Abstract

We conjecture that the Higgs potential can be significantly modified when it is in close proximity to the horizon of an astrophysical black hole, leading to the destabilization of the electroweak vacuum. In this situation, the black hole should be encompassed by a shell consisting of a “bowling substance” of the nucleating new phase bubbles. In a binary black hole merger, just before the coalescence, the nucleated bubbles can be prevented from falling under their seeding horizons, as they are simultaneously attracted by the gravitational potential of the companion. For a short time, the unstable vacuum will be “sandwiched” between two horizons of the binary black hole, and therefore the bubbles may collide and form micro-black holes, which will be rapidly evaporated by thermal emission of Hawking radiation of all Standard Model spieces. This evaporation, being triggered by a gravitational wave signal from the binary black hole merger, can manifest itself in observations of gamma rays and very high energy neutrinos, which makes it a perfect physics case for multi-messenger astronomical observations.

February 2023

1 Introduction

The discovery of the Higgs boson at the LHC\textsuperscript{[1,2]} was a confirmation of the Standard Model (SM) and it provided an exciting opportunity to understand properties of the electroweak (EW)
vacuum. In particular, it was demonstrated [3,4] that there is an available lower energy vacuum state to which the EW vacuum can eventually decay. Actually, this possibility has been known for a long time and comprehensively analyzed in [5–9]. It appears that the Higgs potential is sensitive to the experimental inputs, in particular to the physical masses for the Higgs boson and the top quark and also to physics beyond the SM. The recent measurements of the Higgs boson and top quark masses, \(M_h = 125.25 \pm 0.17\) GeV, \(M_t = 172.76 \pm 0.30\) GeV [10] implies that our universe resides in the unstable SM vacuum state. Thus, if the SM is valid up to energies greater than about \(10^{12}\) GeV, the EW vacuum is meta-stable and the transition into a lower energy state will occur in the future. The transition happens initially locally, nucleating a small bubble of the true vacuum. The bubble then starts expanding at high rate reaching quickly almost the speed of light and converting the meta-stable vacuum to the true one everywhere.

Although the fact of our existence testifies that at the present day vacuum decay rate is extremely low, this was not necessarily the case in the early universe. For example, a high Hubble rate during inflation and high temperatures afterwards could potentially increase the rate significantly [11,12]. The decay rate also can be very sensitive to a presence of new physics, such as an extension of the SM via introduction of higher dimension operators [13,14], or the Higgs potential dependence on the space-time curvature through the direct non-minimal coupling of Higgs field to curvature (see, for example [15]). The presence of a small black hole (BH) can catalyze vacuum decay and make it significantly faster [16,22]. Therefore, the fact that we still observe the universe in its EW vacuum state allows us to place constraints on the cosmological history, for example, on the reheating temperature and the scale of inflation, and on beyond SM parameters, such as coupling constants between the Higgs field and space-time curvature or higher dimension operators.

One could ask a question, whether there is another way, not based on the anthropic arguments, of using the meta-stability of the EW vacuum to study extreme conditions or effects of new physics in cosmology and astrophysics. Namely, would it be possible to think of some physical conditions at which vacuum decay could occur and manifest itself as a potentially observable phenomenon, while not leading to catastrophic consequences for the existence of the universe in its present meta-stable state? In this paper we would like to propose an idea of such kind of phenomenon and elaborate on its driving mechanism and observational signatures

---

1 However, this claim has been questioned in [23].
in multi-messenger astronomy.

The idea is creating physical conditions for putting the EW vacuum in a high decay rate regime within a finite spatial volume for a certain time period. The desired conditions can be realized in a close vicinity of the horizon of a BH of astrophysical origin, as a result of gravitationally induced corrections to the Higgs potential. In particular, the position and the height of the potential barrier, which “screens” the metastable minimum of the Higgs potential, can be modified so significantly that the vacuum becomes unstable already at present temperatures within a certain distance above the horizon of the BH. Since the instability implies a high nucleation rate of the Higgs new phase bubbles, a BH immersed into EW vacuum will be encompassed by a thin shell consisting of a “bowling substance” represented by nucleating new phase bubbles surrounded with the SM vacuum. Although the nucleation is permanently going on within the thickness of the shell, the bubbles immediately fall under the horizon, so that an external observer of a single BH always stays in the EW meta-stable state.

The situation can be different if we consider a binary black hole (BBH) merger \cite{24,26}, where BHs circle their common center. In the merger the BHs spiral inward losing their orbital energies in the form of gravitational radiation so that their horizons get very close to each other and finally coalesce to form a single BH. Just before the coalescence, when the horizons of the components are close to each other, namely at a distance of the order of the thickness of the shells, the nucleated bubbles can be prevented from the falling under their seeding horizon, being pulled out by the gravitational potential of the other component of the BBH merger. Thus, within some volume “sandwiched” in the gap between the approaching each other horizons, a temporal stabilization of the process of the EW vacuum conversion into a new phase can occur. Inside this volume, within the time of its existence, nucleating bubbles will expand, collide and even percolate. Some of these collisions can result in formations of microscopic black holes ($\mu$BHs) via mechanisms described in \cite{28,29}. Namely, when three bubbles collide the surface energy in parts of their walls can be focused to the extent that its density tends to infinity, which converts the triple collision point into a BH \cite{28}. Moreover, the collapse of non-trivial vacuum structure left over after collisions of only two bubbles can also lead to the formation of a BH, as it is argued in \cite{29,30}. The masses of such a “split off” from the merger $\mu$BHs depend on the sizes of the colliding bubble and their walls tension. The sizes of the bubbles

\footnote{See also a recent study of the mechanism \cite{29} presented in \cite{31}.}
at the collisions are mostly determined by the phase transition developed in the volume of the stabilized SM vacuum decay process. The wall tension should depend on the details of modification of the position of the barrier separating the meta-stable EW vacuum from the true vacuum state and should be driven by the energy scale not essentially exceeding the EW one.

The formed $\mu$BHs will start to evaporate emitting thermal Hawking radiation \cite{32} in all SM spices. Finally, the coalescence of the merger results in the formation of a single horizon of the final BH. Thus, the conditions of vacuum instability created in the volume “sandwiched” in the gap between the horizons of the merger are broken so that the stabilized conditions for bubble nucleation are destroyed. All remnants of new vacuum phase and still not evaporated small $\mu$BHs should fall into the final BH. This ensures that an external observer will remain in the EW vacuum state.

The duration of the emission of Hawking radiation by the $\mu$BHs cannot exceed the typical time scale of the last portion of gravitational wave signals from BBH mergers discovered by LIGO and Virgo \cite{24,27}, which is much less than a second. One might expect that the energy release of Hawking radiation can be at the level of isotropic energy equivalents measured for short gamma ray bursts (SGRBs) \cite{33}. Therefore, the electromagnetic part of the burst could be observed by space based gamma ray bursts monitors \cite{34,36} and the telescope \cite{37}. Moreover, the Hawking emission of other SM model particles and, maybe, beyond SM spices can produce a neutrino signal in IceCube \cite{38}. The very high energy spectral part of the electromagnetic component of the Hawking radiation also might produce a signature in very high energy atmospheric Cherenkov facilities \cite{39,43}.

The mechanism described above is akin to so called triboluminescence \cite{44} which refers to the phenomenon that materials could emit light when they are mechanically stimulated, such as rubbing, grinding, impact, stretching, and compression. Here, with a certain degree of analogy, the vacuum “bowling substance”, being the “material” of the shell encompassing the horizon of an astrophysical BH, is getting stretched between two approaching each other horizons in a BBH merger which finally leads to an emission of detectable Hawking radiation.

The paper is organized as follows. In Section 2 we describe heuristically general phenomenological features of the proposed mechanism of the formation and evaporation of $\mu$BHs within the gap between horizons of a BBH merger components. In Section 3 we study basic features
of spectra, temporal characteristics and energy budget of the electromagnetic and neutrino messengers of the phenomenon. In Section 4 we review the Higgs field effective potential in the Standard Model; in Sections 5 and 6 the idea of the mechanism of gravitationally induced corrections to the Higgs potential in a vicinity of a BH horizon is introduced. In Section 7 estimates of basic quantities driving the proposed mechanism are performed in the framework of a toy model. The energy budget of the Higgs induced triboluminescence phenomenon, in the framework of the toy model, is discussed in Section 8. Finally, conclusions are presented in Section 9.

2 Formation of $\mu$BHs in unstable vacuum “sandwich”

To specify further the expected multi-messenger manifestations of the phenomenon outlined in the introduction, it is instructive to give a preliminary heuristic sketch of an underlying mechanism of gravitational corrections to the vacuum decay process, while leaving the description of the details of the Higgs phase transition at nucleation sites located in the vicinity of the horizon for the later sections.

The rate of the first order phase transition with Higgs field, when its nucleation site is located at the center of a BH, has been investigated in [16–21]. In these studies, it was concluded that Higgs true vacuum formation rate can be increased so much that even a single BH of smallest mass ($\ll 1$ g) existed in the past could already destroy the current SM meta-stable vacuum state. Hence, it might happen that any primordial BH with a lifetime smaller than the age of the universe could serve as a source of such a fatal catalysis corresponding to Higgs vacuum phase transition.

