Anomalies are a powerful way to gain insight into possible lattice regularizations of a quantum field theory. In this work, we argue that the continuum anomaly for a given symmetry can be matched by a manifestly-symmetric, local, lattice regularization in the same spacetime dimensionality only if (i) the symmetry action is offsite, or (ii) if the continuum anomaly is reproduced exactly on the lattice. We consider lattice regularizations of a class of prototype models of QCD: the (1+1)-dimensional asymptotically-free Grassmannian nonlinear sigma models (NLσMs) with a $\theta$ term. Using the Grassmannian NLσMs as a case study, we provide examples of lattice regularizations in which both possibilities are realized. For possibility (i), we argue that Grassmannian NLσMs can be obtained from SU($N$) antiferromagnets with a well-defined continuum limit, reproducing both the infrared physics of $\theta$ vacua and the ultraviolet physics of asymptotic freedom. These results enable the application of new classical algorithms to lattice Monte Carlo studies of these quantum field theories, and provide a viable realization suited for their quantum simulation. On the other hand, we show that, perhaps surprisingly, the conventional lattice regularization of $\theta$ vacua due to Berg and Lüscher reproduces the anomaly exactly on the lattice, providing a realization of the second possibility.

I. INTRODUCTION

The Standard Model of particle physics, and in particular the strong sector described by quantum chromodynamics (QCD), has many physically relevant yet so-far inaccessible regimes beyond perturbation theory. While non-perturbative methods such as lattice field theory using classical Monte Carlo (MC) methods have been used with remarkable success, many problems of interest such as real-time dynamics, finite-density or nontrivial $\theta$ vacua remain inaccessible. Recently, the growth of quantum technologies has opened up the possibility of exploring these questions. However, the infinite-dimensional local Hilbert space of standard bosonic lattice field theories limits their applicability to near-term quantum platforms with low qubit counts. This has motivated a search for unconventional lattice regularizations of quantum field theories (QFTs) with finite-dimensional local Hilbert spaces. New lattice regularizations of a given QFT can also provide solutions to sign problems and enable application of cluster algorithms. Success in low-dimensional asymptotically-free prototypes of QCD establishes a route towards developing new tools for lattice studies of QCD, both on classical and quantum hardware [1–35].

If one goes beyond naive discretizations of the continuum Hamiltonian (and perturbative improvements thereof), then the space of possible lattice regularizations of a given QFT is immense. In general, a lattice regularization for a given QFT is any lattice Hamiltonian (or action) which has the correct quantum critical point and relevant parameter (in the renormalization group (RG) sense). We might ask: how do we find new lattice regularizations, perhaps with unique advantages for quantum and classical simulations? While it is clear that symmetries are an important part of this story, the point of view of this work is that this search can be refined by considerations of anomalies.

To make this concrete, in this work, we consider lattice regularizations of a certain class of (1+1)-dimensional nonlinear sigma models (NLσMs) with a $\theta$ term, called the Grassmannian $\text{Gr}_k(N)$ NLσMs, which are well-known prototypes of QCD. These are NLσMs with the target space

$$\text{Gr}_k(N) = U(N)/[U(k) \times U(N-k)],$$

formally defined by the continuum action

$$S = \frac{1}{g^2} \int d^2x \text{Tr}(\partial_\mu P)^2 + \frac{\theta}{4\pi} \int d^2x \epsilon^{\mu
u} \text{Tr} P \partial_\mu P \partial_\nu P$$

(2)

where $P(t,x) \in \text{Gr}_k(N)$ is an $N \times N$ Hermitian projector matrix such that $P^2 = P = P^\dagger$ and $\text{Tr} P = k$. Important examples of this class are the $k = 1$ models, which are also known as CP($N-1$) models. All these models are asymptotically-free, have a dynamically generated mass scale, and admit a $\theta$ term. The $\text{Gr}_1(2) = \text{CP}(1)$ case, also called the O(3) NLσM, has been particularly important as a testbed for developments in lattice QCD.

A majority of the lattice work in understanding these models has used the lattice formulation which is a direct discretization of Eq. (2), which we refer to as the “conventional” lattice regularization. In this regularization, a
satisfactory topological definition of the \( \theta \) term was proposed by Berg–Lüscher for the CP\((N-1)\) model. While it has nice topological properties, a lattice MC study of general \( \theta \) vacua has been limited by a severe sign problem at \( \theta \neq 0 \), except in special cases. (It can be somewhat alleviated for the O(3) model using a meron cluster formulation [36–38].)

Recently, another type of lattice regularization was proposed: as an antiferromagnetic model of qubits [31], such that a controlled continuum limit at arbitrary \( \theta \) can be taken by adding a small extra dimension. We call this a “qubit” regularization. Not only is this a very natural regularization of the \( \theta \) vacua on quantum computers, it also does not suffer from a sign problem at nontrivial \( \theta \) for classical MC computations. However, it does not have manifest topological properties, which only become apparent as one takes the continuum limit. Therefore, both these types of regularizations have their own advantages.

In this work, we take a step back and attempt to understand these two types of regularizations from the point of view of anomalies. In particular, these models have an \( \text{\textquoteleft}t \text{Hooft} \) anomaly at \( \theta = \pi \) [39], which presents obstructions for certain kinds of symmetric lattice regularizations. The obstruction from the anomaly can manifest on the lattice in two ways, and we argue that the two above-mentioned regulators correspond to precisely these two ways.

The presence of an anomaly for a given symmetry \( G \) implies that for a \( G \)-symmetric lattice regularization, the symmetry cannot be both manifest and onsite. (We give a more detailed argument and explain our definitions in Section II.) A \( G \)-anomaly in the continuum theory implies that it should be impossible to gauge \( G \) – this should also be true on the lattice. If the symmetry is offsite, then it cannot be gauged in the usual manner, and therefore the constraint is satisfied. On the other hand, if the symmetry is onsite, then the only way for the lattice regularization to match the anomaly is to explicitly reproduce the anomaly.

We can now place the two regularizations of the CP(1) or the O(3) model in this framework. Here the anomaly is for \( G = \text{SO(3)} \times \text{C} \), where \( \text{C} \) is charge conjugation. This particular anomaly is especially interesting since an analogous anomaly exists for 3+1-dimensional SU(\( N \)) Yang-Mills at \( \theta = \pi \) [39].

The qubit regularization of the \( \theta \) term is of the first kind. Starting from the theory at \( \theta = \pi \), \( \text{C} \) is realized offsite as a translation-by-one symmetry. Therefore, we can tune \( \theta \) away from \( \pi \) by simply breaking the translation symmetry, which can be done by introducing staggered couplings. This generates a \( \theta \) term for the low-energy effective theory.

On the other hand, the conventional regularization with the Berg–Lüscher \( \theta \) term in fact does have an exact \( G \) symmetry with onsite action. As argued above, this should imply that this regularization exhibits the anomaly exactly on the lattice. As we show in this work (see Section IV), this is indeed the case. This is perhaps surprising since it is often assumed that there are no anomalies on the lattice. A gauging procedure, much like the one used to derive the anomalies in the continuum, works for the lattice theory and reproduces the anomaly. In fact, our derivation can also be thought of as an independent computation of the anomaly, using a well-defined lattice model. Therefore, this well-known regularization is an example of the second possibility.

More recently, another illuminating perspective has come in the language of symmetry-protected topological (SPT) phases. \( \text{\textquoteleft}t \text{Hooft} \) anomalies in a \( D \)-dimensional (Euclidean) theory correspond to SPT phases of a \((D+1)\)-dimensional theory, which is the so-called bulk/boundary correspondence [40]. From this point of view, a \( D \)-dimensional theory with an \( \text{\textquoteleft}t \text{Hooft} \) anomaly can naturally arise on the boundary of a \((D+1)\)-dimensional nontrivial SPT phase. However, there are obstructions when trying to formulate theory in a manifestly \( D \)-dimensional setup. Refs. [41–43] have attempted to formulate the Nielsen–Ninomiya theorem in the language of SPT phases. Their claim is that it is impossible to obtain a local, symmetric, manifestly \( D \)-dimensional lattice regularization of the boundary theory. However, as we argue, their conclusions are somewhat incomplete. It is in fact not impossible to obtain a manifestly \( D \) dimensional local realization of the boundary of an SPT phase. The “no-go” theorem can be avoided in a rather direct way: the lattice theory can manifestly exhibit the anomaly.

