Received:

ABSTRACT
We consider the role of a propagation effect such as the stimulated Raman scattering on the polarization of radio pulses. When an intense electromagnetic wave with frequency close to the plasma frequency interacts with the plasma in the pulsar magnetosphere, the incident wave undergoes stimulated Raman scattering. Using typical plasma and magnetic field parameters, we compute the growth rate and estimate the polarization properties of the scattered mode. At some conditions, we find that the polarization properties of the scattered mode can become significantly different from those of the incident wave. The frequencies, at which strong Raman scattering occurs in the outer parts of magnetosphere, fall into the observed radio band. In some pulsars, for example, PSR B0628-28 and 1914+13, a large and symmetric type of circular polarization has been observed. We propose that such an unusual circular polarization is produced by the propagation effects.

Key words: stars:pulsars-plasmas-waves-radiative transfer

1 INTRODUCTION
The investigation of coherent radio emission from the pulsar magnetosphere has attracted a great deal of attention (Cordes \textit{et al.} 1979; Michel 1982; Ass\textsuperscript{e}o \textit{et al.} 1990). A powerful collective emission occurs when relativistic electron beams with density \(\sim 1\) per cent of the pair plasma density, scatter off coherently from concentrations of plasma waves (cavitons) (Benford 1992). The role of collective plasma processes in the absorption and spectral modification of the radio waves is well known (e.g., Beal 1990; Krishan \& Wiita 1990; Benford 1992; Gangadhara \& Krishan 1992, 1993, 1995; Gangadhara, Krishan \& Shukla, 1993). von Hoensbroech, Lesch and Kunzl (1998) have demonstrated that degree of linear polarization decreases with increasing frequency while the degree of circular polarization shows the opposite trend.

In this paper, we estimate the role of stimulated Raman scattering on the polarization of electromagnetic waves propagating in the pulsar magnetosphere. We assume that the physical conditions in the pulsar magnetosphere are those of the classical standard model (Ruderman \& Sutherland 1975) which describes the generation of ultrarelativistic beams of electrons/positrons and the creation of the pair plasma. The beams and the pair plasma are in relativistic motion along the bundle of open magnetic field lines that delimit the active region of magnetosphere. The stimulated Raman scattering is considered as a parametric decay of the initial transverse electromagnetic (pump) wave into another electromagnetic wave and a longitudinal plasma wave. The physics of stimulated Raman scattering in a plasma has been explained in many papers and books (e.g., Drake \textit{et al.} 1974; Liu \& Kaw 1976; Hasegawa 1978; Kruer 1988). In two ways, stimulated Raman scattering may be important in the pulsar environment: first, it may act as an effective damping mechanism for the electromagnetic waves generated by some emission mechanism at the lower altitudes in the pulsar magnetosphere. At those altitudes, the resonant conditions for stimulated Raman scattering, i.e., the frequency and wave number matching might not be satisfied. This results in a short time variability which is generally observed in pulsar radio emission. Secondly, it may provide an effective saturation mechanism for the growth of the electromagnetic waves provided that the conditions for the wave excitation by some mechanism are satisfied in the region where an effective stimulated Raman scattering can take place.

The first case can be simplified by treating the intensity of the pump is constant in time. Then the nonlinear equations, which describe the wave coupling, become linear in amplitudes of the decaying waves, and the exponentially growing solutions will imply an effective energy transfer from the pump wave. This approximation breaks down when the amplitudes of the...
important to determine whether the depolarization is a geometric effect or results from radiation–plasma interactions. There have only been very preliminary attempts to explain depolarization and microvariability using plasma mechanisms (Benford 1992). (e.g., PSR B0628-28, and 1914+13). In concerning the interpretation of the observed polarization, notably large and symmetric circular polarization in some pulsars magnetic wave, and give an analytical expression for the growth rate of the instability. In and compute the polarization states of the scattered electromagnetic wave. The discussion of our findings is given in We begin with a model consisting of a pulsar with nonthermal component of radiation interacting with plasma in the emission

\[ \gamma \approx 10^8 \text{ cm} \]

within the bundle of field lines. For the typical parameters: Lorentz factor of primary particles \( \gamma_\parallel \sim 10^6 \), and for pair plasma particles \( \gamma_\perp \sim 10^5 \), magnetic field \( B_0 \sim 10^6 r_8^{-3} \) G, and pulsar period \( p = 1 \) s, we obtain the particle number density

\[ n_0 = \frac{\gamma_\parallel}{2\gamma_\perp} \frac{B_0}{ecp} \frac{3.5 \times 10^7}{r_8^3} \text{ cm}^{-3} \]

and the plasma frequency

\[ \omega_p = \frac{1}{\sqrt{\frac{n_0}{\epsilon}} \gamma_\parallel} \]

2 POLARIZATION CHANGES DUE TO STIMULATED RAMAN SCATTERING

We begin with a model consisting of a pulsar with nonthermal component of radiation interacting with plasma in the emission region at a distance \( r = 100 R_{NS} = 10^8 \) cm, (neutron star radius \( R_{NS} \approx 10 \) km) from the neutron star surface, where the magnetic field is about \( 10^6 \) G. Plasma particles may be all in their lowest Landau level with no Larmor gyration, however, plasma can have one-dimensional distributions of momenta along the magnetic field (Blandford 1975; Lominadze, Machabeli & Usov 1983). This is because the synchrotron loss time for the decay of the perpendicular component of momentum is always short compared to the transit time at the stellar surface for any velocity. The simplest model for the plasma is density declining in proportion to \( r^{-3} \) with no gradients in the distribution functions across \( \vec{B} \).