Here we conjecture the Higgs phase transition rate also could be substantially increased in the vicinity of the horizon of a BH, while the nucleation site is located outside the BH. Some recent efforts to investigate such a possibility have been made in [45,46]. Heuristically thinking, one presumes that the closer is a nucleation site to the horizon of a BH the higher is the phase transition rate and hence the higher is the probability of formation of a bubble of the true Higgs vacuum. Moreover, one might expect that a BH of any mass, even such as that one of an astrophysical origin, could create a nucleation site in the vicinity of its horizon. In this case, since the nucleation site with a bubble of the true vacuum falls quickly under the horizon, it is obvious that the fatal catalysis of the Higgs vacuum phase transition cannot take place.
The bubble formation probability is driven by \( \exp[-S_4] \), where \( S_4 \) stands for the four-dimensional Euclidean action computed along the tunneling trajectory for the spherical bubble solution \( [47],[49] \). In general, gravitational correction effects in the vicinity of a BH depend on the distance to the horizon, so that \( S_4 \) can be represented as an effective action \( S_4(d_H) \) which implies that the probability of tunneling per unit time per unit volume from a vacuum in the meta-stable state to the true vacuum is given by

\[
\Gamma(d_H) = \mathcal{M}^4 \exp\left[-S_4(d_H)\right],
\]

where the pre-factor \( \mathcal{M} \) is of mass dimension and \( d_H \) is the distance to the horizon measured in units of the Schwarzschild radius \( R_S \) of the BH. For illustration, in the regime of gravitational corrections, one may model the effective action with a simple power law

\[
S_4(d_H) = A_S d_H^a,
\]

where \( A_S \) indicates the value of the action at the distance \( d_H = 1 \), that is to say at one Schwarzschild radius from the horizon and \( a \) is the power to be specified from the details of the gravitational corrections for the Higgs potential \( [5] \). Therefore, the closer is the location of a bubble nucleation site to the horizon the higher is the probability of tunneling from the meta-stable vacuum state at \( v = 246 \) GeV to the true Higgs vacuum. If one goes away from the horizon, the exponential suppression in (1) slows down the bubble nucleation rate so that they would have more time to grow up before starting to collide if they were prevented from falling down into the BH. This effect could take place in a BBH merger consisted of BHs of about LIGO-Virgo scale \( [24],[27] \), just before touching each other by their horizons.

Indeed, between the horizons of the BBH components, at their close enough mutual approach, one might expect an instant formation of a volume with effective zero gravity so that for a short time period the unstable vacuum is kind of “sandwiched” between the horizons of the components. In these conditions bubbles could have enough time to grow up and finally percolate, terminating their existence in wall collisions. In triple bubble collisions the surface energy of the parts of the colliding walls can be focused in a way that they find themselves under their Schwarzschild radius leading to a formation of \( \mu \)BHs, as argued in \( [28] \). The formation

\[^3\]Choosing (2), we were governed by the argument that power laws can naturally satisfy the demand that a distance dependence of the nucleation rate is invariant under arbitrary rescaling, up to normalization measured here by the Schwarzschild radius.
of $\mu$BHs is also possible through evolution of non-trivial vacuum configuration produced in a collision of walls of only two bubbles \[29,30\]. Either case is feasible in conditions of percolation within quite a limited volume. Being formed, the $\mu$BHs will be rapidly evaporated by a thermal emission of Hawking radiation \[32\] with black-body spectrum at an effective temperature which increases as the mass of a $\mu$BH decreases.

In general, the masses of such “split off” $\mu$BHs are defined by sizes of the bubbles at the instance of their collision and their vacuum wall tensions. The wall tension is mostly defined by parameters of the modified Higgs potential, namely by a location of the maximum of the barrier separating the meta-stable EW vacuum from the true vacuum state and the Higgs self-interaction constant $\lambda$, at the barrier. Both parameters for unmodified potential are quite well defined by the measurements of the Higgs and top masses as well as the SM physics renormalization group corrections \[12\].

The surface tension is estimated as

$$\sigma \simeq \sqrt{\lambda} h_b^3,$$

where $h_b$ the Higgs field value defined by a bounce solution at the modified maximum, which, for sanity reasons, cannot substantially exceed the position of the electroweek vacuum, so that

$$h_b \lesssim 1 \text{ TeV} \ .$$

(4)

It is reasonable to assume that the mass of a $\mu$BH formed in a collision contains fraction $\kappa_f$ of the mass of the colliding bubbles. Thus, one can say that a $\mu$BH of mass $M_{\mu BH}$ is created out of a bubble of radius

$$R_{\text{bub}} \approx \frac{M_{\mu BH}^{1/2}}{(4\pi)^{1/2} \Lambda^{1/4} h_b^{3/2} \kappa_f^{1/2}} \approx \frac{l_{\text{Pl}}}{2\sqrt{\pi} \Lambda^{1/4} \kappa_f^{1/2}} \left( \frac{M_{\mu BH}}{M_{\text{Pl}}} \right)^{1/2} \left( \frac{M_{\text{Pl}}}{h_b} \right)^{3/2},$$

(5)

where $l_{\text{Pl}}$ and $M_{\text{Pl}}$ are the Planck length and Planck mass, respectively. The value of $\kappa_f$ depends on the details of a conversion mechanism and, in general, it is expected to amount a non-negligible (up to a per cent) fraction of the bubble mass \[29,30\].

For the sake of simplicity of the rough estimates, let us assume that the volume of the unstable vacuum “sandwich” (UVS) defined by $d_H$ is populated with bubbles of approximately equal sizes, which implies that all $\mu$BHs in this volume are formed with equal masses. In the course of the bubble nucleation and growth, the $\mu$BHs will be created in bubbles double
and triple collisions, as argued above. Therefore, one has to estimate the abundance of such collisions occurring within the volume $V_{\text{UVS}}(d_H)$.

The volume $V_{\text{UVS}}(d_H)$ is assumed to be formed within a narrow gap between the spherical caps of the horizons of the components of the BBH, just before their mutual touching, as shown in Fig. 1. The thickness of the USV can be taken as $2d_H R_S$, provided that the power in (2) is not very high, so that the transition rate does not change dramatically across the UVS. Thus one can represent $V_{\text{UVS}}(d_H)$ as a body bounded between the convex surfaces of two spherical caps separated, at their closest points, by distance $2d_H R_S$, as shown in Fig. 1. The volume $V_{\text{UVS}}(d_H)$ can be calculated as

$$V_{\text{UVS}}(d_H) \approx V_{\text{cyl}}(d_H) - 2V_{\text{cap}}(d_H),$$

where $V_{\text{cyl}}(d_H)$ is the cylindrical volume formed by the base circles of radius $a$ separated by distance $3d_H R_S$. This insures that the width of the UVS, at its edges framed by the caps, does not increase more than by a factor 1.5, keeping the Euclidean action (2) increasing only within factor $(1.5)^a$, which is moderate, provided that, once again, the power $a$ is not very large. Taking into account that according to the construction of the cylinder above (see Fig. 1),
\( b = \frac{1}{2} d_H R_S \), the radius of the base circle is given by

\[
a = \sqrt{b(2R_S - b)} \approx \sqrt{d_H R_S} ,
\]

which allows us to express the UVS volume as\(^4\)

\[
V_{\text{UVS}}(d_H) = \frac{1}{6} \pi b(3a^2 + b^2) \approx \frac{5}{2} \pi d_H^2 R_S^3 .
\]

Evaluating (6), we considered BBH of equal mass components, so that both caps have the same volume. Also, obtaining (8) we ignored everywhere \( d_H \) with respect to values \( \gtrsim 1 \). Taking into account these two approximations, it would be more correctly to say that (6) expresses a sort of upper estimate of the UVS volume within which the action (2) does not variate more than by factor \((1.5)^a\). Thus, bellow, for simple estimates, we will use a constant value of the action (2), defined by \( d_H \) inside the UVS.

Depending of the degree of the closeness of the horizons of the BBH components in the course of their mutual approach, two different scenarios of bubble collisions leading to formation of \( \mu \)BHs of distinct masses are possible.

The first scenario refers to the regime when the bubble nucleation rate is significantly enhanced in comparison with the nucleation rate in the horizons free space, while it is still low in the sense of providing the percolation of the bubbles of radius \( R_{\text{bub}} \) within \( V_{\text{UVS}}(d_H) \). Therefore, in this scenario, the only bubbles which nucleated in closed pairs and closed triplets would collide and form \( \mu \)BHs. In order to estimate the number of these collisions, one can use some findings from the site percolation theory \(^5\), where the random distribution of occupied and empty sites on a lattice is considered. The occupied sites tend to aggregate into clusters of size distribution \( n_s(p) \)\(^6\) which is defined as a number of clusters containing \( s \) occupied sites per one lattice site when the fraction of occupied sites on the lattice is equal to \( p \). The cluster numbers are calculated on the basis of lattice animals counting, and for large clusters and low occupancy \( (p \rightarrow 0) \) it is given by the corresponding equation in \(^5\):

\[
n_s(p) \propto s^{-\theta} p^s C^s ,
\]

where \( C \) is a constant. For a three dimensional lattice, \( \theta = 3/2 \), as inferred in \(^5\). Similar behavior as (9) has been confirmed for small clusters as well in simulations performed in \(^5\).