In the condensed matter literature, some of this has been long appreciated in the context of Lieb–Schultz–Mattis–Oshikawa–Hastings (LSMOH) theorems. In particular, the connection between LSMOH and anomalies has been delineated in Refs. [44, 45]. It is pointed out in Ref. [45], that if a \( D \)-dimensional (Euclidean) continuum theory with a \( G \)-anomaly is known to arise as the low-energy effective theory of a \( D \) dimensional lattice model, then either (i) \( G \) must be offsite, or (ii) \( G \) must not be an exact symmetry of the lattice model. This is sometimes phrased as a “no-go” theorem. Here we show that there is another possibility which is often missed: the symmetry is both onsite and exact, but the lattice theory explicitly has the anomaly.

There have been several other recent examples of anomalies on the lattice. For example, this has been shown for Kähler–Dirac fermions on triangulated lattices [46–50]. In the case of chiral fermions, formulations satisfying the Ginsparg–Wilson relation have been shown to reproduce the anomaly on the lattice for a modified chiral symmetry [51–54].

This manuscript is organized as follows. In Section II, we present our general arguments regarding lattice regularizations for theories with anomalous symmetries, and present an overview of the two examples of lattice regularizations which we consider in this work, explaining how they realize the anomalies in different ways. Then in Section III, we discuss a “qubit” regularization, with finite-dimensional local Hilbert spaces, of the Grassman-
nian nonlinear sigma models. Then in Section IV, we discuss lattice regularizations exhibiting the anomalies explicitly, including a generalization of the well-known regularization of the $\theta$-term in $\text{CP}(N-1)$ models due to Berg–Lüscher to the $\text{Gr}_k(N)$ models. Finally, in Section V, we summarize our results and comment on some future directions.

II. OBSTRUCTIONS TO LATTICE REGULARIZATIONS FROM ANOMALIES

One of the aims of this work is to emphasize how obstructions to regulating a theory on the lattice arising from anomalies guide us in constructing new lattice regularizations.

In this work, we always refer to “anomaly” in the sense of an ‘t Hooft anomaly: a symmetry $G$ is said to be ‘t Hooft anomalous if it cannot be consistently gauged. We emphasize that $G$ is a genuine symmetry of the theory, and that the presence of an ‘t Hooft anomaly does not indicate an inconsistency of the theory. We shall also confine our attention to internal symmetries.

In many cases of interest, the $G$ anomaly has a bit more structure. If $G$ is generated by two subgroups $G_1, G_2$ such that there is no obstruction to gauging $G_1$ or $G_2$ individually, but gauging $G_1$ breaks $G_2$, or vice versa, then we say there is a mixed anomaly between $G_1$ and $G_2$. In other words, $G_1$ and $G_2$ cannot be gauged simultaneously. In all the cases we consider in this work, we always have a mixed anomaly, although the arguments apply more generally.

From the point of view of lattice regularizations, the presence of an ‘t Hooft anomaly shows up as an obstruction to constructing certain type of lattice regularizations: an anomaly in $G$ for a $D$-dimensional continuum theory implies that we cannot have a $D$-dimensional $G$-symmetric lattice regularization with $G$ both manifest and onsite.

By a “manifest” symmetry, we mean an exact symmetry of the theory which is also an invariance of the action. In contrast, a nonmanifest symmetry is one where the action is noninvariant, but all correlation functions are invariant. We emphasize that in both cases, we are referring to an exact symmetry of the theory.

By an “onsite” symmetry, we mean that the symmetry group acts on the full Hilbert space as a tensor product of representations on the local Hilbert spaces. (In bosonic field theories, the full Hilbert space of a lattice model naturally admits a factorization as a tensor product of Hilbert spaces at each lattice site, which we call the local Hilbert space.) We shall also say that a non-onsite symmetry is “offsite.”

If the symmetry $G$ were manifest and onsite, then we could trivially gauge them both on the lattice by introducing appropriate link variables, and this would violate the anomaly. Therefore, a local $G$-symmetric $D$-dimensional lattice regulator for a theory with a $G$ anomaly must

(i) realize $G$ offsite, or

(ii) realize $G$ onsite but nonmanifestly.

Another widely-appreciated possibility is that the $D$-dimensional theory arises as the boundary theory of a $(D+1)$-dimensional lattice model in an spt phase [40, 43, 55]. In such cases, it is possible to obtain a lattice regulator with an exact onsite symmetry, albeit at the cost of introducing an extra dimension. Yet another possibility is to consider lattice regulators in which $G$ is not a symmetry microscopically but arises at large distances. In this work, we only consider symmetric lattice regulators in $D$ spacetime dimensions, in which case we have only the two possibilities listed above.

As mentioned in the introduction, while possibility (i) is well-known, especially in the context of LSMOH theorem in condensed-matter literature [44, 45], possibility (ii) is often missed. Indeed, the anomaly implies that there must somehow be an obstruction to gauging $G$, while if $G$ acts onsite, there seems to be no obstruction to turning on a background gauge field for it. The only possibility, therefore, seems to be that the dependence on the background gauge field cannot be gauge invariant, which is to say that the lattice regulator must

(ii*) explicitly exhibit the anomaly.

Indeed, this will be the case in the examples discussed in Section IV. It is also the case in the modified Villain models [56–59]. We should also note that it may be possible for a lattice regulator with offsite symmetry to also explicitly exhibit an anomaly, such as Ginsparg–Wilson fermions [43, 52].

In this work, we provide examples for both scenarios (i) and (ii), using the $(1 + 1)$-dimensional $\text{Gr}_k(N)$ $\text{NLσM}$ as a case study.

A. O(3) nonlinear sigma model

To simplify the discussion a bit, let us first consider the case of $\text{Gr}_1(2) = \text{CP}(1)$, or the $\text{O}(3)$ model with a $\theta$ term. This model can be formulated in terms of a unit 3-vector field $\vec{n}(x)$ with Euclidean action

$$S = \frac{1}{2g^2} \int d^2x (\partial_\mu \vec{n})^2 + \frac{i\theta}{8\pi} \int d^2x e^{i\nu} \vec{n} \cdot (\partial_\mu \vec{n} \times \partial_\nu \vec{n}).$$

At any $\theta$, the theory has a global $\text{SO}(3)$ symmetry. At $\theta = 0, \pi$ it also has a charge conjugation symmetry,

$$C: \vec{n}(x) \mapsto -\vec{n}(x).$$

At $\theta = \pi$, this theory has a mixed anomaly between $\text{SO}(3)$ and $C$ symmetries [39]. The above argument then implies that a lattice regularization of the $\theta = \pi$ $\text{O}(3)$ $\text{NLσM}$ must either realize $\text{SO}(3) \times C$ offsite, or it must explicitly exhibit the anomaly.
One lattice regularization of the \( O(3) \) NLσM is provided by the spin-\( \frac{1}{2} \) Heisenberg antiferromagnet
\[
H = J \sum_{\langle ij \rangle} \vec{S}_i \cdot \vec{S}_j,
\]
where \( \vec{S}_i \) are spin-\( \frac{1}{2} \) operators and the sum runs over nearest neighbor sites \( i, j \). In one spatial dimension, this is famously known to be described by the \( O(3) \) NLσM at \( \theta = \pi \) at low energies [60–62]. Interestingly, this can be thought of as not just a low-energy effective field theory (EFT) but also a genuine lattice regularization by adding a small extra dimension of size \( L' \) (odd) in the D-theory formulation [5, 6, 14, 15]. As shown in Refs. [31, 63], the continuum limit of the \( O(3) \) model at \( \theta = \pi \) can be obtained by taking \( L' \to \infty \) (odd). This not only reproduces the physics of \( \theta = \pi \) in the infrared (IR), but also the asymptotic freedom in the ultraviolet (UV).

In this regularization, the \( SO(3) \) symmetry is clearly manifest onsite, and therefore can be gauged easily. However, the continuum charge conjugation symmetry acts on the lattice as translation by one unit [64]
\[
C: \vec{S}_i \mapsto \vec{S}_{i+1}
\]
and therefore realizes possibility (i) of the above theorem.

