Abstract

TRAPPIST-1 is an ultracool dwarf hosting a system consisting of seven planets. While orbital properties, radii, and masses of the planets are nowadays well constrained, one of the fascinating open issues is the possibility that an environment hospitable to life could develop on some of these planets. Here, we use a simple formulation of an energy balance model that includes vegetation coverage to investigate the possibility of life affecting the climate of the planets in the TRAPPIST-1 system. Results confirm that planet TRAPPIST-1e has the best chance to be a habitable world and indicate that vegetation coverage significantly affects the resulting temperatures and habitability properties. The influence of vegetation has been evaluated in different scenarios characterized by different vegetation types, land–sea distributions and levels of greenhouse effect. While changes in vegetation type produce small changes, about 0.1%, in the habitable surface fraction, different land–sea distributions, by also affecting the vegetation growth, produce different temperature distributions. Finally, at latitudes where vegetation grows, the lowering of local albedo still represents a relevant contribution in settling the planetary temperature profiles even when levels of greenhouse effect higher than the Earth-like case are considered.

1. Introduction

The large number of exoplanets discovered in recent years (Mayor & Queloz 1995; Marcy & Butler 1996; Petigura et al. 2016, 2017) has led to a remarkable growth in scientific interest in this topic, as also confirmed by the number of dedicated missions developed by NASA (exoplanets.nasa.gov/exep/) and ESA (sci.esa.int/home/51459-missions/). One of the open issues about exoplanets, maybe the most fascinating one, concerns their possible habitability. The very limited amount of information about the physical properties of planets and atmospheres is mainly inferred through spectroscopic measurements (e.g., de Wit et al. 2018) and estimations of composition are made by mass–radius fitting through dynamical models (Quarles et al. 2017; Unterborn et al. 2018). Climate models, which use this information as inputs, can be useful to gain insight into possible habitability. Different approaches, from simple formulations of energy balance models (EBMs) (see e.g., Pierrehumbert 2011; Alberti et al. 2017) to more elaborate three-dimensional climate models (see e.g., Gillon et al. 2017; Wolf 2017, and references therein), were used to investigate this topic.

The TRAPPIST-1 planetary system is formed from seven planets orbiting around an ultracool dwarf hosting star (Gillon et al. 2016, 2017; Kislyakova et al. 2017; Luger et al. 2017). While initially all the planets seemed to be consistent with an Earth-like composition (Quarles et al. 2017), recent analysis of transit timing variations show that TRAPPIST-1c and TRAPPIST-1e (T-c and T-e) likely have largely rocky interiors, while the other planets require volatile-rich envelopes in most cases with water mass fractions less than 5% (Grimm et al. 2018).

The seven planets are all within 0.062 au from their star but the stellar luminosity Lₚ is fainter with respect to our Sun (Lₚ ∼ 5.25 × 10⁻⁴ L☉; the symbol ○ refers to solar parameters at 1 au) and the net flux $S_0$ impinging on the planets is in the range 0.13 $S_0$ ≤ $S_e$ ≤ 4.3 $S_0$ (Gillon et al. 2016, 2017; Wolf 2017). According to Gillon et al. (2016), the seven TRAPPIST-1 planets are temperate, having equilibrium temperatures below ~400 K. Due to their proximity to the hosting star, the planets are likely to synchronously rotate with it, thus generating a permanent dark side on the planetary surfaces (Joshi et al. 1997; Heath et al. 1999; Kopparapu et al. 2014, 2016). This has a strong impact on the planetary climate since on tidally locked planets the tidal synchronization produces heat redistribution by means of atmospheric large-scale heat transport through fluid motions, driven by the day–night temperature contrast (Joshi et al. 1997; Joshi 2003; Merlis & Schneider 2010; Pierrehumbert 2011; Forget & Leconte 2014; Wordsworth 2015; Koll & Abbot 2016; Komacek & Showman 2016).