\(^4\)Standard textbook formulas were used to obtain this result.

\(^5\)This quantity serves a discrete analog of distribution function in statistical physics.
In the context of the formation of $\mu$BHs in bubbles collisions, we are interested in clusters of size $s = 2$ and $s = 3$ aggregated on a simple 3D lattice of volume $V_{UVS}(d_H)$ with sites measured by the volume of individual bubble $V_{bub}$ defined, in its turn, by the radius $\rho_c$. Therefore the number of $\mu$BHs created inside $V_{UVS}(d_H)$ out of collisions of bubbles of volume $V_{bub}$ can be expressed as

$$N_{\mu BH}(p, s) \approx n_s(p) P_{\mu BH}(s) \frac{V_{UVS}(d_H)}{V_{bub}} ,$$

where $s = 2, 3$ and $P_{\mu BH}(s)$ is the probability of formation of the $\mu$BH by two [29] or three [28] bubbles. The fraction of occupied sites on this lattice can be expressed as

$$p(d_H) \approx \langle \Gamma(d_H) \rangle \Delta t_{col} V_{UVS}(d_H) ,$$

where $\langle \Gamma(d_H) \rangle$ is the nucleation rate averaged over $V_{UVS}(d_H)$ and $\Delta t_{col}$ is the time elapsed from the bubbles nucleation to their collisions. For the small clusters number we use the result obtained in [52] for a cubic lattice, which reads

$$n_s(p) \approx s^{-1.5} p^{10^{1.1s}} ,$$

where the numerical values for $\theta$ and $C$ have been inferred reading out the relevant parameters from Fig.5 of [52]. Thus, collecting together (10), (11) and (12), the number of $\mu$BHs created in the UVS can be represented as

$$N_{\mu BH}(d_H, s) \approx s^{-1.5} 10^{1.1s} \langle \Gamma(d_H) \rangle^s \Delta t_{col}^s P_{\mu BH}(s) \frac{[V_{UVS}(d_H)]^{(s+1)}}{V_{bub}} .$$

The collision time in (13) can be evaluated as the time spent by bubbles while they were growing from the critical radius $\rho_c$ up to $R_{bub}$ given in [5], which implies that

$$\Delta t_{col} \approx \frac{R_{bub}}{c} ,$$

where $c$ is the velocity of light.

It is practical to express (13) separately for $s = 2$ and $s = 3$ mechanisms as follows

$$N_{\mu BHs}(d_H, 2) \approx 1.6 \times 10^{31} d_H^{3.8} \lambda^{1/4} (\langle \Gamma(d_H) \rangle)^2 P_{\mu BH}(2) (R_{S\odot})^9 \kappa_f^{1/2} \times \left( \frac{M_{BH}}{M_{\odot}} \right)^9 \left( \frac{M_{Pl}}{M_{\mu BH}} \right)^{1/2} \left( \frac{h_b}{M_{Pl}} \right)^{3/2} \left( \frac{1 \text{ s}^2}{1 \text{ km}^2} \right) ,$$

$$N_{\mu BHs}(d_H, 3) \approx 1.3 \times 10^{-11} d_H^{8} \langle \Gamma(d_H) \rangle^3 P_{\mu BH}(3) (R_{S\odot})^{12} \left( \frac{M_{BH}}{M_{\odot}} \right)^{12} \left( \frac{1 \text{ s}^3}{1 \text{ km}^2} \right) ,$$
where $R_{S\odot} = 2.95$ km stands for the Schwarzschild radius of a solar mass object. Since dynamical effects, which might be caused by gravitational forces applied at the sites of bubbles collisions are not taken into account, the $\mu$BHs counted by (15) and (16) are assumed to be scattered uniformly across the $V_{UVS}(d_H)$.

The **second scenario** refers to the regime when one can allocate a volume, fitting within $V_{UVS}(d_H)$, where the nucleation rate reached the high enough level to make the bubbles of radius $R_{bub}$ percolating. This regime implies that, in fact, all bubbles participate in both double and triple collision mechanisms of $\mu$BHs formation. The necessary condition for realization of such a scenario is quite simple, namely the probability of nucleation of a bubble of critical radius $\rho_c$ (critical volume $V_c$) within the collision time $\Delta t_{col}$ should be close to unity. The latter implies the validity of the following relation

$$\langle \Gamma(d_H) \rangle \Delta t_{col} V_c \simeq 1 ,$$

where the critical radius is defined by the mechanism of the correction of the Higgs potential and will be estimated in Section 7. Unlike in the first scenario, here, the number of created $\mu$BHs cannot be calculated directly but it can be normalized by the total energy output to be estimated in the next section.

It is obvious, that in reality, while the horizons of components in the BBH merger are approaching each other, one has to expect a mixture of contributions from both scenarios. However, this complication does not affect the estimate presented below, so that one can postpone its discussion for later publications.

### 3 The electromagnetic and neutrino signals

In this section we consider possible observational signatures of the Hawking evaporation of the $\mu$BHs, which is the essence of the multi-messenger nature of the phenomenon described above.

The luminosity of gravitation signal from a BBH merger is described by the quadrupole formula

$$L_{GW} = \frac{1}{5} G \langle \dddot{I}_{jk} \dddot{I}_{jk} \rangle ,$$

where $\dddot{I}_{jk}$ is the third time derivative of the quadrupole moment of a relevant mass distribution. For a binary system with similar mass components $M_1 \simeq M_2 \simeq M$ separated by $R_{BBH}$, the
quadrupole moment can be estimated as

\[ I \sim MR^2_{BBH}. \tag{19} \]

Its third derivative is proportional to the third power of the orbital angular frequency

\[ \Omega = \sqrt{\frac{GM}{R^3_{BBH}}}, \tag{20} \]

so that

\[ \ddot{I} \sim \Omega^3 MR^2_{BBH}. \tag{21} \]

Therefore the luminosity \cite{18} can be expressed as

\[ L_{GW} \sim G\Omega^6 M^2 R^4_{BBH} = \frac{G^4 M^5}{R^5_{BBH}}. \tag{22} \]

From the other hand, the gravitational energy of such BBH to be released by a merger can be expressed as

\[ E_{GW} = \frac{GM^2}{R_{BBH}}. \tag{23} \]

Therefore, the time scale of the merger is defined as

\[ t_{mrg} \simeq \frac{E_{GW}}{L_{GW}} \simeq \frac{R^4_{BBH}}{G^3 M^3}. \tag{24} \]

At the final stage of the merger the distance between the components contracts down to their Schwarzschild radius, \( R_S = 2GM \), so that the time scale \cite{24} of this stage is measured in \( t_{mrg} \gtrsim 1 \) ms. Note that a BBH composed of stellar mass BHs localized at separation distance about 10-100 times of their Schwarzschild radii would radiate out its gravitational energy within an hour time scale. While a BBH with \( \simeq 10^3 \) times larger orbit will need a Hubble time scale to exhaust its energy into emission of gravitational waves.

In terms of the gravitational wave signal the final merger stage corresponds to the gravitational wave frequency \( f_{max} \) at which the waveform has a maximal amplitude, as it is shown in Fig. 1 and Fig. 2 of \cite{24} for GW150914, as well as in Fig. 10 of \cite{25} for frequency maps and reconstructed signal waveforms for other BBH events. Using these figures we read out the conservative low values of the maximal frequencies \( f_{max} \simeq 100 \) Hz, which indicates that the horizons of the BHs in a BBH spent about \( t_{mrg} \approx 10 \) ms in the closest vicinity from each other. We treat this time scale as a rough estimate of the upper limit of the lifetime of the UVS.
We assume that during their stabilized existence period the vacuum bubbles will be converted into $\mu$BHs by the mean of the mechanisms described in Section 2, which evaporated emitting SM particles with black body spectrum \[53\],

$$\frac{d^2N}{dEdt} = \frac{\Gamma_s}{2\pi \left( \exp \left( \frac{E}{T_{\mu\text{BH}}} \right) - (-1)^2s \right)} ,$$

characterized by the Hawking temperature

$$T_{\mu\text{BH}} = \frac{1}{8\pi} M_{\text{Pl}} \left( \frac{M_{\text{Pl}}}{M_{\mu\text{BH}}} \right) \approx 10^5 \left( \frac{10^8 g}{M_{\mu\text{BH}}} \right) \text{ GeV} \quad (26)$$

and absorption probability $\Gamma_s$. Provided that Hawking evaporation time is given by

$$t_{ev} = \frac{5120\pi}{M_{\text{Pl}}} \left( \frac{M_{\mu\text{BH}}}{M_{\text{Pl}}} \right)^3 \approx 0.084 \left( \frac{M_{\mu\text{BH}}}{10^8g} \right)^3 \text{ s} ,$$

(27)

one can conclude that $\mu$BHs with mass $M_{\mu\text{BH}} \approx 5 \times 10^7$ g will be completely evaporated out within the time scale of $t_{\text{mrg}} \approx 10$ ms emitting SM species at energies above 200 TeV, as it follows from (26).