It is especially interesting to consider the case of a widely-used lattice regularization of the \( O(3) \) NLσM on a two-dimensional Euclidean spacetime lattice, given by the following action at \( \theta = \pi \):
\[
S_0[\vec{n}] = -\frac{1}{g^2} \sum_{\langle ij \rangle} \vec{n}_i \cdot \vec{n}_j
\]
where the \( \vec{n}_i \) are real unit 3-vectors and the sum runs over nearest neighbor sites \( i, j \) on a square lattice. In the \( g \to 0 \) limit, this defines a lattice regularization for the \( \theta = 0 \) theory. This has a manifest onsite \( G = SO(3) \times C \) symmetry, with \( C: \vec{n}_i \mapsto -\vec{n}_i \).

Let us now assume that there is a local \( G \) symmetric deformation of the action in Eq. (7) which allows us to switch on \( \theta = \pi \),
\[
S_{\theta=\pi}[\vec{n}] = S_0[\vec{n}] + S_1[\vec{n}],
\]
But if this were the case, we would be able to gauge \( G \), violating the constraint from the anomaly. Therefore, we conclude that it is impossible to obtain the \( \theta = \pi \) from Eq. (7) in this manner.

The above argument might at first glance lead one to think that there simply cannot be a lattice regularization of the \( \theta = \pi \) theory with onsite \( SO(3) \times C \) symmetry, but this would be too hasty. Indeed, there is a well-known construction of the \( \theta \) term on the lattice for the \( CP(2N - 1) \) models, due to Berg and Lüscher [65, 66], which is \( SO(3) \times C \) symmetric at \( \theta = 0, \pi \). In their formulation, the action of \( SO(3) \times C \) symmetry is onsite. The reason their formulation avoids the “no-go theorem” is that while the Boltzmann weight \( \exp(-S) \) is invariant under \( C \), the action itself is not. In this sense, the \( C \) invariance is not manifest in their formulation. (A similar point has been made by Ref. [57] in the context of modified Villain models.) Indeed, the same is true in the continuum formulation (7). A “no-go theorem” for this case can be therefore be phrased as

There cannot be a lattice regulator for the \( \theta = \pi \) \( O(3) \) NLσM with manifest onsite \( SO(3) \times C \) symmetry.

On the other hand, there is no obstruction to gauging \( SO(3) \). And if \( SO(3) \times C \) is an exact onsite symmetry of lattice theory such that \( SO(3) \) can be gauged, then the only way out is if the lattice theory explicitly produces the anomaly. As we will show in Section IV, this is indeed the case, giving us an example of possibility (ii) above.

B. Generalization to \( Gr_k(N) \) models

The previous discussion about the \( O(3) \) model can be generalized neatly to the general class of asymptotically-free \( Gr_k(N) \) models with a \( \theta \) term, given by the continuum action in Eq. (2). The \( P \) field transforms under the action of \( PSU(N) \) symmetry, as well as charge conjugation
\[
C: P(x) \mapsto P(x)^*.
\]
PSU(\( N \)) symmetry is present at any \( \theta \), while \( C \) symmetry is present only at \( \theta = 0, \pi \). As discussed in Appendix C, a continuum analysis of mixed anomalies between \( PSU(N) \) and \( C \) symmetries reveals [67]:

1. \( N = \text{even}, k = \text{odd} \): At \( \theta = \pi \), there is a mixed anomaly between \( PSU(N) \) and \( C \) symmetries.

2. Otherwise: There is a “global inconsistency” between the \( \theta = 0 \) and \( \theta = \pi \) theories.

For the first case, we have an immediate generalization of the above argument for the \( O(3) \) model. However, the second case results in a more subtle type of obstruction to lattice regularization.

A “global inconsistency” [39, 68, 69] between the \( \theta = 0, \pi \) continuum theories says that the action cannot be modified by a local symmetric counterterm such that both points are anomaly free. In other words, unlike the case \( (N, k) = (\text{even, odd}) \), we can remove the anomaly at \( \theta = \pi \), but at the cost of introducing an anomaly at \( \theta = 0 \). From the point of view of a lattice regularization, this suggests an interesting type of constraint. While, in principle, it is possible to have lattice regulators with manifest onsite \( PSU(N) \times C \) symmetry at both \( \theta = 0, \pi \) points, we have the following obstruction:

There cannot be a lattice regulator which allows one to continuously tune \( \theta \) from 0 to \( \pi \), such that at \( \theta = 0, \pi \) there is manifest onsite \( PSU(N) \times C \) symmetry.
To see this, let us assume that we have a lattice action \( S_0 \) which furnishes a lattice regularization of the \( \theta = 0 \) theory with a manifest onsite PSU(\( N \)) \( \times C \) symmetry. Now, let us further assume that there is a local PSU(\( N \)) symmetric perturbation \( K_\gamma \) parametrized by a continuously tunable parameter \( \gamma \in [0,1] \),

\[
S_\gamma = S_0 + K_\gamma
\]

The perturbation \( K_\gamma \) is such that \( K_0 = 0 \), and \( S_1 \) furnishes a regularization for the \( \theta = 1 \) theory. If \( K_1 \) is invariant under the onsite \( C \) action, then we can gauge PSU(\( N \)) symmetry such that \( C \) symmetry survives at both \( \theta = 0, \pi \). This contradicts global inconsistency, which requires that \( C \) be explicitly broken at either \( \theta = 0 \) or \( \theta = \pi \). Therefore, such a regulator cannot exist.

We present two kinds of regularizations in this work, generalizing the previous discussion of the CP(1) model to Gr(\( N \)) models. The first kind is based on SU(\( N \)) antiferromagnets, and realizes possibility (i), with an offsite implementation of the \( C \) symmetry. As in the CP(1) case \[31\], a \( \theta \) term can be introduced by staggering the couplings, and continuum limit can be taken with the D-theory prescription. We discuss the details in Section III.

In the second kind, we consider models on Euclidean spacetime lattices, such as the conventional lattice regularization of the Gr(N) models, with the \( \theta = 0 \) theory given by the lattice action

\[
S_0[P] = -\frac{1}{g^2} \sum_{(ij)} \text{Tr} P_i P_j
\]

where \( P_i \in \text{Gr}_k(N) \) are \( N \times N \) Hermitian projector matrices with \( P_i^2 = P_i \) and \( \text{Tr} P_i = k \). We generalize the construction of Berg–Lüscher and construct a lattice \( \theta \) term for this model. This model has an exact onsite PSU(\( N \)) \( \times C \) symmetry, therefore, this model must exhibit the anomaly explicitly on the lattice. Using a method very analogous to the continuum, we indeed find that this model reproduces the continuum anomaly exactly, and therefore provides an example of possibility (ii) of the no-go theorem. We provide details on the construction and the computation of the anomaly in Section IV.

III. A QUBIT REGULARIZATION OF GRASSMANNIAN MODELS

In this section, we propose a lattice regularization for the Grassmannian nonlinear sigma models with a \( \theta \) term using SU(\( N \)) antiferromagnets with staggered couplings, generalizing recent results for the CP(1) model [31].