Concerning the habitability of the planets belonging to the TRAPPIST-1 system, several approaches have been used to investigate the possibility that some of them can reside in the so-called circumstellar habitable zone (HZ), the area around a star where a planet can sustain liquid water on its surface (Kasting et al. 1993; Kopparapu et al. 2013). By using radiative–convective climate models that resolve the fluid dynamics of the atmosphere under different atmospheric compositions (mostly N₂, CO₂, and H₂O) and assuming completely ocean-covered planets, it was found that planet T-e has the most favorable conditions for habitability, T-d presents a runaway greenhouse effect, while inner (outer) planets have higher (lower) surface temperatures than the upper
Here, we take into account the possibility of life affecting the planetary climate by developing a 1D EBM that includes evolving vegetation coverage acting as a feedback on the surface temperature of the tidally locked planets of the TRAPPIST-1 system. The model describes the evolution of the surface temperature $T(\theta, t)$ and the fraction of vegetation coverage $A(\theta, t)$, both functions of time and the tidally locked latitude $\theta$. The main advantage of using an EBM with respect to global climate models, although the latter provide a more complete description, is that it allows exploration of a wider parameter space, reduces the large pool of assumptions of atmospheric and surface conditions required by more complex climate models, and provides direct information about global properties of the planets, such as their habitability. At the same time, global models are less efficient in evaluating the effects of vegetation on the planetary temperature and in resolving the physics behind vegetation feedbacks. The possibility of investigating the effects of vegetation represents a peculiarity of this model and distinguishes it from other works studying the climate of terrestrial exoplanets that do not take into account the feedback of life on the climate. In discussing the results of our model, we show that including the vegetation coverage in exoplanet climate modeling is crucial since it can produce significant features in the climate and affect the habitability.

2. The Model

The equations of the model only depend on the tidally locked latitude $\theta$; variations along the longitudinal direction are neglected as in similar models (Pierrehumbert 2011; Checlair et al. 2017).

The climate model is based on two equations describing the time evolution of surface temperature $T(\theta, t)$ and fraction of vegetation coverage $A(\theta, t)$, both as functions of time and the tidally locked latitude $\theta$ ($\theta = 0$ at the terminator and $\theta = \pi/2$ at the substellar point):

$$C_T \frac{\partial T(\theta, t)}{\partial t} = \left[ 1 - \alpha(T, A) \right] S(a, L_*, \theta) - R(T) 
+ C(T - \langle T \rangle) \right)$$

(1)

$$\begin{cases} 
\frac{\partial A(\theta, t)}{\partial t} = A[\beta(T)(1 - A) - \gamma] \text{ if } \theta \geq 0 \\
A = 0 \text{ if } \theta < 0.
\end{cases}$$

(2)

In Equation (1), $C_T$ is the heat capacity, the first term on the right side represents the thermal energy balance between the incoming stellar radiation $S$ and planetary outgoing flux $R$, and the second term describes the zonal redistribution of heat by the atmospheric dynamics. Equation (2) is a logistic equation for the evolution of the fraction of land covered by vegetation where $\beta$ and $\gamma$ represent vegetation growth and death rates, respectively. Vegetation can affect the evolution of temperature by changing the total albedo $\alpha$. Since the TRAPPIST-1 planets are tidally locked and the nightside is never illuminated by stellar radiation, we consider no vegetation growth in the planetary nightside where A is fixed to 0. The spatial average of the planetary temperature is computed as $\langle T \rangle = \int_{\theta_1}^{\theta_2} T(\theta) \cos \theta d\theta / \int_{\theta_1}^{\theta_2} \cos \theta d\theta$, where the extremes of integration $\theta_1$ and $\theta_2$ vary for global, dayside, and nightside averages.

The stellar irradiation at the orbit of the planets, expressed as $S(a, L_*, \theta) = (L_* / 4\pi d^2) \sin \theta$, depends on the star luminosity $L_*$ and on the star–planet distance $a$. Since the planets are tidally locked, $S$ varies according to the geographical position on the dayside, where $\sin \theta > 0$, and $S(a, L_*, \theta) = 0$ on the nightside, where $\sin \theta < 0$. The planetary outgoing flux is $R(T) = g(T)\sigma T^4$, where $g(T)$ is the grayness function that models the greenhouse effect (Sellers 1969). The grayness function is written as $g(T) = 1 - m \tanh((T_{day}/T_0)^b)$, where $m$ parameterizes the atmospheric attenuation, $(T_{day})$ is the spatially averaged dayside temperature and $T_0 \sim 281 K$. This definition takes into account the infrared emission due to the planetary surface which is assumed to increase with the surface temperature and which implies a relaxation of the blackbody radiation hypothesis.