Photons of energy $E_\gamma$ propagating through a background of soft photons of energy $\epsilon$ will produce $e^+e^-$ pairs, if their energies exceed the threshold \[54\] \[55\]

$$E_\gamma \geq \frac{m_e^2}{\epsilon} \approx 260 \left( \frac{\epsilon}{1 \text{ eV}} \right)^{-1} \text{ GeV} .$$

(28)

Soft photons with energies from 0.1 to 10 eV being produced by star formation in galaxies are abundant in the universe and known as the extragalactic background light (EBL) \[56\] \[57\]. The profile of the spectral energy density of EBL contains two bumps located at the near infra-red energy $\epsilon \simeq 1$ eV, formed due to the direct starlight emission, and the far-infrared energies $\epsilon \simeq 10^{-2}$ eV, produced by scattering of starlight on dust. The energy density of the EBL is estimated to be about $\rho_{\text{EBL}} \approx 10^{-2.5}$ eV/cm$^3$ \[58\], which is a factor $\simeq 10^{-2}$ below than the energy density of CMB. Photons with energies above 100 GeV should interact with EBL, which leads to an energy-dependent suppression of their flux from extra-galactic sources. The mean free path of such $\gamma$-rays is given by

$$\lambda_{\gamma\gamma}(E_{\gamma}) \approx \frac{1}{\sigma_{\gamma\gamma} n_{\text{EBL}}} \approx 410 \left[ \frac{\sigma_{\gamma\gamma}^2}{\sigma_{\gamma\gamma}} \right] \left[ \frac{\epsilon}{1 \text{ eV}} \right] \left[ \frac{10^{-2.5} \text{ eV/cm}^3}{\rho_{\text{EBL}}} \right] \text{ Mpc} ,$$

(29)

where $\sigma_{\gamma\gamma}$ is the $e^+e^-$ pair production cross section \[59\] \[60\]

$$\sigma_{\gamma\gamma} = \pi r_0^2 x^{-1} \left[ (2 + 2x^{-1} - x^{-2}) \ln(\sqrt{x}(1 + \sqrt{1 - x^{-1}})) - (1 + x^{-1})\sqrt{1 - x^{-1}} \right] .$$

(30)
In (30) \( r_0 = 2.82 \times 10^{-13} \text{cm} \) is the classical electron radius, \( x = s/4m_e^2 \), \( m_e \) is the electron mass, and \( s = 2\epsilon E_{\gamma\gamma}(1 - \cos\theta) \) is the squared center of mass energy. The cross section (30) has its maximum \([61] \sigma_{\gamma\gamma} \simeq 2r_0^2 \) at \( \sqrt{s} \simeq 1.44 \text{ MeV} \) leading to the most effective interactions with the EBL photons of energy \( \epsilon \simeq 0.5 \times 10^{-2}(100\text{TeV}/E_{\gamma\gamma}) \text{ eV} \).

Photons created in the vicinity of a BH should experience the gravitational red shift. The photon of energy \( E_{\gamma\text{em}} \) emitted at the radius \( r_{\text{em}} = R_S(1 + d_H) \) is observed at energy

\[
E_\gamma = \frac{E_{\gamma\text{em}}}{z_g + 1},
\]

by an external observer where red shift \( z_g \) is given by (see for example the text book \([62]\))

\[
1 - \frac{1}{\sqrt{|g_{00}(r_{\text{em}})|}} - 1 = \frac{1}{\sqrt{1 - R_S/r_{\text{em}}} - 1}.
\]

Thus, the energy of an exiting photon will be scaled down by factor

\[
z_g + 1 = \sqrt{(1 + d_H)/d_H}.
\]

It implies that for a typical distance \( d_H \simeq 0.3 \) the energy of photons detected by an external observer \( E_\gamma \simeq 100 \text{ TeV} \) would be about a half of the energy of the emitted photons because of photon propagation in strong gravitational fields of the merging BHs.

According to (29) and (30) the mean free path \( \lambda_{\gamma\gamma} \) of most of the photons with energy \( E_\gamma \simeq 100 \text{ TeV} \) can extend up to about 10 Mpc, if photons interact with EBL of \( \epsilon \simeq 10^{-2} \text{ eV} \), which is much less than the typical distance \( D \) to any extra galactic source, so that the source fluxes of such \( \gamma \)-rays are suppressed by factor \( \exp(-D/\lambda_{\gamma\gamma}) \). Since the number density of the target EBL photons increases with the cosmological red shift as \( (1 + z)^3 \), (29) gives the overestimated upper limit of the mean free pass \( \lambda_{\gamma\gamma}(100 \text{ TeV}) \lesssim 10 \text{ Mpc} \). More rigorous calculations (see for example \([63]\) for details) show that \( \lambda_{\gamma\gamma}(100 \text{ TeV}) \lesssim 0.5 - 2 \text{ Mpc} \) for sources at red shifts between 0.5 and 0.1, respectively. We notice that about half of BBH mergers detected in the first and second observing runs (O1 and O2) of the Advanced gravitational-wave detector network \([25]\) and three quarter of BBH mergers seen in the first half of third observing run (O3) \([26]\) performed by advanced LIGO and Virgo detectors are over \( z \simeq 0.2 \).

However, being absorbed on EBL, the very high energy \( \gamma \)-rays inject \( e^+e^- \) pairs in the inter galactic media (IGM). These highly relativistic pairs are aligned with the beam line of \( \gamma \)-rays emitted from the source, at a distance about \( \lambda_{\gamma\gamma} \). Therefore, the full power of the source
contained in the absorbed VHE $\gamma$-rays is transferred into the energy of the pairs. In their turn, electrons and positrons very effectively lose their energies via inverse Compton scattering on CMB photons. The distance of inverse Compton scattering energy attenuation of relativistic pairs of energy $E_e \simeq E_\gamma/2$ is given by \[ D_{IC} = \frac{3m_e^2}{4\sigma_T \rho_{CMB} E_e} \simeq 0.37 \left( \frac{E_e}{1 \text{ TeV}} \right)^{-1} \text{ Mpc} , \] (34)

where $\rho_{CMB} \simeq 0.26 \text{ eV/cm}^3$ is the energy density of the CMB and $\sigma_T$ is the Thomson cross section. The mean energy of the photons produced in the inverse Compton effect is calculated as \[ E_{IC} = \frac{4\epsilon_{CMB} E_e^2}{3m_e^2} \simeq 3.6 \left( \frac{E_e}{1 \text{ TeV}} \right)^2 \text{ GeV} , \] (35)

where $\epsilon_{CMB} \simeq 3T_{CMB}$ stands for the mean energy of the CMB photons.

Therefore, in case of maximally efficient triboluminescence, which implies that $\mu$BHs are small enough to radiate out their whole energy within the duration time of the final stage of the merger, one would have the following picture of the propagation of the electromagnetic component. The primary short duration $t_{mrg} \simeq 10$ ms signal of thermal VHE $\gamma$-rays of energies $E_\gamma \simeq 100$ TeV emitted at the BBH merger will be converted via $e^+e^-$ pair production on EBL and their subsequent inverse Compton scattering of CMB into softer, however still VHE $\gamma$-rays of energies $E_{\gamma IC1} \simeq 10$ TeV, as it follows from (35). This conversion will occur within the main free path of 100 TeV $\gamma$-rays, $\lambda_{\gamma\gamma}(100 \text{ TeV}) \lesssim 0.5 - 2$ Mpc (for sources at red shifts between 0.5 and 0.1), since the Compton scattering distance of $\simeq 50$ TeV pairs is negligibly short (34). In its turn, the mean free path of $\simeq 10$ TeV $\gamma$-rays, which are mostly getting absorbed by the near infra-red part of the EBL spectrum, amounts $\lambda_{\gamma\gamma}(10 \text{ TeV}) \lesssim 50 - 100$ Mpc (for sources at red shifts between 0.5 and 0.1), which implies that, for a distant source, a good fraction of them will be again converted into $e^+e^-$, whose subsequent inverse Compton scattering on CMB will produce $\gamma$-rays of energy $E_{\gamma IC2} \lesssim 300$ GeV. Also, still some of photons will travel a long distance without significant energy loss. Thus, the power of Hawking VHE photons tend to be converted into the secondary sub TeV $\gamma$-rays. For a source, at distance larger than $\lambda_{\gamma\gamma}(10 \text{ TeV})$ the cascade will be also populated by much softer $\gamma$-rays of energy $E_{\gamma IC2} \lesssim 3$ GeV. As it seems, a substantial fraction of the power of the triboluminescence emission produced at a remote BBH merger is transmitted into the secondary $\gamma$-rays of the energy range from 1 GeV to 1 TeV and hence to observe this phenomenon one should rely on the Fermi-LAT [37] and
very high energy atmospheric facilities, MAGIC \[39\], HESS \[40\], VERITAS \[41\], HAWC \[42\] and LHASSO \[43\].