The model is defined on a two-dimensional \( L_X \times L_Y \) square bipartite lattice. We denote the two sublattices as \( \Lambda \) and \( \bar{\Lambda} \). On sublattice \( \Lambda \), we place SU(\( N \)) spins in the representation \( R = (k,p) \) given by the rectangular Young tableau with \( k \) rows and \( p \) columns. On sublattice \( \bar{\Lambda} \), we place SU(\( N \)) spins in the conjugate representation \( \bar{R} = (N-k,p) \), as shown in Fig. 1. Different choices of the bipartitions can be considered. We show two such choices in Fig. 2. Given a choice of the bipartition and representations, we write the nearest-neighbor SU(\( N \)) symmetric Heisenberg Hamiltonian with staggered couplings

\[
H = \sum_{(x,y)} J_{x,y} T_{x,y}^\alpha T_{x+1,y}^\alpha + J' \sum_{(x,y)} T_{x,y}^\alpha T_{x,y+1}^\alpha
\]

where \( T_\alpha \) are the SU(\( N \)) generators (\( \alpha = 1,\ldots,N^2-1 \)) in representation \( R \) or \( \bar{R} \) depending on the site \((x,y)\), \( J_{x,y} \) are the couplings along the \( x \) direction, \( J' \) is the coupling along the \( y \) direction. As shown in Fig. 2, we consider the two configurations for staggering the couplings:

Alternating: \( J' > 0 \), \( J_{x,y} = J[1 + (-1)^{x+y} \gamma] \), \( \gamma > 0 \)

Columnar: \( J' < 0 \), \( J_{x,y} = J[1 + (-1)^{x} \gamma] \), \( \gamma > 0 \)

where \( J > 0 \) is always antiferromagnetic, and \( \gamma \) is the staggering parameter. Given a choice of bipartition \( \Lambda, \bar{\Lambda} \), the couplings \( J, J', \gamma \) are chosen such that interactions within the sublattice are ferromagnetic, while the interactions between different sublattices are antiferromagnetic.

The representations \( R, \bar{R} \) and the couplings are chosen such that the two-dimensional model is in the massless broken phase in the \( L_X, L_Y \to \infty \) limit. (We discuss this in more detail below.) With this choice of representations, a continuum limit can be defined on a \( L_X \times L_Y \) spatial lattice, in the regime \( L_X \gg L_Y \gg 1 \). More precisely, the continuum limit can be taken by considering \( L_Y \) even or odd, and taking \( L_Y \to \infty \) with fixed \( \gamma L_Y \), resulting in the Gr(\( N \)) NLσM with

\[
\theta = \pi p L_Y (1 + \gamma f)
\]

where \( f \) is a non-universal parameter.

Low-energy physics and \( \theta \) vacua

It was shown by Read and Sachdev [70] using coherent-state formalism that in the large-\( p \) limit, the two-dimensional SU(\( N \)) antiferromagnet with the above choice
of representations results in a Gr$_k(N)$ NL$\sigma$M at low energies. For a one-dimensional SU($N$) antiferromagnetic chain, it can also be easily shown that a $\theta$ term is induced at low energies by staggering the couplings (see Appendix D). This can be understood by the fact that the C symmetry is realized offsite as a translation by one site, and therefore a staggered coupling breaks the C symmetry, which should generically induce a $\theta$ term in the NL$\sigma$M. For SU($N$) ladders with $L_Y$ fixed, we can argue that the model is effectively a one-dimensional NL$\sigma$M [71–73] and similar considerations apply. Indeed, in Refs. [71–73] a semiclassical analysis in the large-($SL_Y$) limit was performed for the spin-S SU(2) ladders with staggered couplings, and it was shown that the long-distance physics is that of a (1+1)-dimensional $O(3)$ NL$\sigma$M with $\theta = \pi SL_Y(1 + c')$, where $c$ determines the strength of staggering and $\gamma$ is a nonuniversal parameter.

As we have argued above, the low-energy physics of the SU($N$) model of Eq. (12) is given by the Gr$_k(N)$ NL$\sigma$M with a $\theta$ term. However, to claim that we have a lattice regularization of a QFT, this is not enough – we must have a prescription for taking the continuum limit.

Continuum limit and asymptotic freedom

An elegant prescription for taking the continuum-limit is provided by the $D$-theory approach [5, 14, 15]. In this approach, a $(d+1)$-dimensional asymptotically-free theory can be obtained from a system in $(d+1) + 1$ spacetime dimensions, where the extra spatial dimension is taken to be small in physical units. There are two ingredients for this to work. The first one is that the $(d+1)$-dimensional model should be in a massless phase, and the second is dimensional reduction.

Let us assume that the two-dimensional model is in broken phase with massless Goldstone modes. (We will discuss the conditions for this in more detail below.) We take the extent in the extra spatial dimension to be $L_Y$. The low-energy continuum action (without the $\theta$ term) is

$$S_0 = \frac{1}{2g^2} \int_0^{L_Y} \int dx \, dt \, \text{Tr}[(\partial_x P)^2 + (\partial_t P)^2 + (\partial_y P)^2]$$

where $y$ is the extra dimension. When $L_Y$ is infinite, the system is ordered and the correlation length $\xi$ is finite (Goldstone modes are massless). Now, if $L_Y$ is reduced and made finite, a new length scale $\xi_{SR}(L_Y)$ appears in the system, which we may call the symmetry restoration scale. For scales smaller than $\xi_{SR}(L_Y)$, the system is ordered (symmetry broken), while for scales larger that $\xi_{SR}(L_Y)$, the system is disordered by the fluctuations of the massive Goldstone modes and the symmetry is restored.

For $L_Y$ finite, $\xi_{SR}(L_Y)$ must be finite. This is because, if it were infinite, then for any finite $L_Y$, the system would be ordered along the $y$ direction, and would therefore effectively become (1+1)-dimensional. But this would imply that the (1+1)-dimensional system is ordered and has a broken continuous symmetry, which is impossible due to the Coleman–Mermin–Wagner theorem. In other words, as $L_Y$ is reduced from being infinite to finite, the Goldstone modes pick up a mass $\sim \xi_{SR}^{-1}$, which determines the scale at which the system disorders.

Let us assume that we can make $L_Y$ small enough such that $\xi_{SR}(L_Y) \gg L_Y$. Again, the physics is effectively frozen in the $y$ direction and it can be explicitly integrated over in the low-energy effective action to obtain

$$S_0 = \frac{L_Y}{2g^2} \int dx \, dt \, \text{Tr}(\partial_x P)^2$$

We see that the (1+1)-dimensional theory has an effective coupling $g_{\text{eff}}^2 = g^2/L_Y$. Now, we can use knowledge of the (1+1)-dimensional theory. Asymptotic freedom in the (1+1)-dimensional Grassmannian models implies that the system develops an exponentially large length scale $\xi_{SR} \propto e^{L_Y/\beta_0 g^2}$, where $\beta_0$ is the leading $\beta$ function coefficient.
Therefore, for small enough $L_Y$, we get $\xi_{SR}(L_Y) \gg L_Y$, validating the dimensional reduction scenario. In the above argument, we assumed that $\xi_{SR}(L_Y) \gg L_Y$ by starting from $L_Y$ large. In principle, it possible that this is not valid for some regime of $L_Y$ and dimensional reduction does not occur. However, an independent argument can be given by considering $L_Y = O(1)$ very small. A nonlinear sigma model analysis of the spin ladders with finite $L_Y$ shows that $\xi_{SR}$ is finite (in lattice units) and grows exponentially in $L_Y$, and therefore we can always ensure that $\xi_{SR}(L_Y) \gg L_Y$ [72].

We note that the above discussion is valid for any $\theta$, since the UV physics of asymptotic freedom is the same in all cases. For $\theta = 0$, there is only one length scale in the system, and therefore the symmetry restoration length scale $\xi_{SR}$ and the correlation length $\xi$ coincide. However, for $\theta \neq 0$, $\xi_{SR}$ and $\xi$ are different, due to nonperturbative effects from the $\theta$ term. $\xi_{SR}$ sets the UV scale of asymptotic freedom, while $\xi$ sets the scale for IR physics. In general, we have the following hierarchy of length scales

$$\xi(\theta) \gtrsim \xi_{SR} \gg L_Y \gg a$$

where $a$ is the lattice spacing. Indeed, for the $\theta = \pi$ CP(1) theory, the nonperturbative effects are strong enough that the system becomes gapless with $\xi = \infty$.

**Choice of representations.** We emphasize this approach strongly depends the representations at each site. While in principle, for a given $G_N(N)$, we can choose any $p$ to get a lattice model, not every such model will have a continuum limit in the above prescription. For the alternating configuration, the representations $R, \bar{R}$ needs to be sufficiently large. This is because for the D-theory prescription to work, we need the two-dimensional ($L_X, L_Y \to \infty$) theory to be in massless symmetry-broken phase. Read and Sachdev [70, 74, 75] studied the two-dimensional model at large-$N$ and large-$p$ limits, and obtained the result that the system is in the Néel phase for $p \geq \kappa N$, where $\kappa$ is a constant of order 1. These semiclassical arguments suggest that as long as we choose $n \geq \kappa N$, we are guaranteed the right continuum limit as $L_Y \to \infty$. For example, for $k = 1$, it has been numerically shown that it suffices to choose the fundamental representation for $N = 2, 3, 4$, while larger representations are needed to obtain a Néel ordered ground state in two spatial dimensions for $N \geq 5$ [76].

