Abstract. Light-weight super-resolution (SR) models have received considerable attention for their serviceability in mobile devices. Many efforts employ network quantization to compress SR models. However, these methods suffer from severe performance degradation when quantizing the SR models to ultra-low precision (e.g., 2-bit and 3-bit) with the low-cost layer-wise quantizer. In this paper, we identify that the performance drop comes from the contradiction between the layer-wise symmetric quantizer and the highly asymmetric activation distribution in SR models. This discrepancy leads to either a waste on the quantization levels or detail loss in reconstructed images. Therefore, we propose a novel activation quantizer, referred to as Dynamic Dual Trainable Bounds (DDTB), to accommodate the asymmetry of the activations. Specifically, DDTB innovates in: 1) A layer-wise quantizer with trainable upper and lower bounds to tackle the highly asymmetric activations. 2) A dynamic gate controller to adaptively adjust the upper and lower bounds at runtime to overcome the drastically varying activation ranges over different samples. To reduce the extra overhead, the dynamic gate controller is quantized to 2-bit and applied to only part of the SR networks according to the introduced dynamic intensity. Extensive experiments demonstrate that our DDTB exhibits significant performance improvements in ultra-low precision. For example, our DDTB achieves a 0.70dB PSNR increase on Urban100 benchmark when quantizing EDSR to 2-bit and scaling up output images to ×4. Code is at https://github.com/zysxmu/DDTB.

1 Introduction

Single image super-resolution (SISR) is a classic yet challenging research topic in low-level computer vision. It aims to construct a high-resolution (HR) image from
Fig. 1. The first column shows the activation histograms. The second and third columns show the maximum and minimum activation values of different samples. We perform experiments with EDSR [24] and RDN [47] on DIV2K [38] dataset.

a given low-resolution (LR) image. Recent years have witnessed the revolution of deep convolutional neural networks (DCNN), which leads to many state-of-the-arts [24,47,5] in SISR task.

When looking back on the development of DCNN in SISR, we find that the record-breaking performance is accompanied by a drastically increasing model complexity. SRCNN [5], the first work to integrate DCNN to SR, has only three convolutional layers with a total of 57K parameters. Then, EDSR [24] constructs a 64-layer CNN with 1.5M parameters. Equipped with a residual dense block, RDN [47] introduces 151 convolutional layers with 22M parameters. Also, it requires around 5,896G float-point operations (FLOPs) to produce only one 1920×1080 image (upsampling factor $\times4$). On the one hand, the high memory footprint and computation cost of DCNN-based SR models barricade their deployment on many resource-hungry platforms such as smartphones, wearable gadgets, embedding devices, etc. On the other hand, SR is particularly popular on these devices where the photograph resolution must be enhanced after being taken by the users. Therefore, compressing DCNN-based SR models has gained considerable attention from both academia and industries. In recent years, a variety of methodologies are explored to realize practical deployment [25,20,10,8].

By discretizing the full-precision weights and activations within the DCNN, network quantization has emerged as one of the most promising technologies. It reduces not only memory storage for lower-precision representation but computation cost for more efficient integer operations. Earlier studies mostly focus on high-level vision tasks, such as classification [20,7,35,26,27,48] and segmentation [44,45]. A direct extension of these methods to SR networks has been proved infeasible since low-vision networks often have different operators with these high-level networks [23]. Consequently, excavating specialized quantization methods for DCNN-based SR models recently has aroused increasing attention in the research community. For example, PAMS [23] designs a layer-wise quantizer
Fig. 2. Example of “quantization unfitness” using RDN [47] on DIV2K [38]. The orange bar denotes the quantization levels. The red arrows show the quantization level of activations. (a) Two quantization levels are wasted on the region without activations. (b) High-magnitude activations are quantized to a small quantization level. (c) The distribution of the quantization levels from dual bounds in our DDTB.

with a learnable clipping to tackle the large ranges of activations, but severe performance degradation occurs in ultra-low precision settings (e.g., 2-bit and 3-bit) as shown in Sec. 4.2. A recent study DAQ [11] adopts a channel-wise distribution-aware quantization scheme. Despite the progress, the performance improvement comes at the cost of considerable overhead from normalizing and de-normalizing feature maps, as well as the expensive per-channel quantizer. Therefore, existing studies are stuck in either heavy extra costs or severe performance drops when performing ultra-low precision quantization.

In this paper, we realize that the inapplicability of existing studies comes from the contradiction between the layer-wise symmetric quantizer and the asymmetric activation distribution in DCNN-based SR models. Specifically, it has been a wide consensus [24,47,46,9] that removing batch normalization (BN) layers increases the super-resolution performance since low-level vision is sensitive to the scale information of images while BN reduces the range flexibility of activations. However, the removal of BN leads to highly asymmetric activation distribution, as well as diverse maximum and minimum activations for different input samples. Illustrative examples with EDSR [24] and RDN [47] are given in Fig. 1. Despite some previous works equip SR networks with BN layers, they have to compensate for the performance drops by other strategies. For example, SRResNet [22] constructs a highway that propagates the activations of the first convolutional layer to the outputs of every other block, which again leads to activation distributions like Fig. 1.