Since the electron is massive the arrival timing of the secondary $\gamma$-rays should be delayed by amount of

$$\Delta t(E_e) \simeq \frac{D_{IC}}{c} \frac{m_e^2}{2E_e^2},$$

where the velocity of light $c$ is introduced explicitly. Thus, for $\simeq$ GeV secondary $\gamma$-rays, which are produced by $\simeq$ TeV electrons \[35\] covering the Compton scattering distance \[34\] of about $D_{IC(\text{TeV})} \simeq 600$ kpc, the delay \[36\] can be as large as $\Delta t(1 \text{ TeV}) \approx 4$ s, which exceeds essentially the duration of the original signal $t_{\text{obs}} = (1 + z)t_{\text{mrg}}$, in the observer’s frame for a BBH at $z \lesssim 1$. In particular, it seems that the very short pulse of VHE $\gamma$-rays of Hawking radiation from sources at redshift over $z_C \approx 0.2$ (at luminosity distance over 1 Gpc), will be converted into a burst of $\simeq$ GeV to $\simeq$ 10 TeV $\gamma$-rays of $\lesssim 4$ s duration.

The Hawking luminosity,

$$L_{\mu\text{BH}} \simeq 10^{29} \left(\frac{10^8 g}{M_{\mu\text{BH}}}\right)^2 \text{ erg/s}$$

implies that a $\mu$BH releases the energy in amount of

$$E_{\mu\text{BH}} \simeq 10^{28} \left(\frac{M_{\mu\text{BH}}}{10^8 g}\right) \text{ erg}$$

within its evaporation time \[27\].

For further estimates let us assume that the total energy release, for the considered effect, at least, could be comparable with the isotropic equivalent energy of SGRBs, which is of the order of $10^{49} - 10^{51}$ erg. Thus, to emit $E_{\text{mrg}} \approx 10^{49}$ erg of the isotropic equivalent energy, in the process of the triboluminescence one would need to evaporate about

$$N_{\mu\text{BHs}}^{\text{SGRB}} \simeq 10^{21}$$

of $\mu$BHs of mass $M_{\mu\text{BH}} \approx 5 \times 10^7$ g, so that the cumulative mass of the evaporated $\mu$BHs capable to provide the radiation power similar to a SGRB amounts $M_{\mu\text{BHs}}^{\text{tot}} \simeq 10^{28}$ g $\approx 10^{-5} M_\odot$. The value \[39\] may serve as a lower estimate of the amount of $\mu$BHs capable to provide an observable electromagnetic counterpart of the phenomenon. The gravitation waves energy radiated in BBH mergers discovered by LIGO and VIRGO ranges from few to several solar masses \[24, 25\] and is estimated with precision of about 10% (see Table III in \[25\]). It is reasonable to accept
as the maximal possible energy budget of the electromagnetic messenger the amount $0.1 M_\odot$ ($E_{\text{mrg}} \approx 10^{53}$ erg), which implies a generation of

$$N^{10\% M_\odot}_{\mu \text{BHs}} \approx 10^{24} \quad (40)$$

in a BBH merger.

Along with $\gamma$ rays, the $\mu$BHs will emit the same amount of isotropic energy equivalent,

$$E_{\text{tribo}} \approx 10^{49} \div 10^{53} \text{ erg} \quad (41)$$
in neutrinos of the mean energy, observed by an external observer, about 100 TeV, in the process of Hawking evaporation. Therefore, one expects that the phenomenon should be manifested in arrival of about 10 ms long high energy neutrino signal in temporal and directional coincidence with the GWs signal from a BBH merger. The energy release in such neutrino burst can be compared with that one of the neutrino flare $[65]$ arrived from the direction of the blazar TXS 0506+056 prior to the first multi-messenger event in the neutrino-photon astronomy, baptized IceCube-170922A $[66]$. The energy fluence of the TXS 0506+056 flare implies that the average isotropic neutrino luminosity delivered by the source during 158 days is $[65]$

$$L_\nu = 1.2^{+0.6}_{-0.4} \times 10^{47} \text{ erg s}^{-1} \quad (42)$$

This luminosity is at least two orders of magnitude lower than that one which could be provided by the triboluminescence phenomenon,

$$L^{\text{tribo}}_\nu \approx \frac{E_{\text{tribo}}}{\Delta t_{\text{mrg}}} \approx 10^{51} \div 10^{55} \text{ erg s}^{-1} \quad (43)$$
The TXS 0506+056 flare mostly consists of neutrinos with energies $\gtrsim 20$ GeV, which is an order of magnitude lower than the energy of neutrinos emitted by the $\mu$BHs. Therefore, the number of neutrinos in the burst which might arrive from the BBH merger should be at least one order of magnitude higher than that one in the TXS 0506+056 flare $[65]$. We notice that the energy of IceCube-170922A $[66]$ is reported to be 290 TeV, which is similar to the average neutrino energy expected from the $\mu$BHs created in a BBH merger. Therefore, one may expect that IceCube will be able to detect a neutrino burst from the multi-messenger effect of the triboluminescence.
4 Standard model effective potential

To fix notations we start from an explicit renormalizable Lagrangian that leads to a vacuum expectation value for the Higgs field $H$

$$L = |D_\nu H|^2 - \lambda (|H|^2 - v^2) ,$$  \tag{44}

where the low energy self-coupling constant and vacuum expectation value (VEV) are,

$$\lambda \approx 0.13 , \quad v \approx 246 \text{ GeV} .$$  \tag{45}

The expansion of the complex Higgs doublet,

$$H = \frac{1}{\sqrt{2}} \begin{pmatrix} 0 \\ v + h \end{pmatrix} ,$$  \tag{46}

generates a canonically normalized physical Higgs scalar $h$ of the mass

$$M_h = \sqrt{2\lambda v} \approx 125 \text{ GeV} ,$$  \tag{47}

with the potential

$$U_0 = \frac{M_h^2}{2} h^2 + \lambda v h^3 + \frac{\lambda}{4} h^4 ,$$  \tag{48}

which has a minimum $U_0 = 0$ at $h = 0$. In this way, the Higgs doublet develops a non-zero VEV, so that $SU(2)_L \times U(1)_Y$ is broken. The VEV $v = 246$ GeV corresponds to the EW vacuum, which is stable at tree level. However, the Higgs potential obtains radiative corrections, so that coupling constants must be running when the energy regime, or correspondingly, the field value, changes.

In quantum field theory, in Minkowski space, the standard regularization [67] appears from specific integrals, e.g. for a scalar particle of mass $m$ [68][69],

$$\int \frac{dE d^3p}{(2\pi)^4} \frac{1}{(E^2 - p^2 - m^2 + i\varepsilon)^2} \to -\frac{i}{16\pi^2} \ln \frac{m^2}{\Lambda^2} ,$$  \tag{49}

where $\Lambda$ is a regularization scale. This implies that an observable, at energy scale $\sim m$, differs from its value at higher energy scale $\sim \Lambda$ by a logarithmic term. Therefore, when quantized, the Higgs field potential [48] becomes modified by corrections like [49], so that

$$U_{\text{eff}}(\Lambda) = U_0 + U_1(\Lambda) ,$$  \tag{50}
with radiative corrections term expressed in the general form as

$$U_1(\Lambda) = \sum_i \frac{n_i}{64\pi^2} M_i^4 \left[ \ln \left( \frac{M_i^2}{\Lambda^2} \right) - C_i \right].$$

(51)

In (51), the index $i$ runs over particle species, $n_i$ counts degrees of freedom (with a minus sign for fermions), and the field-dependent mass squared of $i$-th specie is given by

$$M_i^2(h) = \Lambda_i^2 + g_i h^2,$$

(52)

where $g_i$ are coupling constants, while $C_i$ are some definite constants [69].

For the regularization scale $\Lambda$, in (51), the VEV of the Higgs field can be chosen as $v$, since this is the scale where the running SM parameters still can be associated with experimentally observed values, so that the Higgs potential is to be well approximated by its classical form. It is known, that the leading terms of the one-loop corrections (corresponding to the $t$ quark, $W$ and $Z$ bosons, Higgs and Goldstone bosons, respectively) are [5–9],

$$U_1(v) = \frac{1}{64\pi^2} \left\{ -12 \left( \frac{1}{2} Y_t^2 h^2 \right)^2 \left[ \ln \frac{Y_t^2 h^2}{2v^2} - \frac{3}{2} \right] + 
+ 6 \left( \frac{g_2^2}{4} h^2 \right)^2 \left[ \ln \frac{g_2^2 h^2}{4v^2} - \frac{5}{6} \right] + 3 \left( g_1^2 + g_2^2 \right)^2 h^2 \left[ \ln \frac{(g_1^2 + g_2^2) h^2}{4v^2} - \frac{5}{6} \right] + 
+ (3\lambda h^2 - \mu^2)^2 \left[ \ln \frac{3\lambda h^2 - \mu^2}{v^2} - \frac{3}{2} \right] + 3 (\lambda h^2 - \mu^2)^2 \left[ \ln \frac{\lambda h^2 - \mu^2}{v^2} - \frac{3}{2} \right] \right\},$$

(53)

where $\mu^2 = M_h^2/2$ is the Higgs potential mass constant and the $t$-quark Yukawa coupling and gauge bosons coupling constants have the values:

$$Y_t = \frac{\sqrt{2} M_t}{v} \approx 0.99, \quad g_2 = \frac{M_W}{v} \approx 0.33, \quad \sqrt{\frac{g_1^2 + g_2^2}{2}} = \frac{M_Z}{v} \approx 0.37.$$

(54)

The factor of 12 in the $t$-quark contribution in (53) (first line), corresponds to the 3 colors times 4 components of a Dirac spinor and the minus sign reflects the Fermi statistics. The factor of 3 in the vector boson terms (second line) comes from tracing the numerator of the gauge-boson propagator in the Landau gauge and additional factor 2 in the first term of the second line appears due to the existence of two $W$-boson species.