**IV. LATTICE FORMULATIONS OF THE GRASSMANNIAN MODELS WITH ANOMALIES**

In this section, we discuss lattice regularizations of the $G_N(N)$ models in which both C and PSU($N$) act onsite. As mentioned above, this can only be compatible with the anomaly of the continuum theory if the anomaly is present on the lattice.

In the continuum, the charge conjugation symmetry at $\theta = \pi$ is not manifest in the sense that the action is not invariant but is shifted by $2\pi i Q$. It is thanks to the integer quantization of $Q$ that the integrand $\exp(-S)$ of the path integral is preserved by $C$. The statement of the mixed anomaly between the PSU($N$) symmetry and $C$ is that when background gauge fields for the former are present, the partition function is no longer invariant under the latter [39, 67, 77–79]. At a technical level, this is due to the fact that the presence of such background fields replaces the topological charge quantization in units of 1, which as we just said was necessary for $C$ invariance at $\theta = \pi$, by quantization in units of $1/N$. This anomaly can therefore be regarded as a consequence of the more basic fact that in the presence of background fields for the PSU($N$) symmetry, the period of the $\theta$ dependence should become $2\pi/\bar{N}$ so that the partition function fails to be $2\pi$ periodic in $\theta$ once the PSU($N$) symmetry is gauged. We may describe this more basic situation as a mixed anomaly between PSU($N$) symmetry and $2\pi$ periodicity in $\theta$.

All this is equally true in the lattice models we shall describe below.

### A. Berg–Lüscher $\theta$ term

We begin with a discretization on a two-dimensional triangular Euclidean spacetime lattice based on the continuum action (2) [80]:

$$S[P] = -\frac{1}{g^2} \sum_{(xy)} \langle x, y | P_x P_y - i\theta \sum_{p} q_p \rangle$$

where the first sum runs over all nearest-neighbor bonds $\langle x, y \rangle$ on the triangular lattice, the second sum runs over all positively oriented triangular plaquettes $p$. The fields $P_x$ are Hermitian $N \times N$ projection matrices such that $\langle x, y | P_{x} = k$, and $q_p$ is the topological charge density to be defined below. The choice of a triangular lattice is motivated by the definition of the topological charge density. At $g \to 0$ with a fixed $\theta$, the lattice action in Eq. (18) defines a continuum limit of the $G_N(N)$ $\text{NLMN}$. For $\theta = 0$, this model has been extensively studied for various $N$. There is a symmetry of the action under $P_x \mapsto u P_x u^\dagger$, for $u$ an element of SU($N$). Note that since the $P_x$ do not transform under the center of SU($N$), the correct (faithful) symmetry group of the action is SU($N$)/$Z_N \cong \text{PSU}(N)$. Charge conjugation acts by sending $P_x \mapsto P_x^*$, and so clearly preserves the action at $\theta = 0$.

For $G_N(N) = \text{CP}(N - 1)$, Berg and Lüscher [65] have defined $4\pi q_p$ to be the minimal signed area spanned by the geodesic triangle in the CP($N - 1$) manifold with vertices $P_x, P_y, P_z$, where $x, y, z$ are the vertices of the plaquette $p$ in counterclockwise order. Explicitly,

$$\exp(2\pi i q_p) = \frac{\text{Tr} P_{x} P_{y} P_{z}}{|\text{Tr} P_{x} P_{y} P_{z}|}.$$  

The branch ambiguity implied by this equation is fixed by requiring that $q_p$ lie in the interval $(-\frac{1}{2}, \frac{1}{2})$. (The same should be understood in similar formulas below.)
The total topological charge \( Q = \sum_q q_p \) is obtained by summing over all positively oriented plaquettes. By construction it is an integer for periodic boundary conditions (see Appendix B). Notice that \( C : q_p \rightarrow -q_p \). Therefore, the \( C \) symmetry at \( \theta = \pi \) here is not manifest, just as in the continuum.

We shall generalize this definition of the topological charge for \( G_{\ell_k}(N) \) fields below. But let us first demonstrate the existence of the anomaly in \( CP(N - 1) \) model.

Our strategy is to background-gauge the \( PSU(N) \) symmetry (see Fig. 3), and then examine the \( \theta \) dependence of the partition function. We start by introducing an external link field \( V_\ell \in SU(N) \). The action should incorporate in such a way that it be invariant under the local \( SU(N) \) transformations

\[
P_x \rightarrow v_x P_x v_x^\dagger, \quad V_{xy} \rightarrow v_x V_{xy} v_y^\dagger.
\]

This can be achieved by modifying the kinetic part of the action in Eq. (18) to

\[
\bar{S}_0[P, V] \equiv -\beta \sum_{(xy)} \text{Tr} P_x V_{xy} P_y V_{yx}.
\]

and the topological charge density in Eq. (19) to

\[
\exp(2\pi i\hat{q}_p) \equiv \frac{\text{Tr} P_x V_{xy} P_y V_{yz} P_z V_{zx}}{\text{Tr} P_x V_{xy} P_y V_{yz} P_z V_{zx}}.
\]

We note that \( \hat{Q} = \sum_p \hat{q}_p \) is still an integer (see Appendix B).

However, we are gauging not \( SU(N) \) but \( PSU(N) \). Two elements of the former that differ from each other only by an \( N \)th root of unity are identified as elements of the latter. In view of this fact, we postulate a gauge invariance under local \( \mathbb{Z}_N \) transformations of the link fields,

\[
V_\ell \mapsto V_\ell \exp(2\pi i n_\ell /N)
\]

with \( n_\ell \in \mathbb{Z}_N \). The new kinetic term is already invariant under this gauge transformation. The topological term, however, is not; it transforms as

\[
\exp(2\pi i\hat{q}_p) \mapsto \exp(2\pi i\hat{q}_p) \prod_{\ell \in p} \exp(2\pi i n_\ell /N).
\]

To fix this, we further introduce an external plaquette field \( b_p \in \mathbb{Z}_N \) with a gauge transformation rule chosen to precisely compensate for the noninvariance of \( \hat{q}_p \). Thus, if instead of (23) we postulate a gauge invariance under the combined transformations

\[
V_\ell \mapsto V_\ell \exp(2\pi i n_\ell /N),
\]

\[
b_p \mapsto b_p + \sum_{\ell \in p} n_\ell,
\]

then the topological charge density can be made invariant by modifying it to

\[
\exp(2\pi i\hat{q}_p) \equiv \exp(2\pi i\hat{q}_p) \exp(-2\pi i b_p /N)
\]

(See Appendix B for a derivation.) Note that for \( k = 1 \), the determinant is the same as the trace, and therefore this reduces to Eq. (19) for \( CP(N - 1) \).
With the correct definition of the topological charge in hand, we can now detect the mixed anomaly between $2\pi$ periodicity in $\theta$ and PSU($N$) symmetry as before. We introduce an SU($N$) link field $V_\ell$ and a $\mathbb{Z}_N$ plaquette field $b_p$ and modify the kinetic term to (21), and the topological charge density to

$$
\exp(2\pi i q_\ell) = \exp(2\pi i q_\ell) \exp(-2\pi i k b_p/N),
$$

where

$$
\exp(2\pi i q_\ell) = \prod_{\langle xy \rangle \in p} \frac{\det \phi_x \phi_y V_{xy} \phi_y \phi_x}{\det \phi_x \phi_y}.
$$

We note that in the last exponent of (31), the factor of $k$ appears because of the determinant of $k \times k$ matrices in (30). After literal repetition of the preceding argument, we find

$$
\tilde{Z}[V, b, \theta + 2\pi] = \exp(-2\pi i k B/N).
$$

We note that the anomalous phase for the $\text{Gr}_k(N)$ models is $k$ times that of the CP($N - 1$) model.