The total albedo $\alpha(T, A)$ depends on the fraction of ocean and land of the planetary surface as

$$\alpha(T, A) = p(\theta)[\alpha_o + \alpha_x(1 - A)] + [1 - p(\theta)]\alpha_o(T),$$

(3)

where $p(\theta)$ is the fraction of land covering the planetary surface as a function of the latitude, and $\alpha_o$ and $\alpha_x$ are the albedos of vegetation and bare ground, respectively. The albedo $\alpha_o$ of the ocean linearly depends on temperature as

$$\alpha_o(T) = \alpha_{\text{max}} + (\alpha_{\text{min}} - \alpha_{\text{max}}) \left[ \frac{T - T_{\text{low}}}{T_{\text{up}} - T_{\text{low}}} \right]$$

(4)

in the range of temperatures $T_{\text{low}} < T < T_{\text{up}}$; $\alpha_o = \alpha_{\text{max}}$ for an ocean completely covered by ice ($T \leq T_{\text{low}}$) and $\alpha_o = \alpha_{\text{min}}$ for an ice-free ocean ($T \geq T_{\text{up}}$). The vegetation growth rate is assumed to be a quadratic function of temperature (Watson & Lovelock 1983; Alberti et al. 2015, 2018; Rombouts & Ghil 2015)

$$\beta(T) = \max \{ 0; 1 - k(T - T_{\text{opt}})^2 \},$$

(5)

with $k$ and $T_{\text{opt}}$ defining the temperature range inside which vegetation can grow, while the vegetation death rate $\gamma$ is assumed to be constant (Watson & Lovelock 1983; Alberti et al. 2015, 2018; Rombouts & Ghil 2015).

The distance from the star and irradiation for the seven TRAPPIST-1 planets are taken from Gillon et al. (2016). All the planets are supposed to have an atmosphere with the Earth’s composition and Earth-like greenhouse conditions ($m = 0.6$) have been considered. The fraction of planetary surface $p(\theta)$ occupied by land mimics that of the Northern Hemisphere of a tidally locked Earth with the North Pole at the terminator and the substellar point located at the Earth longitude $0^\circ$. The insolation shape and the fraction of planet surface occupied by land, used in the model, are shown in Figure 1.

In order to parameterize the atmosphere’s large-scale heat transport through fluid motions, we introduce a global relaxation term in the form $C(T - \langle T \rangle)$ (see e.g., Checlair et al. 2017), where $\langle T \rangle$ is the spatially averaged temperature, which mimics the processes determining heat redistribution.
from the dayside to nightside on tidally locked planets. The coupling coefficient \( C \) is a constant calculated as \( \rho_{s}c_{p}C_{D}U \), where \( \rho_{s} \) is the surface density of the atmosphere, determined by \( \langle T \rangle \) and the surface pressure via the ideal gas law (a surface pressure of \( \rho_{s} = 1 \) atm is assumed), \( c_{p} \) is the atmospheric specific heat, \( U \) is a typical surface wind speed, and \( C_{D} \) is a dimensionless drag coefficient having a typical value of 0.001 over moderately rough surfaces (Garratt 1994; Koll & Abbot 2016). A typical value of Earth’s surface winds of 5 m s\(^{-1}\) has been chosen (Pierrehumbert 2011).

Equations (1) and (2) have been numerically integrated by using a second order explicit Runge–Kutta time scheme for the time marching and a latitude grid with a resolution \( \sim 1^\circ \) (128 points). The initial latitudinal temperature profile is flat with a value equal to \( T_{\text{eq}} \) determined by solving the radiative equilibrium for Equation (1). The initial vegetation coverage is randomly distributed over latitude. For all planets, the final temperature profiles are not affected by the initial condition for the vegetation distribution. Indeed, by varying the initial vegetation profile (e.g., a constant vegetation coverage in the dayside or in the full planet) changes of the final temperature profiles are at most of the order of 2%.