Below, we review the behavior of $U_{\text{eff}}(h)$ for different values of $h$.

**EW regime.** For the EW regime, namely at $h \simeq v$, logarithm terms in (53) are smaller than corresponding constants $C_i$ in square brackets. The largest contribution comes from the
$t$-quark, which appears to be positive making the entire correction $U_1$ to the Higgs tree level potential $U_0$ also positive. Therefore, at EW scales, radiative corrections do not destabilize the Higgs vacuum which is located at $U_0(h = 0) = 0$.

Intermediate regime. The one loop approximation (53) is still valid at intermediate scales, $h \simeq 10v \simeq 1$ TeV. At this regime logarithm terms in (53) become positive and larger than constants $C_i$, so that the effective potential (50) is well approximated by

$$U_{\text{eff}}(h) \approx \left[ \frac{\lambda}{4} + \frac{3}{64\pi^2} \left( 3\lambda^2 - Y_t^4 \right) \ln \frac{h^2}{v^2} \right] h^4 .$$

Due to the minus sign in front of the $t$-quark term the one loop correction becomes negative, i.e. the SM effective potential has a local minimum. However, due to the large value of the denominator, $64\pi^2$, the second term in (55) is smaller than $\lambda/4$, so that the effective potential remains positive, i.e. higher than the vacuum value $U_0 = 0$. Therefore, in Minkowski space, at the scales $\sim 1$ TeV, the global minimum of the Higgs system is still located at $h = 0$.

Large Higgs field regime. For larger values of the Higgs field $h >> 1$ TeV the effective potential (50) can be approximated \cite{3,4,12} as

$$U_{\text{eff}}(h) \approx \frac{\lambda(h)}{4} h^4 .$$

where $\lambda(h)$ is the running coupling. The behavior of the running coupling $\lambda(h)$ in the renormalization group approach is shown in Fig. 2. The renormalisation group evolution of the running coupling demonstrates that $\lambda(h)$ becomes negative above $10^8$ GeV and is very sensitive to the

\begin{figure}[h]
\centering
\includegraphics[width=0.5\textwidth]{fig2.png}
\caption{Higgs self-coupling $\lambda$, obtained in the framework of $\overline{\text{MS}}$ renormalization scheme for central values $M_h = 125.3$ GeV and $M_t = 172.76$ GeV. Deviations for $M_t \pm 1$ GeV, $M_t \pm 2$ GeV, $M_t \pm 3$ GeV are shown.}
\end{figure}
top quark mass [70,71]. Therefore, in general, SM vacuum is a local minimum and it becomes unstable at energies much higher than the EW scale.

5 Gravitational Corrections to Vacuum Decay

Although the vacuum decay rate in Minkowski space is extremely slow, that is not necessarily the case in strong gravitational fields. The full theory of quantum gravity is unknown and only exists a simple semi-analytic approximation that captures the leading gravitational corrections [72,73]. It was found [16–21,74,75] that due to external gravitational field the vacuum decay can be significantly increased. This raises the question of SM vacuum stability in external classical gravitational potential. For example, close to the horizon of a BH the strong local spacetime curvature can enhance vacuum decay rate to a level incompatible with the age of the Universe [17–19].

Existing calculations on gravity mediated Higgs vacuum decay mainly consider small BH's located inside new phase bubbles and are taking into account only the effects of curvature on the running of the SM constants. These corrections appear after inserting the non-minimal coupling term, $\sim |H|^2 R$, into the action that connects the Higgs field $H$ to the scalar curvature $R$.

In this paper we want to estimate the impact of gravitational potential on the rate of the nucleation of the new phase bubble close to the horizon of a BH of astrophysical origin. Let us ask the important question: Is the SM vacuum stable in large gravitational potential? The models of quantum theory in curved spacetime is a topic of intense research [76,77], which revealed many interesting phenomena such as the Hawking radiation and the Unruh effect, etc. Here we will consider modifications of the dispersion relations for quantum fields in the renormalization integrals (49) in external large static gravitational potential. Similar ideas were considered in models of quantum theory in cosmological spaces, where dispersion relation in the integrals (49) is modified by inserting of the scale factor $a(t)$ describing cosmic expansion (see the recent review [78]).

Note that the gravitational deformation of dispersion relations assumes an effective violation of the Lorentz invariance. Several models predict a departure from exact Lorentz invariance [79], when the free particle dispersion relation exhibits extra momentum dependent terms, apart from the usual quadratic one occurring in the Lorentz invariant dispersion relation. Most of
the studies were performed in the QED, gravity, and for some of the SM particles, where strong constraints on the Lorentz invariance violating terms were obtained \[80\]. However, not much studies were done for the Higgs sector \[81\], especially on curved backgrounds. Higgs is much different from other fundamental fields and one cannot exclude a possibility that the large effective Lorentz violation, close to the horizon of a BH, could be important only in the Higgs sector.

Usually, it is assumed that close to the horizon of an astrophysical BH, where gravitational invariants are negligible, a curvature has a small impact on quantum particles. In many cases the most useful invariant is the Kretschmann scalar \[83\], which is inversely proportional to the sixth power of the radius of a BH. However, quantum vacuum is not empty Minkowski space and a large gravitational potential can significantly change renormalization parameters. It is known that the density of particles states at large energy grows exponentially \[82\]. So, if a gravitational energy is pumped into the system, new higher mass states are produced (rather than that the energy of already existing states is increased, which implies an increase in the temperature), which can amplify loop corrections in quantum vacuum.

In general, if quantum fluctuations in the Higgs sector create a bubble of a new phase that is large enough, it is energetically favorable for this bubble to expand due to the gain in volume energy over the energy stored in the bubble wall. On the other hand, if the bubble is small its surface tension compresses the bubble and it disappears. The addition of an external gravitational potential, i.e. an additional energy, can change the situation dramatically. The distortion of space changes the balance between volume and surface energies, the “cost” of bubbles formation is lower and the bubbles with smaller radii can be created.

6 Quantum vacuum at a horizon

Let us estimate the impact of the large gravitational potential on the properties of a quantum vacuum close to the horizon of a BH of mass \( M \). For simplicity, we write the Schwarzschild metric in isotropic coordinates,

\[
ds^2 = V^2(R)dt^2 + A^2(R)\delta_{ij} dx^i dx^j, \quad (i, j = 1, 2, 3)
\]

where the metric coefficients are

\[
V(r) = \frac{1 - M/2R}{1 + M/2R}, \quad A(r) = \left(1 + \frac{M}{2R}\right)^2.
\]
Here the radial function $R^2 = \delta_{ij}x^i x^j$ has the following expression in terms of the Schwarzschild radial coordinate $r$:

$$2R = r - M + \sqrt{r^2 - 2Mr} , \quad (59)$$

which only holds if $R \to \infty$ when $r \to \infty$, and outside the event horizon, $r \geq 2M$. It follows from (59) that close to the horizon $r \to 2M$, we have $2R \to M$ and $V(r) \to 0$ and, unlike the Schwarzschild case, the isotropic metric (57) leads to a real singularity at the Schwarzschild horizon, since the determinant

$$\sqrt{-g} = VA^3 = \left(1 - \frac{M}{2R}\right) \left(1 + \frac{M}{2R}\right)^5 , \quad (60)$$

becomes zero at $R = M/2$, or at $r = 2M$.

Since $V^2 \leq 1$ and $A^2 \geq 1$, for a distant observer the gravitational potential $M/2R$ effectively reduces the speed of light and increases spatial distances close to the BH horizon. This will reduce the volume of integration,

$$d^4x \to |VA^3|d^4x = \left(1 - \frac{M}{2R}\right) \left(1 + \frac{M}{2R}\right)^5 \, d^4x , \quad (61)$$

and thus will modify the Euclidean action with an external gravitational potential for the bounce solution,

$$S_4 \to \left(1 - \frac{M}{2R}\right) \left(1 + \frac{M}{2R}\right)^5 S_4 . \quad (62)$$

So, the bounce has a smaller action and the vacuum decay process can be significantly enhanced for the large gravitational potentials ($M/2R \to 1$) at some proper distance from the Schwarzschild horizon.