B. Lattice gauge theory formulation

We have given one lattice formulation of the two-dimensional $\text{Gr}_k(N)$ model that explicitly exhibits the anomaly, but we wish to emphasize that the anomaly was inevitable given that the symmetries were realized onsite. Thus, in this subsection, we present a different lattice regularization in which the same is true. It is based on the continuum action

$$
S = \int d^2 x |\partial_\mu \phi - \phi A_\mu|^2 + \frac{\theta}{2\pi} \int \text{Tr} dA,
$$

where $\phi$ is a $N \times k$ complex matrix–valued scalar field satisfying $\phi^\dagger \phi = 1_k$, $A_\mu$ is a U($k$) gauge field and we use the notation $|M|^2 \equiv \text{Tr} M^\dagger M$ for matrices $M$. (The gauge field is auxiliary and can be trivially integrated out to write the action entirely in terms of $\phi$.) The relation to the projector-valued field $P$ is simply $P = \phi \phi^\dagger$.

The standard discretization\textsuperscript{1} on a square lattice gives

$$
S = -\beta \sum_{\langle xy \rangle} \text{Tr} \phi_x \phi_y U_{xy} - i\theta \sum_p q_p,
$$

where the $\phi_x$ are complex $N \times k$ matrices defined on sites such that $\phi_x^\dagger \phi_x = 1_k$, the $U_{\ell}$ are elements of U($k$) defined on links, and the topological charge $q_p$ in a plaquette $p$ is defined by

$$
\exp(2\pi i q_p) = \prod_{\ell \in p} \det U_\ell.
$$

By taking the product of this last equation over all plaquettes, we clearly see that $Q = \sum q_p$ is an integer. Moreover, it is clear that $q_p$ has the right continuum limit, using the correspondence $\det U_p(x) \rightarrow \exp(a \text{Tr} A_p(x))$ ($a$ is the lattice spacing). For CP($N - 1$), this reduces to the definition used in [81]. The lattice action has a gauge symmetry under

$$
\phi_x \rightarrow \phi_x u_x, \quad U_{xy} \rightarrow u_x^\dagger U_{xy} u_y,
$$

where $u_x \in U(k)$. It also has a global symmetry under

$$
\phi_x \rightarrow v \phi_x, \quad U_\ell \rightarrow U_\ell,
$$

for $v \in \text{SU}(N)$. But for $v$ in the center of SU($N$), i.e., $v = \exp(2\pi i n/N) 1_N$, this transformation is equivalent to a gauge transformation with $u_x = \exp(2\pi i n/N) 1_k$, so as before the true symmetry group is PSU($N$). Finally, we have charge conjugation, which acts as

$$
C: \phi_x \rightarrow \phi_x^*, \quad U_\ell \rightarrow U_\ell^*.
$$

In particular, we have $C$: $q_p \rightarrow -q_p$, so C invariance is manifest at $\theta = 0$ but not at $\theta = \pi$, as before.

The demonstration of the anomaly here more or less follows the same lines as the above. We introduce an external gauge field for the PSU($N$) symmetry via a pair consisting of a link-field $V_\ell \in \text{SU}(N)$ and a plaquette-field $b_p \in \mathbb{Z}_N$ with the gauge transformation rule

$$
V_{xy} \rightarrow v_x V_{xy} v_y^\dagger \exp(2\pi i n_{xy}/N),
$$

$$
b_p \rightarrow b_p + \sum_{\ell \in p} n_\ell,
$$

where $v_x \in \text{SU}(N)$ and $n_\ell \in \mathbb{Z}_N$. These background fields may be coupled to the dynamical fields in a gauge-invariant fashion as follows. We replace the kinetic term by

$$
\sum_{\langle xy \rangle} \text{Tr} \phi_x V_{xy} \phi_y U_{xy},
$$

which is invariant under the transformation (40) of the background fields combined with the following transformation of the dynamical fields:

$$
\phi_x \rightarrow v_x \phi_x, \quad U_\ell \rightarrow U_\ell \exp(2\pi i n_\ell/N).
$$

The nontrivial transformation rule for $U_\ell$ then forces us to replace the topological charge density by

$$
\exp(2\pi i q_\ell) \equiv \exp(-2\pi i k b_p/N) \prod_{\ell \in p} \det U_\ell.
$$

Taking the product of the last equation over all plaquettes, we get

$$
\exp(2\pi i \tilde{Q}) = \exp(-2\pi i k B/N),
$$

from which the same anomaly (33) follows.

\textsuperscript{1} For CP($N - 1$) an alternative discretization via the modified Villain formalism was given in Ref. [56], which can be shown to also explicitly exhibit the anomaly.
V. CONCLUSION

Anomalies have long been a powerful way to probe non-perturbative aspects of QFTs. For lattice regularizations, they imply constraints on the way anomalous symmetries may be realized. Indeed, a QFT with an anomalous symmetry $G$ is such that $G$ cannot be gauged; the same must be true for any symmetric lattice regulator thereof.

In this work, we have explored the connection between discrete anomalies and lattice regularizations for a class of NLσM with target space given by the Grassmannian manifold $\text{Gr}_k(N)$, which includes the well-known CP($N-1$) models as the case with $k=1$. These models have a mixed anomaly between PSU($N$) and C symmetries.

[39, 67, 77–79]. The question we have tried to address in this work is: What do these anomalies imply for constructing a symmetric lattice regulator? Generally, it is thought that an anomaly in a symmetry implies that on the lattice the symmetry cannot be realized onsite, because then one could always gauge the symmetry by introducing appropriate link variables. However, this is incorrect – there is also the possibility that the anomaly is explicitly reproduced on the lattice. This can be surprising, since it is often remarked that “there are no anomalies on the lattice.” Indeed, one of the most well-known early constructions of the $\theta$ term in the (1+1)-dimensional CP($N-1$) NLσM due to Berg and Lüscher [65], already exhibits this mixed anomaly between PSU($N$) and C, as we have demonstrated in this work.

We also noted that in some cases, strictly speaking, there is no anomaly but a more subtle scenario referred to as a “global inconsistency” [39, 68, 69]. In such cases, we argued that the usual no-go theorem gets modified and presents a new kind of obstruction, which prevents us from finding lattice regulators with manifest onsite symmetry for the two points of global inconsistency that can be continuously connected to each other.

Of course, it is possible that the anomalous symmetry is realized offsite, in which case it is not possible to gauge it in the usual way. This is another way that an anomaly may be reflected in a lattice regularization. We demonstrated this possibility by constructing a new regularization for the $\text{Gr}_k(N)$ NLσM with a $\theta$ term, using the D-theory formulation. This regularization uses SU($N$) spins as fundamental degrees of freedom with local antiferromagnetic interactions on a two-dimensional spatial $L_X \times L_Y$ lattice. In the large-representation limit, the low-energy limit can be shown to be that of (1+1)-dimensional $\text{Gr}_k(N)$ NLσM for a fixed $L_Y$. Extending on recent work for the O(3) NLσM [31], we argued that a similar construction allows us to obtain the obtain continuum limit of the $\text{Gr}_k(N)$ NLσM at arbitrary non-zero $\theta$, by keeping $\gamma L_Y$ fixed as we take the $L_Y \to \infty$ limit. For the CP($N-1$) models, this provided the first completely sign-problem free lattice regularization of the $\theta$ vacua [7, 31]. In the case of SU($N$) antiferromagnets in the $(k,p)$ representation with $k \neq 1$, efficient sign-problem free algorithms are not known. Even though a direct numerical confirmation of our regularization is currently limited due to this, it is interesting to note that the sign-problem in SU($N$) $(k,p)$ antiferromagnets in general is of a totally different character than the conventional Berg–Lüscher $\theta$ term. After all, $(k,p)$ SU($N$) antiferromagnets have a sign problem even at $\theta = 0$. Changing $\theta$ by adding staggered couplings does not make it more severe. This suggests that if an efficient algorithm for SU($N$) antiferromagnets with $k \neq 1$ representations can be found at $\theta = 0$, we would also automatically have a sign-problem free approach to arbitrary nontrivial $\theta$ for the entire class of $\text{Gr}_k(N)$ NLσM.