The nonlinear interaction of radiation with plasma causes the modulation instability leading to enhancement of nonresonant density perturbations and the radiation amplification by free-electron-maser, which produces intense electromagnetic waves (Lesch, Gil & Shukla 1994; Gangadhara, Krishan & Shukla 1993; Gangadhara & Krishan 1992). Since the frequency of these electromagnetic waves is close to the plasma frequency, they resonantly couple with the subpulse-associated plasma column in the pulsar magnetosphere and drive the stimulated Raman scattering.

Consider a large amplitude electromagnetic wave \( \vec{E}_0 \) with an electric field:

\[ \vec{E}_0 = \varepsilon_{x0} \cos(k_x \cdot r - \omega_0 t) \hat{e}_x + \varepsilon_{y0} \cos(k_y \cdot r - \omega_0 t + \delta) \hat{e}_y \]

interacts with the plasma in the pulsar magnetosphere.

We follow Ruderman & Sutherland’s (1975) approach to estimate the density and plasma frequency of the plasma moving within the bundle of field lines. For the typical parameters: Lorentz factor of primary particles \( \gamma_\parallel \sim 10^6 \), and for pair plasma particles \( \gamma_\perp \sim 10^5 \), magnetic field \( B_0 \sim 10^6 r_8^{-3} \) G, and pulsar period \( p = 1 \) s, we obtain the particle number density

\[ n_0 = \frac{\gamma_\parallel}{2\gamma_\perp} \frac{B_0}{ecp} \frac{3.5 \times 10^7}{r_8^3} \text{ cm}^{-3} \]

and the plasma frequency

\[ \omega_p = \frac{1}{\sqrt{\frac{n_0}{\epsilon}} \gamma_\parallel} \]
\[
\omega_p = 2\gamma \left( \frac{4\pi n_0 e^2}{\gamma m_c} \right)^{1/2} = 2 \times 10^{10} \text{ rad s}^{-1}.
\]

The plasma in the emission region of pulsar magnetosphere may be birefringent (Melrose & Stoneham 1977; Melrose 1979; Barnard & Arons 1986; von Hoensbroech, Lesch and Kunzl 1998). In these models, two modes of wave propagation is generally allowed in magnetoactive plasma: one mode is polarized in the magnetic field direction and the other mode is polarized perpendicular to it. Following these models, we resolve \( \mathbf{E} \) into two modes \( \mathbf{E}_{\parallel} = \varepsilon_{\parallel} \cos(\mathbf{k}_i \cdot \mathbf{r} - \omega_i t)\mathbf{e}_x + \varepsilon_{\parallel} \cos(\mathbf{k}_i \cdot \mathbf{r} - \omega_i t + \delta_i)\mathbf{e}_y \) such that they are polarized in the directions parallel and perpendicular to the \( \mathbf{k}_i - \mathbf{B} \) plane, respectively. It is well known from laser-plasma interactions that large amplitude electromagnetic waves resonantly interact with the plasma when the radiation frequency becomes close to the plasma frequency. Since the two modes have different indexes of refraction (McKinnon 1997), i.e., the response of plasma is not same for the two radiation modes, it is reasonable to assume that \( \mathbf{E}_{\parallel} \) couples with the density perturbation \( \Delta n_1 = \delta n_1 \cos(\mathbf{k}_i \cdot \mathbf{r} - \omega t) \), and \( \mathbf{E}_{\perp} \) couples with \( \Delta n_2 = \delta n_2 \cos(\mathbf{k}_i \cdot \mathbf{r} - \omega t + \delta) \) in the plasma medium.

Since the ponderomotive force is proportional to \( \nabla E_{\parallel}^2 \) and \( \nabla E_{\perp}^2 \), the coupling between the radiation and the density perturbations is nonlinear. Hence the density perturbations grow up which lead to currents and mixed electromagnetic–electrostatic side-band modes at \( (\mathbf{k}_i \pm \mathbf{k}_s, \omega_i \pm \omega) \). In turn these side-band modes couple with the incident wave field, producing a much stronger ponderomotive force, which amplifies the original density perturbation. Hence a positive feedback system sets in, which leads to an instability.