Due to the uncertainty about the physical properties of the TRAPPIST-1 planets, we consider the parameters of the model, listed in Table 1, as for an Earth-like planet. The choice of the parameters presents some differences with respect to Alberti et al. (2017) where a 0D EBM with the same equation for the fraction of vegetation coverage was developed. Here a \( C_{T} \) value closer to the effective heat capacity of the Earth’s ocean, of about 14 \( \pm \) 6 W yr K\(^{-1}\) m\(^{-2}\) (Schwartz 2007), has been chosen. At the same time lower values of \( \alpha_{\text{min}} \) and \( \alpha_{\text{max}} \) for the ocean albedo has been considered here. Indeed, the stellar spectrum of the M-dwarf TRAPPIST-1 is significantly redder than a Sun-like star and at longer wavelengths the albedos of ice-free and ice-covered ocean are lower than with respect to what is expected for the Earth (Shields et al. 2013). Finally, a temperature \( T_{\text{low}} = 253 \) K, below which the ocean is completely covered by ice, and a value of \( k \) allowing the growth of vegetation up to \( \sim 317 \) K have been chosen. All the other parameters are the same as in Alberti et al. (2017).

### Table 1

| Symbol | Value | Units |
|--------|-------|-------|
| \( C_{T} \) | 15.2 | W yr K\(^{-1}\) m\(^{-2}\) |
| \( \alpha_{c} \) | 0.1 |...|
| \( \alpha_{p} \) | 0.4 |...|
| \( \alpha_{\text{max}} \) | 0.55 |...|
| \( \alpha_{\text{min}} \) | 0.2 |...|
| \( T_{\text{low}} \) | 253 | K |
| \( T_{\text{up}} \) | 300 | K |
| \( T_{\text{opt}} \) | 283 | K |
| \( k \) | 0.0008 | yr\(^{-1}\) K\(^{-2}\) |
| \( \gamma \) | 0.1 | yr\(^{-1}\) |
| \( c_{p} \) | 10\(^{-3}\) | J K\(^{-1}\) K\(^{-1}\) |
| \( m \) | 0.6 |...|

### 3. Results

#### 3.1. The Effect of Vegetation

To investigate the role of vegetation in self-regulating planetary temperatures, two cases have been considered: a planet with no vegetation, only covered by bare soil and oceans that can be frozen, and a planet covered by vegetation in addition to soil and sea. Temperature and vegetation profiles at some time steps of the simulation for all the planets of the TRAPPIST-1 system are shown in Figure 2 for both cases with and without vegetation. The average dayside, nightside, and global temperature resulting at the last step of the simulation are shown in Table 2. Figure 3 shows the final (at the last step of the simulation) planetary surface temperature as a function of the latitude.

When comparing the results for the cases with and without vegetation, significant differences in the temperature profiles are observed only for T-e. For this planet, indeed, the surface temperature at some latitudes allows vegetation to grow, which in turn has a feedback on the temperature. Vegetation growth is also allowed for T-d in a very restricted range of tidally locked latitudes (about 4\(^\circ\)) near the terminator (third row of Figure 2). Since it occurs only in a small fraction of the planetary surface, this growth does not significantly affect the T-d temperature profile, which is the same as the case without vegetation (the difference in the average temperature between the cases with and without vegetation is 0.01 K). For the other planets the vegetation growth rate is almost zero and, since the death rate is
constant in the model, they evolve toward a state with no vegetation at all. Since the planets are tidally locked, so that the stellar irradiance is 0 on the dark side, the temperature is constant on the nightside of all the planets. The inner planets (T-b, T-c, and T-d), show dayside temperature of 515, 438, and 370 K, higher or very close to the boiling point of water. This indicates that large fractions of the daysides of these planets, which are the places in principle more suited to developing life since they receive direct stellar radiation, do not sustain liquid water at the surface and they are likely to be hot and dry. These results agree with those obtained by more complex 3D climate models (Gillon et al. 2016; Wolf 2017). On the other hand, for the external planets (T-f, T-g, and T-h) the star irradiance is too low to sustain surface temperatures above the melting point of water, and these planets should be in a snowball state (Gillon et al. 2016; Wolf 2017). These considerations can be quantified by introducing a measure of the habitable fraction (HF) of the planet as the percentage of the planet’s dayside surface residing in the HZ. The HF quantifies if and where the planet can sustain liquid water on its surface: by assuming a CO$_2$–H$_2$O–N$_2$ atmosphere and under the assumption of an Earth-like geology for the resulting greenhouse effect and carbon–silicate weathering cycle, this condition corresponds to having a local surface temperature in the range 273–373 K. For

Table 2

| Planet | $T_n$ (K) | $T_d$ (K) | $T_{avg}$ (K) |
|--------|-----------|-----------|---------------|
| T-b    | 350       | 515       | 433           |
| T-c    | 327       | 438       | 382           |
| T-d    | 303       | 370       | 336           |
| T-e    | 267       | 307       | 287           |
| T-f    | 194       | 211       | 203           |
| T-g    | 177       | 188       | 182           |
| T-h    | 151       | 156       | 153           |
| T-e    | 275       | 320       | 297           |

Note. The last line refers to T-e for the case with vegetation coverage.
the three inner planets the HF is at most 38% (being 3%, 11%, and 38% respectively) and for the external planets it is 0%.