As an example let us consider a scalar particle of mass $m$ on the Schwarzschild background. The radial geodesic equation has the form:

$$\frac{E^2}{1 - 2M/r} - \left(1 - \frac{2M}{r}\right) p_r^2 - m^2 = 0 . \quad (63)$$

Note that close to the horizon $r \to 2M$, or for the relativistic case $p_r \gg m$, the mass term in (63) can be neglected. It is known that the energy of a relativistic particle and hence its frequency in static gravitational potential does not depend on the distance from the gravitating body [84]. As the energy $E$ does not depend on $r$, we immediately obtain from (63) that its momentum $p_r$ does depend and in the $m \to 0$ limit

$$p_r \approx \frac{E}{1 - 2M/r} . \quad (64)$$
So, the closer is the particle to the horizon, the larger is its momentum. In the isotropic coordinates with the constant parameters \( V \) and \( A \) the dispersion relation takes the form

\[
E^2 - P^2 - V^2m^2 = 0, \quad \left( P^2 = \frac{V^2}{A^2m^2} \right)
\]

and the integral is modified as

\[
\frac{A^3}{V} \int \frac{dE d^3 P}{(2\pi)^4} \frac{1}{(E^2 - P^2 - V^2m^2 + i\varepsilon)^2} \rightarrow -\frac{iA^3}{16V\pi^2} \ln \frac{m^2}{\Lambda^2}.
\]

One may comment that in static gravity, to preserve dispersion relations with constant energy, the momentum and mass terms should be modified. Then in Pauli-Villars regularization, for example, we have a real and the ghost particle, with the mass \( m \) and some fixed large mass \( \Lambda \gg m \), both affected by \( V \),

\[
\int \frac{dE d^3 P}{(2\pi)^4} \left[ \frac{1}{(E^2 - P^2 - V^2m^2 + i\varepsilon)^2} - \frac{1}{(E^2 - P^2 - V^2\Lambda^2 + i\varepsilon)^2} \right] \rightarrow -\frac{i}{16\pi^2} \ln \frac{m^2}{\Lambda^2},
\]

so that the factor \( V \) does not show up in the logarithm.

Similar results can be obtained for vector particles. The definition of the fermion propagators summing is performed by tetrads instead of metric. However, the factor containing the gravitational potential for the fermionic loop contribution, in (50), is the same as for scalars and vectors, since the trace of an odd number of Dirac \( \gamma \)-matrices is zero and we must consider an even number of fermion propagators. Then the calculation becomes exactly the same as for the scalar and vector cases except the important difference of an overall minus sign (due to the Fermi statistics) for the fermionic loop integral.

Thus, we conclude that close to the BH horizon the entire radiative corrections in (50) will be modified by the universal factor \( A^3/V \),

\[
U_1 \rightarrow \frac{A^3}{V} U_1.
\]

Contrary to the seemingly natural assumption that an astrophysical BH cannot possess a large enough curvature, even at the horizon, to be able to influence the regularization discussed above, one can elaborate as follows. For the case of the Schwarzschild solution, the origin point

\[\text{The example is considered in order to stress the point that the energy of a particle does not depend on gravitational potential } M/2R, \text{ so that, in the dispersion relation, the momentum and the mass terms are affected by } V. \text{ Also, at the horizon } V \rightarrow 0, \text{ which implies that } V \cdot m \rightarrow 0 \text{ and hence the mass term does not destroy the renormalization scheme.}\]
is considered as a true physical singularity, which appears in quantities that are independent of the choice of coordinates, like the Kretschmann scalar. In contrary, the singularity at the horizon is called a coordinate singularity, which can be avoided by changing to “good” coordinates. However, the necessary ingredient of all these singular coordinates is the so called Regge-Wheeler’s tortoise coordinate, which does not belong to the $C^2$-class of admissible coordinate transformations. Then, the singular transformations (like introduced by Kruskal-Szekeres, Eddington-Finkelstein, Lemaitre, or Gullstrand-Painleve) give delta-functions in the second derivatives (see, for example [62], for details). This means that transformed metric tensors at the horizon are not differentiable, i.e. they are of unacceptable class $C^0$. The Einstein equation for these metrics is altered with fictitious delta-sources at the horizon. For a sufficiently large BH, one can let Kretschmann invariant to be arbitrarily small at the horizon. This would be usually interpreted as we had not a large curvature, so that one can use Minkowski space to describe particles. However, the conclusion on a finiteness of the Kretschmann invariant, at the horizon, is usually based on an assumption of a mutual cancellations of delta-function source like divergences. The same is true for other invariants of the gravitational field. In general, metric components are independent functions and the cancellation of their zeros at the horizon is accidental, since it follows from the exact validity of the vacuum Einstein equations implying a perfect sphericity. However, a perfect spherical symmetry and true vacuums are rarely observed, if ever. Therefore, a smallness of the Kretschmann scalar does not mean that curvature is small at the BH horizon. Indeed, the three from six non-zero independent components of the mixed Riemann tensor for Schwarzschild metric blow up at the horizon. So, we consider a model where at the BH horizon space-time is not Minkowskian (see, for example [85–87]).

7 The toy model

In order to estimate a vacuum decay rate and new phase bubble parameters let us consider a toy model presenting the effective potential $U(h)$ in the form

$$U(h) \approx \frac{\lambda}{4} h^4 \left[1 - \frac{2}{k} \ln \frac{h}{v} \right]. \quad (68)$$

Recall that the $C^2$-differentiability assumption for metric tensors plays a key role in the singularity theorems of the general relativity. Thus the second order partial derivatives of the metric tensor should exist and be continuous. The initial value analysis also leads to the restriction that admissible coordinate transformations are to be of class $C^2$, since they should not change the Riemann tensor, which would lead to the fictitious extra source in the Einstein equations.
In \((68)\) \(k\) parameter is given by

\[
k = \frac{16\pi^2\lambda V(R)}{3(Y_t^4 - 3\lambda^2)} A(R)^3 \approx 9.3 \frac{V(R)}{A(R)^3} \approx 0.073 d_H \ll 1 ,
\]  

where couplings were defined at \(M_t\) scale as \(Y_t \approx 0.934\) and \(\lambda \approx 0.127\) and changes in these couplings were neglected up to a few TeV scale. It follows from \((68)\) that in Minkowski space-time, where \(V = A = 1\), the SM vacuum at \(h = 0\) is meta-stable but the probability of its decay is extremely low. However, in a strong gravitational field close to a BH horizon the parameter \((69)\) decreases and at some distance to the horizon the potential \((68)\) becomes negative already at \(h \approx v\) leading to a significant vacuum instability. The potential \((68)\) is shown in Fig. 3 at \(k = 0.1\).

The probability of vacuum decay can be calculated by solving numerically the equation of bounce motion. The presence of a BH breaks the translational symmetry and as the result a bounce shape corresponding to the minimal action can be not spherically symmetric. However, a solution with \(O(4)\) symmetry can be used as the lower bound on the vacuum decay probability.

The \(O(4)\) bounce solution \([47]\) is a configuration satisfying the Euclidean field equation

\[
\frac{\partial^2 h}{\partial \rho^2} + \frac{3 \partial h}{\rho \partial \rho} = \frac{\partial U(h)}{\partial h} ,
\]  

with the boundary condition \(U \to 0\) (false vacuum) as \(\rho \to \infty\), where \(\rho\) is the Euclidean
Figure 4: The bounce solution of Eq. (70) at $k = 0.1$.

4-radius

$$ \rho = \sqrt{t^2 + x_i x^i} . \quad (i = 1, 2, 3) $$ (71)

The equation (70) is not exactly solvable. We solve it numerically by using SimpleBounce, a C++ package [88] for finding the bounce solution for the false vacuum decay. An example of a numerical solution with $k = 0.1$ obtained in an assumption that a distance to the Schwarzschild sphere is constant during nucleation and collapse of the new phase bubble presented in Fig. 4. For different values of $k$ the bounce solution can be parameterized as

$$ h(\rho) \approx \frac{6.36v}{\sqrt{1 + \left(\frac{\lambda}{2k}\right)^2 \left(bv\rho\right)^4}} $$ (72)

where $b \approx 5.9$ and the critical radius $\rho_c$ of a true vacuum bubble is given by

$$ \rho_c \approx \frac{0.045}{\sqrt{\lambda v}} \sqrt{\frac{k}{0.01}} \approx 10^{-17} \sqrt{\frac{k}{0.01}} \text{ cm} . $$ (73)

At high nucleation rate, one distinguishes expanding and contracting bubbles. In order for the bubbles to expand rather than contract, it is necessary that the gain in volume energy from the bubble interior being in the lower free energy phase overcomes the unfavorable surface tension of the bubble. This will happen if the bubble radius is larger than the critical radius $\rho_c$, for which the two effects balance out [47,48,89].
For the $O(4)$ bounce the Euclidean action is given by the equation:

$$ S_4 = 2\pi^2 \int d\rho \, \rho^3 \left[ \frac{1}{2} \left( \frac{dh}{d\rho} \right)^2 + U(h) \right]. $$

(74)

This equation, in combination with (62), gives the action for the critical bubble in a gravitational field

$$ S_4 \approx 0.0645 \frac{k}{0.01} \frac{128}{\lambda} d_H \approx 480 d_H^2. $$

(75)

8 Discussion

The toy realization, described above, implies that the modification of the Higgs vacuum decay in the vicinity of a BH corresponds to $A_s \approx 480$ and $a = 2$ introduced in heuristic formula (2).

Besides this, as it follows from Fig. 3, the Higgs potential is modified in a way that the position of its maximum is moved close to the values of the EW scale. In its turn, the bounce solution, presented in Fig. 4, indicates that

$$ h_b \approx 6v \approx 1.5 \text{ TeV}, $$

(76)
in (3). Therefore, according to (5), bubbles which are capable to convert into a $\mu$BHs of mass $M_{\mu\text{BH}} \approx 5 \times 10^7$ g by the Higgs vacuum decay at $h_b \approx 1.5$ TeV should have radius $R_{\text{bub}} \approx 9 \times 10^{-4}$ cm. This implies that the collision (percolation) time $\Delta t_{\text{col}} \approx 30$ fs is negligible being compared with the merging time $t_{\text{merg}} \approx 10$ ms, which ensures that in the case of maximal effective triboluminescence discussed in Section 3 the $\mu$BHs of required masses will be formed almost immediately to have enough time to evaporate out completely and produce the detectable gamma ray and neutrino signals with characteristics elucidated in Section 3.