The electric field \( \mathbf{E}_s \) of the electromagnetic wave scattered through an angle \( \phi_s \) with respect to \( \mathbf{k}_i \) can be written as
\[
\mathbf{E}_s = \varepsilon_{\parallel} \cos(\mathbf{k}_s \cdot \mathbf{r} - \omega_s t)\mathbf{e}_x + \varepsilon_{\parallel} \cos(\mathbf{k}_s \cdot \mathbf{r} - \omega_s t + \delta_s)\mathbf{e}_y.
\]

The propagation directions of incident wave \( (\mathbf{k}_i, \omega_i) \) and scattered wave \( (\mathbf{k}_s, \omega_s) \) are illustrated in Fig. 1, such that \( \mathbf{k}_i \parallel \mathbf{e}_x \), \( \mathbf{k}_s \parallel \mathbf{e}_y \) and \( \mathbf{e}_s \parallel \mathbf{e}_y \). The primed coordinate system is rotated through an angle \( \phi_s \) about the y-axis. Then the scattered wave in the unprimed coordinate system is given by
\[
\mathbf{E}_s = \varepsilon_{\parallel} \cos(\phi_s \cos(\mathbf{k}_s \cdot \mathbf{r} - \omega_s t)\mathbf{e}_x + \varepsilon_{\parallel} \cos(\mathbf{k}_s \cdot \mathbf{r} - \omega_s t + \delta_s)\mathbf{e}_y - \varepsilon_{\parallel} \sin(\phi_s) \cos(\mathbf{k}_s \cdot \mathbf{r} - \omega_s t)\mathbf{e}_z,
\]
where \( \varepsilon_{\parallel} = \varepsilon_{\parallel s} \).

The quiver velocity \( \mathbf{u}_\pm \) of positrons and electrons due to the radiation fields \( \mathbf{E}_i \) and \( \mathbf{E}_s \) is given by
\[
\frac{\partial \mathbf{u}_\pm}{\partial t} = \pm \frac{e}{m_0} (\mathbf{E}_i + \mathbf{E}_s),
\]
where \( e \) and \( m_0 \) are the charge and rest mass of the plasma particle.

The wave equation for the scattered electromagnetic wave is given by
\[
\left( \nabla^2 - \frac{1}{c^2} \frac{\partial^2}{\partial t^2} \right) \mathbf{E}_s = \frac{4\pi}{c^2} \frac{\partial \mathbf{J}}{\partial t},
\]
where \( c \) is the velocity of light and \( \mathbf{J} \) is the current density.

The components of equation (7) are
\[
D_s \varepsilon_{\parallel s} \cos(\phi_s) \cos(\mathbf{k}_s \cdot \mathbf{r} - \omega_s t) = -\frac{2\pi e^2}{m_0} \frac{\omega_s}{\omega_i} \varepsilon_{\parallel s} \delta n_1 \cos(\mathbf{k}_s \cdot \mathbf{r} - \omega_s t)
\]
and
\[\copyright\ 0000\ RAS,\ MNRAS\ 000,\ 000-000\]
\[
D_s \varepsilon_{yz} \cos(k_s \cdot \vec{r} - \omega_s t + \delta_s) = - \frac{2\pi \varepsilon^2 \omega_s}{m_0 \omega_i} \varepsilon_{yz} \delta_n \cos(k_s \cdot \vec{r} - \omega_s t + \delta) \tag{9}
\]

and

\[
D_s \varepsilon_{xz} \sin(\phi_s) \cos(k_s \cdot \vec{r} - \omega_s t) = 0, \tag{10}
\]

where \(D_s = k_s^2 \varepsilon^2 - \omega_s^2 + \omega_p^2\) and \(\omega_s = \omega_i - \omega\), \(k_s = k_i - k\). \(\tag{11}\)

In quantum language these two relations may be interpreted as the conservation of energy and the momentum along the magnetic field, respectively. When these conditions are satisfied, stimulated Raman scattering is excited resonantly and the expression \(D_s = 0\) becomes the dispersion relation of the scattered electromagnetic mode.

If we cancel the instantaneous space and time dependent cosine functions on both sides of equation (8), we get

\[
D_s \varepsilon_{yz} \cos \phi_s = \frac{2\pi \varepsilon^2 \omega_s}{m_0 \omega_i} \varepsilon_{yz} \delta n_1. \tag{12}
\]

Similar to the phase matching conditions (equation 11), equation (9) gives the condition between the initial phases:

\[
\delta_s = \delta_i - \delta \tag{13}
\]

and hence we obtain

\[
D_s \varepsilon_{yz} = - \frac{2\pi \varepsilon^2 \omega_s}{m_0 \omega_i} \varepsilon_{yz} \delta n_2. \tag{14}
\]

Dividing equation (14) by equation (12), we have

\[
\alpha_s = \alpha_i \eta \cos(\phi_s), \tag{15}
\]

where \(\alpha_i = \varepsilon_{yz} / \varepsilon_{xi}, \alpha_s = \varepsilon_{yz} / \varepsilon_{xz}\) and \(\eta = \delta n_2 / \delta n_1\). The value of \(\eta\) is determined by \(\vec{E}_i\) in such way that \(\Delta n_1\) couples with \(\vec{E}_{xi}\) and \(\Delta n_2\) couples with \(\vec{E}_{yz}\).