For the inner planets and T-e the temperature profile shows quite a monotonic trend increasing toward high $\theta$. The external planets show, instead, a temperature decrease for $\theta \leq 65^\circ$ due to the steep decrease in $p(\theta)$ beyond the relative maximum at $\theta \sim 65^\circ$. This behavior is due to the effect of the ocean on the planetary albedo. For the hotter planets (T-b, T-c, T-d, and T-e), the temperature profile is monotonic like the insolation pattern: the contribution of the stellar irradiance is high and the albedo fluctuations due to the bare soil and ocean (the ocean albedo $\alpha_0$ has the minimum value $\alpha_{\min}$) introduce small variations. On the other hand, for external colder planets, the stellar irradiance is lower and the latitudinal pattern of the ocean albedo (which is higher, being $\alpha_0 = \alpha_{\max}$ since the planet is completely covered by ice), determined by the function $p(\theta)$, contributes more in defining the general behavior of the temperature profile.

For the case with no vegetation, planet T-e represents the best candidate for a habitable world, showing an average global temperature of 287 K. T-e dayside temperatures, always below the boiling point of water, allow it to sustain liquid water and make the planet resident in the HZ; on the other hand, the nightside, with an average temperature of 267 K, is ice-covered. The HF of T-e is very high, reaching 93%. When vegetation coverage, with an albedo of 0.1, is introduced in the model, the surface temperature profile of T-e changes. An increase of the T-e dayside surface temperature at low-intermediate latitudes, forming a bump in the latitudinal temperature profile, is observed. This is located is the range of latitudes where the conditions for vegetation growth are favorable, thus affecting the resulting surface temperature. In the dayside the net effect of vegetation is to produce a microclimate, in a given latitude range, where the surface temperature locally changes. As a consequence, the HF of T-e increases and reaches 100%. Since for Earth-like conditions T-e is the best candidate to habitability, in the following we will focus on this planet.

3.2. Changing Vegetation Types

One of the peculiarities of the model is the possibility to explore the vegetation-albedo feedback acting together with the planet’s ice-albedo feedback. Since the albedo depends on the vegetation species, we investigate how the change of vegetation type can affect the planetary temperature. To this purpose the values of the vegetation albedo $\alpha_v$ in the model are changed to take into account the effect of different types of vegetation. To cover the range of albedos associated with different species (from $\sim 0.08$ for a conifer site to $\sim 0.2$ for green grass, Betts & Ball 1997) we evaluated the T-e temperature for different $\alpha_v$.

![Figure 3. Surface temperature as a function of the latitude at the last step of the simulation for all the TRAPPIST-1 planets. Results for a model with (magenta curves) and without (blue curves) vegetation are shown.](image_url)
The Astrophysical Journal, 891:24 (8pp), 2020 March 1

namely 0.05, 0.1, 0.15, and 0.2 (Figure 4). The global shape of the temperature profile does not change by varying the vegetation albedo but the dayside/total average temperatures decrease from 321/298 K to 318/295 K when \( \alpha \) increases from 0.05 to 0.2. The changes in the temperature profile are observed, as expected, in the bump at intermediate latitudes while everywhere else the temperature profiles collapse on almost the same values.