Notice, the temporal properties of disturbed space-time dynamics at the merging are also defined by $t_{\text{merg}}$. Since it takes a negligible fraction of the merging time to grow the bubbles to the relevant size, any dynamical evolution of the space-time within UVS, during the bubbles conversion into $\mu$BHs, should not affect the formation of $\mu$BHs. Also, it is assumed that the Hawking evaporation of $\mu$BHs, immersed into rapidly evolving space-time within the gap of the merger, stays intact.

One can express the total numbers of $\mu$BHs (15), (16) created by $s = 2$ and $s = 3$ mechanisms, in the first scenario allocated in section 2, as follows

$$ N_{\mu\text{BHs}}(d_H, 2) \approx 5.5 \times 10^{174} d_H^{d_H} \frac{P_{\mu\text{BH}}(2)}{\langle \Gamma(d_H) \rangle^2} \left( \frac{1}{1 \text{ GeV}^8} \right), $$

(77)
\[ N_{\mu\text{BHs}}(d_H, 3) \approx 4.3 \times 10^{247} d_H^8 \mathcal{P}_{\mu\text{BH}}(3)(\Gamma(d_H))^3 \left( \frac{1}{1 \text{ GeV}^{12}} \right). \] (78)

These estimates are obtained for a BBH merger with components of mass $10M_\odot$. Using the numerically computed action (75) along with (1) and (2) one can express the average decay rate as follows

\[ \langle \Gamma(d_H) \rangle \approx \mathcal{M}^4 \exp \left[ -480d_H^2 \right]. \] (79)

Some examples of analytical and numerical calculations of the pre-factor $\mathcal{M}$ can be found in [90–93]. In the following $\mathcal{M} = v$ will be used as a rough value in (77) and (78).

Comparing the estimates (77) and (78) with the number of $\mu$BHs needed to provide the energy budget of detectable electromagnetic counterpart, as discussed in Section 3, we arrive to the following estimate

\[ d_H \lesssim 0.64, \] (80)

made for $\kappa_f \approx 10^{-3}$, taken from assessment of [29]. The estimate (80) is valid for both $s = 2$ and $s = 3$ mechanisms.

Due to the logarithmic dependence defining the value $d_H$ of (80), $d_H$ is quite weakly sensitive to $\kappa_f$ and $\mathcal{P}_{\mu\text{BH}}(s)$ and stays almost the same for both quantities (39) and (40).

Finally, evaluating the condition (17) which corresponds to the second scenario, discussed in section 2 we obtain

\[ d_H \lesssim 0.23. \] (81)

These results, obtained in the framework of the toy model above, support our conjecture that the nucleation of new phase bubbles can be enhanced in a region “sandwiched” between horizons of merging black holes.

Notice that, in second scenario, in order to produce the $\mu$BHs in amount of $N_{\mu\text{BHs}}^{\text{SGRB}} \approx 10^{21}$ and $N_{\mu\text{BHs}}^{10\%M_\odot} \approx 10^{24}$, the colliding bubbles need to occupy the volumes about $3 \times 10^{-3}$ km$^3$ and 3 km$^3$, respectively. Certainly, these volumes can fit inside $V_{\text{UVS}}(d_H) \approx 1.1 \times 10^4$ km$^3$ calculated from (8) for $d_H = 0.23$ in case of $\approx 10M_\odot$ components of BBH merger. In other words, the amount of the Higgs meta-stable vacuum needed to produce a planetary cumulative mass of

\footnote{Our current ignorance of details of the mechanism of $\mu$BHs formation in bubble collisions which might be represented by a poor knowledge of the value of $\mathcal{P}_{\mu\text{BH}}(s)$, say up to about 10 orders of magnitude uncertainty ($10^{-10} \lesssim \mathcal{P}_{\mu\text{BH}}(s) \lesssim 1$), results only in about 10% variation in estimate (80). A detailed consideration of the formation of BHs in bubble collisions is in preparation [30].}
μBHs, which are capable to provide SGRB energy budget for the electromagnetic messenger, is about $3 \times 10^{-3}$ km$^3$. A 3 km$^3$ of the Higgs meta-stable vacuum is capable to emit about 10% of $M_\odot$ in Hawking radiation.

It is expected that a combination of both scenarios, discussed in section 2, will take place. This implies that photons and neutrinos are suppose to be emitted within the distance range $0.6 \lesssim d_H \lesssim 0.2$, defined by (80) and (81), so that the gravitational energy reduction factor (33), $z_g + 1 \approx 2$. This red shift was used for the model of the electromagnetic and neutrino signals, developed in section 3, for $\simeq 100$ TeV outgoing photons and neutrinos.

It is extremely unlikely that any expanding bubble wall, escaping from the UVS, would survive in a way to be able to trigger the decay of the SM metastable vacuum everywhere. Indeed, to reach the outer space by its domain wall an expanding bubble should ultimately fill in the entire volume of UVS which will contain already a great multitude of small, while already overcritical bubbles, due the conditions of high nucleation rate created inside UVS within $t_{\text{mrg}} \simeq 10$ ms. Colliding with the multitude of bubbles the expanding wall will be numerous perforated so that the continuous topology of the wall providing the vacuum decay conditions will be destroyed leaving only some rapidly decaying peaces of the wall escaping out of the UVS. Moreover, occupying the entire volume a potentially escaping bubble should ultimately touch the horizons of the components of a BBH merger, which in their turn still covered by the ongoing process of bubble nucleation. The collisions with those at horizons bubbles the constituents of the bowling substance will also lead to the ultimate perforation of the escaping wall and destruction of its continuous topology. The bubble with expanding walls, if any, will fill in the entire volume of UVS and collides with the horizons provided that $V_{\text{escB}} = \frac{4}{3}\pi(ct_{\text{mrg}})^3$ exceeds $V_{\text{UVS}}$ given by (8). This condition can be recast into constraint on the mass of BBH component, which reads $M_{\text{BH}} \lesssim \frac{800M_\odot}{d_H}$. Therefore, it is extremely unlikely that BBH mergers with parameters considered in this study could trigger the decay of the global metastable state of the SM vacuum.

9 Conclusions

In this paper we explored the phenomenon that may occur in a vicinity of a BH horizon due to the gravitational corrections to the Higgs potential. The gravitational corrections can provide conditions for the Higgs vacuum decay, so that a BH being immersed into the EW vacuum will
be encompassed by a thin shell consisting of a “bowling substance” represented by nucleating bubbles of new vacuum phase surrounded by the SM vacuum. Since the nucleating bubbles fall under the horizon an external observer of a single BH should always stay in the EW meta-stable state. However, in the gap between components of a BBH merger, one might expect a formation of a volume with effective zero gravity, so that for a short time period the unstable vacuum is kind of “sandwiched” between the horizons of the components. Within the time of existence of the “sandwich” the bubbles, nucleated in its volume, will collide and convert their energy into \( \mu \)BHs, which in their turn will be evaporated by emission of the Hawking radiation within the final stage of the coalescence of the BBH. The energy release in this burst-like evaporation, at a BBH of LIGO-Virgo scale, may range from the isotropic energy equivalent of SGRBs up to 10% fraction of \( M_\odot \). We call this phenomenon the Higgs induced triboluminescence in an analogy to that one existing in solid state physics when materials could emit light being mechanically stimulated, such as rubbing, grinding, impact, stretching, and compression.

Due to the emission of very high energy radiation \( \gtrsim 100 \) TeV of all SM particles and, maybe, beyond SM species the phenomenon of Higgs induced triboluminescence in BBH mergers should have quite distinguishable multi-messenger signatures. Indeed, a gravitational wave signal from a BBH merger arriving at currently running LIGO, VIRGO and KAGRA, or to be constructed in the future, more sensitive, gravitational wave facilities, should be accompanied with a \( \gtrsim 100 \) TeV neutrino signal in IceCube detected from the same direction and with an electromagnetic counterpart to be registered by space based gamma ray monitors \cite{34,36}, the high energy gamma ray telescope \cite{37} and/or very high energy atmospheric Cherenkov facilities \cite{39,43}. Propagating through the universe, gamma rays of such a high energy will develop electromagnetic cascades due to \( e^+e^- \) pair production on cosmic microwave background and extra-galactic background light, which will multiply the TeV-GeV spectral component at the cost of very high energy thermal Hawking emission. However, whatever the arrived spectrum of the gamma rays is, we have always to expect a burst-like temporal behavior of the signal. The observation of this phenomenon involves a detection of three types of messengers, namely gravitational waves, very high energy neutrinos and gamma rays, which makes it a perfect physics case for the multi-messenger campaign.

In the case of observation of the effect of Higgs induced triboluminescence in BBH mergers one benefits for valuable impacts on understanding of at least two very intriguing topics of
contemporary physics, namely, the decay of meta-stable state of the EW vacuum and the evaporation of BHs via Hawking radiation.