We consider the Vlasov equation to find the low frequency plasma response:

\[
\frac{\partial f}{\partial t} + \vec{v} \cdot \nabla f + \frac{1}{m_0}(e \nabla \phi - \nabla \psi \cdot \vec{v}) \frac{\partial f}{\partial \vec{v}} = 0, \tag{16}
\]

where \(\phi(\vec{r}, t)\) is the scalar potential associated with the electrostatic waves, \(f(\vec{r}, \vec{v}, t)\) is the particle distribution function and \(\psi(\vec{r}, t)\) is the ponderomotive potential.

Using \(f(\vec{r}, \vec{v}, t) = f_0(\vec{v}) + \Delta f_1(\vec{r}, \vec{v}, t) + \Delta f_2(\vec{r}, \vec{v}, t)\), we can linearize equation (16), and obtain:

\[
\frac{\partial (\Delta f_1)}{\partial t} + \frac{\partial (\Delta f_2)}{\partial t} + \vec{v} \cdot \nabla (\Delta f_1) + \vec{v} \cdot \nabla (\Delta f_2) + \frac{1}{m_0}(e \nabla \phi - \nabla \psi \cdot \vec{v}) \frac{\partial f_0}{\partial \vec{v}} = 0, \tag{17}
\]

where \(\Delta f_1 = \delta f_1 \cos(\vec{k} \cdot t + \omega f t + \delta)\) and \(\Delta f_2 = \delta f_2 \cos(\vec{k} \cdot t + \omega t + \delta)\). The ponderomotive force of the radiation field depends quadratically on the amplitude of the electric field. Physically, it is a radiation pressure which amplifies the density perturbations by exciting the slow longitudinal fields and motions. The ponderomotive potential is given by:

\[
\psi = \frac{e^2}{2m_0} \left( \left| \left( \begin{array}{c} \vec{E}_i \\ \omega_i \end{array} \right) \frac{\omega_s}{\omega_i} \right| \right)^2 \omega_s \tag{18}
\]

where the bracket \(\langle \rangle\) represents the average over the fast time scale \((\omega_i \gg \omega)\).

In the presence of a strong magnetic field, the pair plasma becomes polarized and one dimensional. If there is some relativistic drift between the electrons and the positrons then the ponderomotive force becomes effective, which will induce the nonlinear density perturbations (Assëo 1993):

\[
\delta n_{\pm} \approx - \frac{1}{32\pi \kappa T_p \omega_p^2} \frac{1}{\gamma_{\pm}} \tag{19}
\]

where \(\varepsilon_{||}\) is the envelope of the parallel electric field of Langmuir wave which is slowly varying with space and time, and \(T_p\) is the plasma temperature. Using these density perturbations and Poisson equation, we can self–consistently derive the potential \(\phi\):

\[
\phi = - \frac{4\pi e}{k^2} (\Delta n_1 + \Delta n_2). \tag{20}
\]

Now, substituting the expressions for \(\Delta f_1, \Delta f_2, \Delta n_1, \Delta n_2, \phi\) and \(\psi\) into equation (17) and using the condition (13), we obtain
\[ \delta f_2 + \delta f_1 \mu + \left[ \frac{4\pi e^2}{m_0 k^2} (\delta n_2 + \delta n_1 \mu) + \frac{e^2}{2m_0^2 \omega_i^2} \cos(\phi) \omega + \alpha_i \alpha_s \delta n \right] \frac{\vec{k} \cdot \frac{\partial f_a}{\partial \nu} \cdot \vec{v}}{(\omega - \vec{k} \cdot \vec{v})} = 0, \]  

(21)

where \( \mu = \sin(\vec{k} \cdot \vec{r} - \omega t)/\sin(\vec{k} \cdot \vec{r} - \omega t + \delta) \). For \( \delta = 0 \) and \( \pi, \mu = \pm 1 \), while at the other values of \( \delta \) we have to find the average \( \langle \mu \rangle = \mu_a \) over the time scale \( T = 2\pi/\omega \). Therefore, we have

\[ \delta f_2 + \delta f_1 \mu = \frac{4\pi e^2}{m_0 k^2} \left[ \delta n_2 + \delta n_1 \mu + \frac{e^2 k^2}{8\pi m_0^2 \omega_i^2} \right] \frac{\vec{k} \cdot \frac{\partial f_a}{\partial \nu} \cdot \vec{v}}{(\omega - \vec{k} \cdot \vec{v})}, \]  

(22)

where \( A = (\mu_a \cos \phi + \alpha_i \alpha_s) \delta n \). The sum of density perturbations \( \delta n_2 + \delta n_1 \mu \) can be estimated as

\[ \delta n_2 + \delta n_1 \mu = \int_{-\infty}^{\infty} n_0 (\delta f_2 + \delta f_1 \mu) d\vec{v} = - \left[ \delta n_2 + \delta n_1 \mu + \frac{e^2 k^2}{8\pi m_0^2 \omega_i^2} A \right] \chi, \]  