The discussion of anomalies and lattice regularizations presented in this work is especially relevant in the context of four-dimensional Yang–Mills theories. Indeed, at $\theta = \pi$, pure SU($N$) Yang–Mills theory exhibits a mixed anomaly involving time-reversal and center symmetry [39] that is quite analogous to the anomaly studied here. There already exist proposals for qubit regularizations for Yang–Mills as quantum link models [6, 15], while the conventional lattice regularization admits a topological construction for the $\theta$ term [66]. There seems to be a parallel discussion to be had in these cases. We leave this for a future publication.

We note that Read and Sachdev [70] use the parametrization of the Grassmannian manifold can also be defined as the set of complex matrices such that \( \phi^\dagger \phi = 1_k \), which allows us to rewrite Eq. (A1) as \( P = \phi \phi^\dagger \). Note that if the Gr\(_k(N)\) field theory is written in terms of the \( \phi \) (or \( \bar{z}_i \)) fields, we must add a \( U(k) \) gauge field to account for the redundancy in the choice of reference vectors \( \bar{z}_i \):

\[
Z = \int D\phi D\phi^\dagger DA e^{-S[\phi, \phi^\dagger, A]}.
\]  

(A5)

It may also be useful to point out that the conventional formulation of the Gr\(_1(2)\) = CP(1) or the O(3) model in terms a real unit vector \( \bar{n} \) (as in Eq. (7)) is related to the projector formalism by

\[
P = \frac{1}{2} (1_2 + \bar{n} \cdot \bar{\sigma}), \quad \text{or} \quad \bar{n} = \text{Tr}(P \bar{\sigma}).
\]  

(A6)

Note that charge conjugation \( P \to P^* \) sends

\[
(n_1, n_2, n_3) \mapsto (n_1, -n_2, n_3),
\]  

(A7)

which differs from the given in Eq. (4) \( (\bar{n} \mapsto -\bar{n}) \) by an additional \( \pi \)-rotation about the second axis.

### Appendix B: Some properties of the Berg–Lüscher lattice \( \theta \) term

In this section, we discuss some properties of the Berg–Lüscher lattice \( \theta \) term and provide its generalization for Gr\(_k(N)\) fields.

It will be convenient to use the redundant parametrization of Gr\(_k(N)\) by \( N \times k \) complex matrices \( \phi \) satisfying \( \phi^\dagger \phi = 1_k \). In this notation, the Berg–Lüscher \( \theta \) term for CP\((N-1)\) = Gr\(_1(N)\) reads

\[
\exp(2\pi i q_p) = \prod_{\langle xy \rangle \in p} \frac{(\phi_x, \phi_y)}{|(\phi_x, \phi_y)|},
\]  

(B1)

where in this section we use the notation \( \langle \ldots \rangle \) for the Hermitian scalar product of vectors. We see that \( \exp(2\pi i q_p) \) takes the form of a product of link variables in \( U(1) \) around the boundary of \( p \). Thus, in taking the product of this equation over all positively oriented plaquettes, the link variables cancel in pairs, so that

\[
\exp(2\pi i Q) = \prod_p \exp(2\pi i q_p) = 1.
\]  

(B2)

Hence, the total topological charge \( Q \) is an integer.

We can now easily address an issue which was elided in Section IV. There, background SU\((N)\) link variables \( V_i \) were introduced, and the topological charge \( q_p \) got replaced by \( \bar{q}_p \) which depends on the \( V_i \) as in (22). An important property of \( \bar{q}_p \) (which was not explained in the main text) is that \( \bar{Q} = \sum_p \bar{q}_p \) be integer-quantized. We
can now clearly see that this is so, as we can rewrite (22) in the new notation as
\[ \exp(2\pi i\tilde{q}_p) = \prod_{(z_y) \in \mathcal{P}} \frac{(\phi_x, V_{xy}\phi_y)}{|(\phi_x, V_{xy}\phi_y)|}. \] (B3)

Let us now find the generalization of (B1) for the Gr$_k(N)$ model. We first note that it is possible to realize Gr$_k(N)$ as a submanifold of the complex projective space $P(\wedge^k \mathbb{C}^N) \cong CP((N^k) - 1)$ via the Plücker embedding, which is given by
\[ \text{Gr}_k(N) \rightarrow P(\wedge^k \mathbb{C}^N) \]
\[ [z_1, \ldots, z_k] \mapsto [z_1 \wedge \cdots \wedge z_k]. \] (B4)

Here $z_1, \ldots, z_k$ is a set of orthonormal column vectors in $\mathbb{C}^N$, so $[z_1, \ldots, z_k]$ denotes the $k$-dimensional subspace of $\mathbb{C}^N$ generated by these vectors, and $[z_1 \wedge \cdots \wedge z_k]$ denotes the 1-dimensional subspace in $\wedge^k \mathbb{C}^N$ generated by $z_1 \wedge \cdots \wedge z_k$.

This embedding is helpful because it allows us to define the topological charge of a Gr$_k(N)$ field by mapping it to a $P(\wedge^k \mathbb{C}^N)$ field and then defining the expression of the topological charge for $P(\wedge^k \mathbb{C}^N)$ fields. To see the validity of this claim, consider a $P(\wedge^k \mathbb{C}^N)$ field $\Phi$ of the form $\Phi = z_1 \wedge \cdots \wedge z_k$ with $(z_i, z_j) = \delta_{ij}$, which by the Plücker embedding corresponds to a Gr$_k(N)$ field $\phi = (z_1, \ldots, z_k)$. Then the topological charge $Q$ of $\Phi$ as a $P(\wedge^k \mathbb{C}^N)$ field is given by
\[ 2\pi Q = \int d(\Phi, d\Phi) = \int d(z_1 \wedge \cdots \wedge z_k, d(z_1 \wedge \cdots \wedge z_k)) \]
\[ = \int d \sum_{j=1}^{k} (z_1 \wedge \cdots \wedge z_k, z_1 \wedge \cdots \wedge dz_j \wedge \cdots \wedge z_k) \]
\[ = \int d \sum_{j=1}^{k} (z_j, dz_j) \]
\[ = \int d \text{Tr} \phi^j d\phi. \] (B5)

In the fourth line, we have used the formula for the scalar product in $\wedge^k \mathbb{C}^N$ induced by the standard scalar product in $\mathbb{C}^N$:
\[ (z_1 \wedge \cdots \wedge z_k, w_1 \wedge \cdots \wedge w_k) = \det_{ij}(z_i, w_j). \] (B6)

The last line is just the topological charge of $\phi$ as a Gr$_k(N)$ field. Our claim is thus proved.

Back to the lattice, we see with the help of formula (B6) that the Berg–Lüscher definition (B1) (replacing there CP($N - 1$) by $P(\wedge^k \mathbb{C}^N)$ and $\phi_x$ by $\Phi_x$) gives the desired definition of the topological charge for lattice Gr$_k(N)$ fields $\phi_x$ as
\[ \exp(2\pi i\tilde{q}_p) = \prod_{(z_y) \in \mathcal{P}} \frac{\det \phi_x^\dagger \phi_y}{|\det \phi_x^\dagger \phi_y|}. \] (B7)

For completeness, we note that it is possible to give an expression in terms of the projector-valued field $P_x$:
\[ \exp(2\pi i\tilde{q}_p) = \frac{\text{Tr} \wedge^k P_x \cdot \wedge^k P_y \cdot \wedge^k P_z}{|\text{Tr} \wedge^k P_x \cdot \wedge^k P_y \cdot \wedge^k P_z|}. \] (B8)

where $\wedge^k P_x$ is the operator on $\wedge^k \mathbb{C}^N$ induced by the operator $P_x$ on $\mathbb{C}^N$.

### Appendix C: Continuum presentation of the Gr$_k(N)$ model anomalies

This appendix reviews the continuum presentation of the mixed anomaly in the two-dimensional Gr$_k(N)$ model between PSU($N$) symmetry and charge conjugation C [67], which the lattice presentation in the main text mirrors closely. The analysis is very similar to that of the two-dimensional CP($N - 1$) model [39, 77–79].