### 3.3. Changing the Land–Sea Distribution

An important role in defining the planetary temperature profile is played by the land–sea distribution, since it can significantly modify the planetary albedo. The planetary response to changes in land–sea percentage can be very complex. This is because the total albedo is also affected by the vegetation coverage that can change if the land coverage increases or decreases. To investigate the effect of changes in the land–sea distribution on the resulting T-e planetary temperature, three extreme cases have been considered: (i) 99% of the nightside is covered by land (with the dayside completely covered by sea; in this case there is no vegetation growth); (ii) 99% and (iii) 50% of the dayside are covered by land (with the nightside completely covered by sea). The resulting temperature profiles for the three different land–sea distributions are shown in Figure 5 together with profiles for the Earth-like case. Case (i) shows higher temperatures when compared with results of cases (ii) and (iii) with no vegetation. This is because at these temperatures the total albedo for case (i) is just the ocean albedo which favors higher temperatures, having a lower value with respect to the albedo of the bare soil with no vegetation. The behavior of the temperature profiles for cases (ii) and (iii) without vegetation at high \( \theta \), where the albedo is only determined by the percentage of soil and ocean, reflects the behavior observed at the same latitudes for the planets including vegetation. When the growth of vegetation is taken into account, temperature profiles for (ii) and (iii) confirm that the vegetation coverage plays a role in structuring the temperature of the planet. Indeed they show, as for the Earth-like case, a bump at low latitudes with increased width for (ii) due to a broader range of latitudes at which vegetation can grow. For the three temperature profiles, higher values of temperature are observed at high latitudes where the albedo of (i) reaches the minimum value \( \alpha_{\min} \) and the total albedo of (ii) and (iii) also includes the contribution of the bare soil only (due to the high temperatures vegetation does not grow), thus resulting in higher temperatures. A difference of about 10 K is observed between (ii), for which the total dayside albedo is almost completely determined by the bare soil, and (iii), for which the albedo is reduced due to a higher ocean percentage.

On the other hand, at lower latitudes (between 0° and 18°) both the increase of the albedo of the ocean, being the temperature between \( T_{\text{low}} \) and \( T_{\text{up}} \) (see Equation (4)), and the growth of vegetation, producing a decrease of the total albedo, result in comparable temperatures for the three cases. At these latitudes, case (ii) shows a larger increase of temperature than (iii) since a larger land percentage implies a higher fraction of vegetation coverage and a higher decrease of the total albedo.

For the case with no vegetation, a reduced efficiency of the heat transport is observed when a higher percentage of oceans is present in the dayside. The day–night gradient is larger for case (i) when the land coverage is confined to the nightside and decreases for (iii) and (ii), respectively. Changes in the heat transport efficiency have been also observed in global climate models when dry and moist atmospheres are considered (e.g., Yang et al. 2013). On the other hand, for planets with vegetation but different land–sea coverage, the day–night temperature difference is almost the same. This suggests that the vegetation coverage acts to counteract, by varying the planetary albedo, the heat redistribution along the planet.

### 3.4. Changing the Composition of the Atmosphere

At the last stage of our study, we investigated the response of the system when the atmospheric composition is changed by increasing the CO\(_2\) content of the Earth-like T-e atmosphere. Changes in the CO\(_2\) content act on the large-scale heat transport in Equation (1) and also affect the greenhouse effect by changing the atmospheric attenuation \( m \) in the grayness function. According to Sellers (1969), we can roughly estimate that a variation of a factor of 10 in the CO\(_2\) content changes \( m \) by about 10%. This means that for an increase of the CO\(_2\) content of a factor of 5, 10, and 15, with respect to an Earth-like atmosphere, the parameter \( m \) increases to 0.63, 0.66, and

![Figure 4. Surface temperature for T-e, as a function of the latitude at the last step of the simulation, obtained by using different vegetation types characterized by different albedos.](image1)

![Figure 5. Surface temperature for T-e, as a function of the latitude at the last step of the simulation, obtained by using different land–sea profiles and the same initial random distribution of vegetation.](image2)
0.69, accordingly. The results of the planetary temperatures for different atmospheric compositions are shown in Figure 6. As expected, the increase of the CO2 content in the atmosphere produces a higher average planetary temperature: an increase of ∼18 K in the average planetary temperature, with respect to an Earth-like planet, is found when CO2 content is increased by a factor of 15. The addition of greenhouse gas in the atmosphere mainly affects the areas with no vegetation. The differences among temperature profiles obtained with different CO2 contents are lower in the range of latitudes where vegetation can grow while they are enhanced at higher latitudes where only bare soil and ocean are present. For a more quantitative comparison, we evaluated the average temperature for the curves of Figure 6 in the ranges of latitude Δθl = [0°, 24°], where vegetation grows, and Δθh = [50°, 180°], where there is no vegetation. Average temperatures calculated in both Δθl and Δθh increase, with respect to the Earth-like atmosphere, when the CO2 content is increased. However, the increase of temperatures in Δθl are lower by 1, 3, and 6 K with respect to those calculated in Δθh, when the CO2 content increases by factors of 5, 10, and 15.