(23)

where

\[ \chi = \frac{\omega_i^2}{k^2} \int_{-\infty}^{\infty} \frac{\vec{k} \cdot \frac{\partial f_a}{\partial \nu} \cdot \vec{v} \\delta \nu}{(\omega - \vec{k} \cdot \vec{v})} d\vec{v}, \]  

(24)

is the susceptibility function (Liu & Kaw 1976; Fried & Conte 1961). Using \( \eta = \delta n_2/\delta n_1 \), we can write

\[ \left( 1 + \frac{1}{\chi} \right) (\eta + \mu_a) \delta n_1 = - \frac{e^2 k^2}{8\pi m_0^2 \omega_i^2} A. \]  

(25)

Multiplying equation (12) by \( e_i \mu_a \) and equation (14) by \( \alpha_i \varepsilon_i \), and adding we get

\[ (\alpha_i \alpha_s + \mu_a \cos \phi) \varepsilon_s = \frac{2\pi e^2}{m_0} \frac{\omega}{\omega_i} \varepsilon_i (\mu_a + \alpha_i \eta) \delta n_1 / D_s, \]  

(26)

where \( \varepsilon_s = \varepsilon_{sx} \) and \( \varepsilon_s = \varepsilon_{sz} \).

Now, using equations (25) and (26), we obtain the dispersion relation for stimulated Raman scattering:

\[ \left( 1 + \frac{1}{\chi} \right) (\eta + \mu_a) = \frac{e_i^2 k^2}{4 \omega_i} \frac{\mu_a + \alpha_i \varepsilon_i}{2} \frac{1}{\omega_i} \frac{1}{D_s}, \]  

(27)

where \( e_i = e_i \sqrt{1 + \alpha_i^2} / m_0 \omega_i \) is the quiver velocity of plasma particles due to the electric field of incident electromagnetic wave.

If \( L = L_{30} \times 10^{30} \) erg s\(^{-1}\) is the luminosity of pump radiation with frequency \( \omega_i = 2\pi v_i = \nu_{10} \times 10^{10} \) rad s\(^{-1}\) at a distance \( r = r_8 \times 10^8 \) cm from the source then

\[ v_0 = \frac{e}{m_0 \omega_i} \left( \frac{2L}{r^2 c} \right)^{1/2} = 4.3 \times 10^9 \left( \frac{L_{30}}{r_8} \right)^{1/2} \text{ cm s}^{-1}. \]  

(28)

When the phase matching conditions are met, the instability becomes more efficient, and \( D_s = 2\omega \omega_i - \omega^2 - 2c^2 k_i k + c^2 k^2 \approx 0 \) represent the dispersion relation of the Stokes mode.

The thermal speed \( v_t \) of the plasma can be expressed in terms of its energy spread in the laboratory frame. Let \( v_\pm = c(1/\gamma^2 \pm 1)^{1/2} \) be the velocity of electron-positron plasma, then the velocity spread \( \delta v_\pm \) is given by (Hasegawa 1978; Gangadhara & Krishan 1992)

\[ \delta v_\pm \approx c \frac{\delta \gamma_\pm \gamma}{\gamma^3} \quad \text{for} \quad \gamma \gg 1. \]  

(29)

Now, using the Lorentz transformation of velocity, we can show that

\[ \delta v_\pm = \delta v_t = c \frac{\delta v'_t}{\gamma^2 (1 + v_\pm v'_t/c^2)} \approx \frac{\delta v'_t}{\gamma^2} = \frac{v_t}{\gamma^2}. \]  

(30)

because \( v'_t = 0 \). Hence the thermal speed, in the plasma frame, is given by

\[ v_t = c \frac{\delta \gamma_\pm}{\gamma}. \]  

(31)

For \( \gamma_\pm = 10^3 \), we get \( v_t = 3 \times 10^3 \delta \gamma_\pm \) cm s\(^{-1}\).

If we separate equation (27) into real and imaginary parts, we get two coupled simultaneous equations. By solving them numerically, we find the growth rate \( \Gamma \) of stimulated Raman scattering. Figure 2 shows the growth rate as function of \( r_8 \) and \( \omega_i/\omega_p \). Since the plasma density decreases with \( r \) as \( 1/r^3 \), growth rate decreases as \( r_8 \) increases. Also, if the radiation frequency becomes higher than the plasma frequency, then radiation and plasma do not couple resonantly, which leads to the decrease of growth rate at higher values of \( \omega_i/\omega_p \).
Figure 2. The growth rate $\Gamma$ of stimulated Raman scattering is plotted with respect to $r_B$ and $\omega_i/\omega_p$.