We shall work with the continuum action
\[ S = \int |d\phi - \phi\lambda| + \frac{\theta}{2\pi} \int \text{Tr} da. \] (C1)

To detect the mixed anomaly, we shall need to activate a background gauge field for the PSU($N$) symmetry, which can be regarded as a pair of fields consisting of a $U(N)$ gauge field $A$ and a $U(1)$ 2-form gauge field $B$ that satisfy the constraint $NB = \text{Tr} dA$ [82]. (In our conventions, $B$ is pure imaginary.) This pair transforms under a generalized gauge transformation of the form
\[ A \mapsto gA^{-1} + g \lambda \mathbf{1}_N, \quad B \mapsto B + d\lambda \] (C2)

where $g$ is a $U(N)$-valued function and $\lambda$ is a $U(1)$ 1-form gauge field. To couple these background fields to the dynamical fields in a gauge invariant fashion, we replace the action by
\[ \tilde{S} = \int |d\phi + A\phi - \lambda| + \frac{\theta}{2\pi} \int \text{Tr}(da - B\mathbf{1}_k). \] (C3)

This is invariant under the transformation (C2) of the background fields provided we also make the following transformation on the dynamical fields:
\[ \phi \mapsto g\phi, \quad a \mapsto a + \lambda \mathbf{1}_k. \] (C4)

It is now straightforward to find that the partition function in the presence of the background fields satisfies
\[ \tilde{Z}[A, B, \theta + 2\pi] = \tilde{Z}[A, B, \theta] \exp(k \int B), \] (C5)

which indicates a mixed anomaly between the PSU($N$) symmetry and the $2\pi$-periodicity in $\theta$. An important dynamical consequence of this result is that the theory cannot be trivially gapped for all values of $\theta \in [0, 2\pi]$.

To go further, we consider the charge conjugation symmetry at $\theta = 0, \pi$. Charge conjugation acts by complex conjugating all fields:
\[ C : \phi \mapsto \phi^*, \quad a \mapsto a^*, \quad A \mapsto A^*, \quad B \mapsto B^*. \] (C6)
But in the action, complex conjugating the fields is equivalent to reversing the sign of \( \theta \); i.e.,
\[
\tilde{S}[\phi^*, a^*, A^*, B^*, \theta] = \tilde{S}[\phi, a, A, B, -\theta]
\] (C7)

Thus, at \( \theta = 0 \), charge conjugation leaves the partition function invariant, while at \( \theta = \pi \), it is equivalent to shifting \( \theta \) by \(-2\pi\), which by (C5) causes the partition function to pick up the phase factor \( \exp(-k \int B) \):
\[
C:\begin{cases}
\tilde{Z}[A, B, \theta = 0] & \rightarrow \tilde{Z}[A, B, \theta = 0],
\tilde{Z}[A, B, \theta = \pi] & \rightarrow \tilde{Z}[A, B, \theta = \pi] \exp(-k \int B).
\end{cases}
\] (C8)

From this, we see that at \( \theta = 0 \), there is no anomaly, while at \( \theta = \pi \), there may or may not be an anomaly. The reason we cannot yet conclude that there is an anomaly at \( \theta = \pi \) is that we have not yet considered the most general procedure of gauging PSU(\(N\)). Said differently, we are free to add to the action any gauge-invariant local “counterterm” depending only on the background fields.

Appendix D: The Gr\(_k\)(\(N\)) model from an SU(\(N\)) spin chain

In this appendix, we show that the two-dimensional Gr\(_k\)(\(N\)) model with a \( \theta \) term arises as the large distance effective field theory of the antiferromagnetic SU(\(N\)) spin chain (see Fig. 4) given by the Hamiltonian
\[
H = J_- \sum_n \bar{S}_\alpha^n (n) S_\alpha^n (n) + J_+ \sum_n \bar{S}_\beta^n (n) S_\beta^n (n + 1).
\] (D1)

Coherent states

Introduce \( N \times k \) harmonic oscillators
\[
[a^{\alpha i}, a^{\beta j}] = \delta_\alpha^\beta \delta_i^j,
\] (D2)

where \( \alpha, \beta = 1, \ldots, N \), \( i, j = 1, \ldots, k \), to represent the SU(\(N\)) spin operators by
\[
S_\alpha^n = a_{i\alpha} a^{\alpha i}.
\] (D3)

The \((k, p)\) representation of SU(\(N\)) is given by the subspace on which
\[
N^j_i \equiv a_{i\alpha} a^{\alpha j} = p a_{i\alpha}^j.
\] (D4)

For any \( N \times k \) complex matrix \( \phi = (\phi^{\alpha i}) \), the operator
\[
\Phi \equiv (k!)^{-\frac{1}{2}} a_{i\alpha_1} \cdots a_{i\alpha_k} \phi^{\alpha_1} \cdots \phi^{\alpha_k} = (k!)^{-\frac{1}{2}} \det(a^i \phi).
\] (D5)
We thus find the coherent state path integral
\[
\text{Tr} |\phi\rangle = \text{det}(\beta x(\phi) \beta_\alpha) \tag{D8}
\]
and one finds the Euclidean Lagrangian
\[
\mathcal{L} = \sum_n \text{Tr}(p\rho_n^\dagger \partial_\tau \phi_n - p\chi_n^\dagger \partial_\tau \chi_n)
\]
\[
- \frac{p^2}{k^2} J_- \sum_n |\phi_n^\dagger \chi_n|^2 - \frac{p^2}{k^2} J_+ \sum_n |\phi_n^\dagger \phi_{n+1}|^2 \tag{D20}
\]
We note that for \(J_+ = J_-\) this Lagrangian is invariant under the offsite transformation
\[
\phi_n \rightarrow \chi_n^*, \quad \chi_n \rightarrow \phi_{n+1}^*, \tag{D21}
\]
which we shall later interpret as charge conjugation. To obtain the large-distance effective field theory, we expand about a slowly varying Neél configuration by writing
\[
\phi_n = \phi(x), \quad \chi_n = \left[1 + \frac{1}{k} |\epsilon(x)|^2 \right]^{\frac{1}{2}} \phi(x) + \epsilon(x). \tag{D23}
\]
Here, \(\phi(x)\) is taken to be a slowly varying background, \(\epsilon(x)\) a rapidly varying fluctuation, and we have introduced the continuum coordinate \(x = an\), \(a\) being the lattice spacing. Inserting this into the Lagrangian, and keeping only terms at most second order in \(\epsilon\) and \(\partial\), we find
\[
a\mathcal{L} = \frac{p^2}{k^2} \epsilon^2 J_- |D_x \phi|^2 + \frac{p^2}{k^2} (J_- + J_+) |\epsilon|^2
\]
\[
- \text{Tr} \left( \frac{p^2}{k^2} a J_+ D_x \phi + p D_\tau \phi \right)
\]
\[
- \text{Tr} \left( \frac{p^2}{k^2} a J_+ D_x \phi^\dagger - p D_\tau \phi^\dagger \right) \epsilon \tag{D24}
\]
where \(D_\mu \phi \equiv \partial_\mu \phi - \phi(\partial_\mu \phi)\). Integrating out the fluctuation field \(\epsilon\) yields
\[
\mathcal{L} = \frac{a^2}{k^2} J_- J_+ |D_x \phi|^2 + \frac{k^2}{a} J_- J_+ |D_\tau \phi|^2
\]
\[
+ p \frac{J_+}{J_- + J_+} e^{\mu \nu} \text{Tr}(D_\mu \phi^\dagger D_\nu \phi). \tag{D25}
\]
This is the continuum Lagrangian of the Gr\(_k\)(\(N\)) model with coupling given by
\[
\frac{1}{g^2} = p \frac{(J_- J_+)}{J_- + J_+} = \frac{1}{2} \mu [(1 - \gamma)(1 + \gamma)]^{\frac{1}{2}} \tag{D26}
\]
with a \(\theta\) parameter given by
\[
\theta = 2\pi p \frac{J_+}{J_- + J_+} = \pi p (1 + \gamma), \tag{D27}
\]
where we have introduced the staggering parameter \(\gamma \equiv J_+ / J_- = (1 + \gamma)(1 - \gamma)\). For \(\gamma = 0\), we recover the result \(\theta = \pi p\) obtained in Ref. [70]. Thus the presence of the lattice symmetry (D21) exactly coincides with the presence of charge conjugation symmetry in the effective field theory.