This indicates that even when the greenhouse effect is enhanced to higher values with respect to the Earth, thus producing a global increase of the planetary temperature, the lowering of the albedo due to vegetation growth is still effective in structuring the temperature profiles. The allowance of vegetation growth in the model, by locally changing the albedo, can thus reduce the effects of the greenhouse effect with respect to the same model with no vegetation.

4. Conclusions

A 1D EBM model, with latitudinal dependency, was developed and used to investigate the vegetation feedback on the climate of the planets in the TRAPPIST-1 system. Besides the vegetation-albedo feedback, the model includes also a parametric description of the greenhouse effect and the possibility to vary the land–sea distribution. First, the temperature profiles of all the TRAPPIST-1 planets were obtained by using model parameters of an Earth-like planet. However, since for a M-dwarf like TRAPPIST-1 the stellar spectrum is redder than for the Sun, the maximum and minimum values of the ocean albedo have been lowered with respect to the Earth-like case. T-d and T-e are the only planets for which vegetation is able to grow at some latitudes. Since for planet T-d vegetation grows only in a very small latitude range close to the terminator, the temperature profile is not affected and it is the same as the case without vegetation. On the other hand, vegetation growth occurs for T-e in a larger fraction of the planetary surface giving rise to significant changes in the temperature profiles.

Since it is characterized by an average global temperature of 287/297 K, for the cases without/with vegetation, T-e presents the most favorable conditions for habitability, in agreement with the results of previous works (Bolmont et al. 2017; Bourrier et al. 2017; Kopparapu et al. 2017; Wolf 2017); actually the presence of a vegetation coverage slightly increases the HF of the planet. These findings differ from results of Alberti et al. (2017) who found, by implementing a 0D EBM model with vegetation coverage, that the inner planets T-b, T-c, and T-d are the best candidates for habitability, while planet T-e can present water oceans only for greenhouse effect conditions different from those of Earth. These differences can arise both from differences in the model equations, such as the addition of a spatial dimension to the model and the inclusion of a day–night heat transport term in the 1D model described here, and differences in the values of some parameters (see Section 2).

By varying the vegetation albedo we investigated the effect of different types of vegetation on the planetary temperatures. Changes in vegetation albedo (between 0.05 and 0.2, in the range of values measured for the different species commonly observed on the Earth) produce quite small changes in the temperatures and habitable surface fraction, the latter changing by at most 0.1%.

We then studied how changes in the land–sea distribution affect planetary temperatures. When no vegetation growth is considered, a planet with the dayside being 99% ocean reaches the highest temperature with respect to planets with other land–sea distributions. For planets with the nightside completely covered by sea but with different percentages of land in the dayside, 99% and 50%, the final temperature profiles show a similar shape of the Earth-like case. Nevertheless, different land–sea distributions result in a broader/wider range of latitude where the vegetation can grow and an enhanced temperature difference between low and high latitudes.

A significant effect is produced by changes in the atmospheric composition by adding different quantities of CO2 (which both affects the large-scale heat transport and increases the grayness parameter) to an Earth-like planetary atmosphere. It is found that the increase of CO2 leads, as expected, to higher average planetary temperatures: for example, when the CO2 content of the planetary atmosphere is increased by a factor of 15, with respect to an Earth-like atmosphere, an increase of about 18 K in the average planetary temperature is found. However, the increase of greenhouse gas abundance in the atmosphere mainly affects the regions with no vegetation. The effect of vegetation coverage in settling the final planetary temperature profile is still relevant even for a greenhouse effect much higher than the Earth-like case.

A new set of parameters for the TRAPPIST-1 planets, slightly differing from those provided by Gillon et al. (2016), have been published by Delrez et al. (2018). New planet–star
distances are on average increased by about the 2% while
irradiation decreases by 7% on average. The results of our
model remain substantially unchanged if these new parameters
are used. Indeed, due to the decrease of the stellar irradiation,
the global average temperature decreases and the habitability
slightly changes (326 K/291 K and 44%/97% for planets T-d
and T-e respectively, for the case with vegetation).
