O₃. This was also supported by above ground biomass results, which showed higher values under elevated CO₂. Our findings suggest that elevated CO₂ can reduce the negative effect of abiotic stress, such as droughts and O₃ in canola and wheat plants. The measurement of Chl a fluorescence can be used to screen the effect of elevated CO₂ and O₃ in canola and wheat plants cultivated locally. Further studies should seek to investigate several local varieties of canola and wheat responses to elevated CO₂, O₃ and droughts and their interaction.
Author Contributions: J.M.B. and P.M.I. were leaders of the project. All authors were responsible for experimental and project design.

Funding: This study was supported by the Cuomo Foundation, through the partnership with the Intergovernmental Panel on Climate Change (IPCC) scholarship programme and the Applied Centre for Climate and Earth Systems Science (ACCESS).

Conflicts of Interest: The authors declare no conflict of interest.