To study the variation of $\Gamma$ in the $\alpha_i - \delta\gamma$ plane, we have made a contour plot (Fig. 3), the labels on the contours indicate the values of $\log(\Gamma)$. Debye length increases with the increase of $\delta\gamma$, therefore, plasma wave experiences a large Landau damping, which leads to the drop in growth rate. The parameter $\alpha_i$ is the ratio of amplitudes of electromagnetic waves, which are polarized in the directions parallel and perpendicular to the $\vec{k}_i - \vec{B}$ plane. When $\alpha_i$ is small, the wave polarized in the direction parallel to $\vec{k}_i - \vec{B}$ plane becomes strong and will have a component along $\vec{B}$. Therefore, the coupling between radiation and plasma will be strong, which leads to the higher growth rate at the smaller values of $\alpha_i$.

Figure 3. Contour plot of $\Gamma$ in the $\delta\gamma - \alpha_i$ plane. The labels on the contours indicate the $\log(\Gamma)$ values.

For $\omega \ll c^2 \vec{k}_i \cdot \vec{k}/\omega_i$, Stokes mode becomes resonant, and anti-Stokes mode becomes non–resonant. Then the equation (27) can be written as
\[ (\omega - \omega_i + i\Gamma) (\omega - \omega_i + i\Gamma_s)(\eta + \mu_a) = -10^{18} \frac{L_{30}}{r_8^{1/2} \nu_{10}} \frac{(\mu_a + \alpha_i^2 \eta)}{(1 + \alpha_i^2)} \ \text{rad}^2 \ \text{s}^{-2}, \]  
(32)

where \( \omega_i^2 = \omega_p^2 + (3/2)k^2v_i^2 \), and

\[ \Gamma_l = \frac{\sqrt{2}}{2} \left( \frac{\omega_p}{k\lambda_D} \right)^2 \left[ \frac{1}{2(k\lambda_D)^2} - \frac{3}{2} \right] + \nu_c, \]  
(33)

is the damping rate of the plasma wave, and the Debye length \( \lambda_D = v_i/\sqrt{2}\omega_p \). For \( k\lambda_D \sim 1 \), we find \( \Gamma_l \approx 2.5 \times 10^9 r_8^{3/2} \ \text{s}^{-1} \). The pair plasma collision frequency \( \nu_c \approx 2.5 \times 10^{-3} \ln \Lambda/r_8^3 \delta^{-3} \ \text{s}^{-1} \) and Coulomb logarithm \( \ln \Lambda \approx 10 \). The collisional damping rate of the scattered electromagnetic wave is given by \( \Gamma_s = \omega_p^2 \nu_c/2\omega_p^2 \approx 0.06/\nu_{10}^2 r_8^6 \delta^{-3} \ \text{s}^{-1} \).

For \( k\lambda_D > 1 \), plasma waves are highly damped and hence plasma loses its collective behaviour. Therefore, stimulated Raman scattering changes into the induced Compton scattering of electromagnetic waves by the plasma particles. In the conventional treatment of induced Compton scattering in pulsars (e.g., Blandford & Scharlemann 1976; Sincell & Krolik 1992) the collective effects of the plasma are ignored. The collective treatment of the wave scattering by plasma particles is justified if the condition \( k\lambda_D \ll 1 \) or \( v_{ph} >> v_i \) is met, where \( v_{ph} = \nu_p/k \) is the phase velocity of the plasma wave. This condition implies that the wave number of oscillation of the electrons in the beat wave of the incident and scattered waves be much less than the inverse of the Debye length. It is not satisfied, when the beat wave is strongly Landu damped (\( k\lambda_D > 1 \)) or the beat wave will not feel the presence of a medium (\( k\lambda_D \gg 1 \)), so that the scattering process will be described as induced Compton scattering.

When \( k\lambda_D \ll 1 \), by setting \( \omega = \omega_i + i\Gamma \), we can solve equation (32) for the growth rate:

\[ \Gamma = \frac{1}{2}(\Gamma_l + \Gamma_i) \pm \frac{1}{2} \sqrt{(\Gamma_l - \Gamma_i)^2 + 4.3 \times 10^{18} \frac{L_{30}}{r_8^{1/2} \nu_{10}} \frac{(\mu_a + \alpha_i^2 \eta)}{(1 + \alpha_i^2)(\eta + \mu_a)}}, \]  
(34)

Stimulated Raman scattering is a threshold process: if the intensity of the pump exceeds the threshold, then only it would start converting its energy into the decay waves. The threshold condition for the excitation of stimulated Raman scattering is given by

\[ \left( \frac{L_{30}}{r_8^8} \right)_{thr} = 9.3 \times 10^{-19} \nu_{10}^2 r_8^{3/2} \Gamma_i \Gamma_s \frac{(1 + \alpha_i^2)(\eta + \mu_a)}{(\mu_a + \alpha_i^2 \eta)}. \]  
(35)

The typical threshold intensities for stimulated Raman scattering are of the order of the observed intensities, implying that pulsar magnetosphere may be optically thick to Raman scattering of electromagnetic waves.

The growth rate just above the threshold is given by

\[ \Gamma = 4.3 \times 10^8 \frac{L_{30}}{r_8^{1/2} \nu_{10}} \frac{(\mu_a + \alpha_i^2 \eta)}{(1 + \alpha_i^2)(\eta + \mu_a)} \ \text{s}^{-1}, \]  
(36)

which is proportional to \( L_{30} \). The maximum growth rate attainable for \( \omega_p > \Gamma > \Gamma_l \), on the other hand, is

\[ \Gamma = 10^9 \sqrt{\frac{L_{30}}{\nu_{10}^2 r_8^8} \frac{(\mu_a + \alpha_i^2 \eta)}{(1 + \alpha_i^2)(\eta + \mu_a)}}, \]  
(37)

3 STOKES PARAMETERS

When the phase matching conditions are satisfied, the growth rate \( \Gamma \) becomes large, and the scattered mode is amplified and become a normal mode of the plasma. Under some conditions, the scattered mode leaves the plasma with polarization which may be different from the polarization of the incident wave. The polarization states of the incident and scattered waves can be described more accurately using the Stokes parameters (Rybicki & Lightman 1979):

\[ I_j = \varepsilon_{ij} \varepsilon_{*ij}^* + \varepsilon_{ij} \varepsilon_{*ij}^*, \]  
(38)

\[ Q_j = \varepsilon_{ij} \varepsilon_{*ij}^* - \varepsilon_{ij} \varepsilon_{*ij}^*, \]  
(39)

\[ U_j = 2\varepsilon_{ij} \varepsilon_{*ij}^* \cos(\delta_j), \]  
(40)

and

\[ V_j = 2\varepsilon_{ij} \varepsilon_{*ij}^* \sin(\delta_j), \]  
(41)

where \( j = i \) for the incident wave, and \( s \) for the scattered wave. The linear polarization is given by

\[ L = \sqrt{U_j^2 + Q_j^2}, \]  
(42)

© 0000 RAS, MNRAS 000, 000–000
and the polarization position angle is given by
\[ \chi_j = \frac{1}{2} \arctan(U_j/Q_j). \] (43)

The transfer of energy between the modes will be efficient only when the energy of the pump wave is strong enough to overcome the damping losses or escape of the generated waves. Using the Manley–Rowe relation (Weiland & Wilhelmsson 1977)
\[ \frac{I_i}{\omega_i} = \frac{I_s}{\omega_s}, \] (44)
we find the relation between the incident flux \( I_i \) and the scattered flux \( I_s \):
\[ I_s = \left(1 - \frac{\omega}{\omega_i}\right)I_i. \] (45)

In the following two subsections, we consider the cases where the polarization state of the incident wave is linear and circular, and compute the polarization states of the scattered mode.

### 3.1 Linearly polarized incident wave

Consider a linearly polarized electromagnetic wave (\( \delta_i = 0 \), \( \alpha_i = 10 \) and \( \chi_i = 90^\circ \)), which excites stimulated Raman scattering in the magnetospheric plasma. Using the plasma and magnetic field parameters discussed in the previous section, we computed the growth rate of stimulated Raman scattering. For \( k\lambda_D \ll 1 \), the instability becomes quite strong and the Landau damping of Langmuir wave is minimal. Hence, the stimulated Raman scattering is resonantly excited. Figure 4 shows the behaviour of linear (solid line) and circular (broken line) polarization of scattered mode with respect to \( \eta \). It shows at some values of \( \eta \), which are close to 0.1, the linear polarization of the incident wave can be converted almost completely into circular polarization of scattered wave. Charge density variations within the pulse window could enhance the conversion efficiency of linear to circular polarization to vary.

![Figure 4](image)

**Figure 4.** The solid line and broken line curves indicate the variation of linear \( (L_s) \) and circular \( (V_s) \) polarization of the scattered mode with respect to \( \eta \). The normalizing parameter \( I_s \) is the intensity of scattered mode.

The variation of polarization angle of the scattered wave with respect to \( \eta \), at different values of \( \delta \), is shown in Fig. 5. For \( \delta = 90^\circ \) and \( \eta \leq 0.1 \), the scattered mode becomes orthogonally polarized with respect to the incident wave. Furthermore, if there is any variation in the plasma density or radiation intensity, the value of \( \eta \) fluctuates and the scattered modes produced with \( \eta \leq 0.1 \) become orthogonally polarized with respect to those produced with \( \eta > 0.1 \).

© 0000 RAS, MNRAS 000, 000-000
3.2 Circularly polarized incident wave

Suppose that the incident wave is circularly polarized ($\delta_i = \pi/2$ and $\alpha_i = 1$) then the scattered mode will be linearly polarized for $\eta \leq 0.2$, while at the other values, both linear and circular polarizations with different proportion exist, as indicated by Fig. 6. For $\delta_i < 0$ and $\delta_s = \delta_i - \delta < 0$ the sense of circular polarization of the scattered mode becomes opposite to that of the incident wave. Hence depending upon the plasma and radiation conditions, stimulated Raman scattering can change the polarization of the pulsar radio signals.

Figure 6. The variation of linear ($L_s$) and circular ($V_s$) polarization of the scattered mode, with respect to $\eta$, are indicated by the solid line and broken line curves. The normalizing parameter $I_s$ is the intensity of the scattered mode.
The variable nature of circular polarization is evident from the polarization distributions by Manchester, Taylor and Huguenin (1975), Backer and Rankin (1980) and Stinebring et al. (1984a,b). Very high degrees of circular polarization are occasionally observed in individual pulses, even up to 100 per cent (Cognard et al. 1996), while the integrated or average pulse profiles generally indicate much smaller degree of circular polarization (e.g., Lyne, Smith & Graham 1971), which show that the sign of circular polarization is variable at any given pulse phase. Radhakrishnan and Rankin (1990) have identified two extreme types of circular polarization in the observations: (a) an antisymmetric type wherein the circular polarization changes sense in midpulse, and (b) a symmetric type wherein it is predominantly of one sense. The correlation of sense of antisymmetric type of circular polarization with the polarization angle swing indicates the geometric property of emission process, and is highly suggestive of curvature radiation.

The diverse nature of circular polarization may be the consequence of pulsar emission mechanism and the subsequent propagation effects in the pulsar magnetosphere (e.g., Melrose 1995; von Hoensbroech, Lesch and Kunzl 1998). It seems rather difficult to explain the various circular polarization behaviours using the widely accepted magnetic pole models (e.g., Radhakrishnan & Cooke 1969; Komesaroff 1970; Sturrock 1971; Ruderman & Sutherland 1975).

The symmetric type of circular polarization observed in some pulsars (e.g., PSR B1914+13, 0628-28) as shown in Figs. 7 and 8, may be due to the propagation effects. However, it seems difficult for propagations effects to explain, how the sign of the circular polarization can change precisely at the center of the pulse in the case of antisymmetric type, as seen in many pulsars e.g., PSR B1859+03 and B1933+16 (Rankin, Stinebring & Weisberg 1989).

Figure 7. PSR B0628-28, an example of a pulsar with ‘symmetric’ circular polarization and high linear polarization (From Lyne & Manchester 1988).

If we are to understand the radio emission mechanism, we must understand the physical state of the radio-loud plasma in the polar cap. It is this plasma that is the site of instabilities which are thought to produce coherent radio emission. The role of different propagation effects on the pulsar polarization has been discussed by Cheng and Ruderman (1979), Beskin, Gurevich and Istomin (1988) and Istomin (1992). The mechanisms proposed by these authors predict a frequency dependence for circular polarization, with weaker polarization at higher frequencies. This is seen in some pulsars (e.g., PSR B0835-41, 1749-28, 1240-64) but it is not generally the case (Han et al. 1998). Istomin suggested that the linearly polarized incident wave becomes circularly polarized as a result of generalized Faraday rotation, however, it is observationally known that no generalized Faraday rotation is evident in pulsar magnetospheres (Cordes 1983; Lyne & Smith 1990).
We have presented a model to explain the polarization changes due to the propagation of radio waves through the magnetospheric plasma. The features like a large change in polarization angle, sense reversal of circular polarization and extremely rapid temporal changes in intensity would help us to explain many observations, for which, the existing mechanisms proved to be inadequate. Because of the very strong dependence of polarization angle on plasma parameters via the growth rate, in an inhomogeneous plasma medium the depolarization is a natural outcome. We believe that the plasma process such as the stimulated Raman scattering may be a potential mechanism for the polarization variability in pulsars. The circular polarization of a number of pulsars varies with frequency. The two clear examples are PSR B1240-64 and 2048-78, from which the opposite senses or transitions of circular polarization have been observed at lower and higher frequencies (Han et al. 1998).

5 CONCLUSION

We considered the stimulated Raman scattering of the transverse electromagnetic waves in the electron-positron plasma of pulsar magnetosphere. The value of radiation–plasma coupling parameter $\eta$ is determined by the polarization of the incident wave, and its value can be determined only by the nonlinear analysis. In the process of three-wave interaction, the phase matching condition (equation 13) between the initial phases ($\delta_i, \delta_s, \delta$) and the value of $\eta$ determine the polarization state of the scattered wave.

Many short time scale polarization variabilities, in individual pulses, such as variations in amount of linear and circular polarization, sense reversal of circular polarization and polarization angle swings can be accounted for by considering the stimulated Raman scattering. The time scales over which the changes takes place, in individual pulses, are of the order of e-folding time, which is the inverse of the growth rate of stimulated Raman scattering.

It seems rather unlikely that the diverse behaviour of circular polarization can be accounted for by a single mechanism. Both intrinsic emission and propagation effects seem possible. The strong symmetric type of circular polarization observed in some pulsars is most probably generated by propagation effects, such as the stimulated Raman scattering. Further simultaneous observations over a wide frequency range would be valuable in sorting out the importance of propagation effects.
ACKNOWLEDGMENTS

We are grateful to Y. Gupta and A. von Hoensbroech for discussions and comments.