Although these abnormal activation distributions benefit a full-precision SR network, they are unfriendly to the quantized version which often constructs a symmetric quantizer with only one clipping bound to perform network quantization, resulting in the issue of “quantization unfitness”. Fig. 2 illustrates a toy example. With an asymmetric activation distribution, a large clipping wastes two quantization levels on the region without any activation items, while a small clipping quantizes large-magnitude activations to a small quantization level which leads to large quantization error and causes details loss in high-resolution im-
ages. Thus, an adaptive quantizer to the activation distribution is crucial to the quality of the reconstructed high-resolution images.

Motivated by the above analysis, in this paper, we propose dynamic dual trainable bounds (DDTB) to quantize the activations in SR models. DDTB innovates in: 1) A layer-wise quantizer with trainable upper and lower bounds to tackle the highly asymmetric activations; 2) A dynamic gate controller to adaptively adjust the upper and lower bounds based on different input samples at runtime for overcoming the drastically varying activation ranges over different samples. To minimize the extra costs on computation and storage, the dynamic gate is quantized to 2-bit and applied to part of the network based on the dynamic intensity in each layer. We also introduce an initializer for DDTB. Specifically, we first use the activation statistics from the full-precision network instead of the quantized version to initialize the upper and lower bounds. Then, the dynamic gate controller is trained individually towards its target output of 1 for all inputs in the early several epochs. Combining with the proposed initializer, DDTB provides significant performance improvements, especially when SR models are quantized to the case of ultra-low bits. For instance, compared with the state-of-the-art, our DDTB achieves performance gains by 0.70dB PSNR on Urban100 benchmark [12] when quantizing EDSR×4 [24] to 2-bit.

2 Related Work

2.1 Single Image Super Resolution

Owing to the strength of deep convolutional neural networks, DCNN-based SR methods have gained great performance boosts and dominated the field of SISR. SRCNN [5] is the first to construct an end-to-end CNN-based mapping between the low- and high-resolution images. By increasing the network depth, VDSR [17] manifests significant performance improvements. Nevertheless, the increasing depth also weakens the capacity of overcoming the gradient vanishing problem and retaining image detail. Consequently, the skip-connection based blocks, such as the residual block [22] and the dense block [39], have become a basic component of the SR models [24,47]. Also, many other complex network structures like channel attention mechanism [46,30] and non-local attention [33,32] are also integrated into SR for a better performance. With the increasing popularity of CNNs on resource-hungry devices, developing efficient SR models has aroused much attention recently. Most works in this area are indicated to devising lightweight network architectures. For example, DRCN [18] and DRRN [37] adopt the recursive structure to increase the network depth while mitigating the model parameters. To escape from the expensive up-sampling operator, FSR-CNN [6] introduces a de-convolutional layer while ESPCN [36] devises a sub-pixel convolution module. Many others resort to enhance the efficiency of intermediate feature representation [21,1,13,28]. However, these computation savings are very limited compared to costs from the full-precision convolution.
2.2 Quantized SR Models

As a promising technique to compress SR models, network quantization has received ever-growing attention [29,43,15,11,23,41]. Ma et al. [29] pioneered 1-bit quantization over the weights of SR model. Performance drops severely if binarizing the activations as well. To remedy this issue, the structure of SR models is often adjusted. For example, BAM [43] and BTM [15] introduce multiple feature map aggregations and skip connection layers. Except for 1-bit quantization, other ultra-low quantization precision such as 2-bit, 3-bit and 4-bit is discussed in many studies as well. To handle the unstable activation ranges, Li [23] proposed a symmetric layer-wise linear quantizer that adopts a trainable clipping bound to clamp the abnormal activations. As for weights, the same symmetric quantizer is adopted but the clipping variable is simply set to the maximum magnitude of the weights. Moreover, the quantized model is enhanced by the structured knowledge transfer from its full-precision counterpart. Wang et al. [41] chose to quantize all layers of SR models and perform both weights and activations quantization using a symmetric layer-wise quantizer equipped with a trainable clipping variable. DAQ [11] observes that each channel has non-zero distributions and the activation values also vary drastically to the input image. Based on this observation, a channel-wise distribution-aware quantizer is adopted where the activations are normalized before discretizing and de-normalized after convolution.

3 Methodology

3.1 Preliminaries

Previous low-bit SR adopt a symmetric quantizer to perform quantization upon the premise of activations and weights with a symmetric distribution. Specifically, denoting $b$ as the bit-width, $x$ as weights or activations, $\alpha$ as the clipping bound, the symmetric linear quantizer is defined as:

$$\bar{x} = \text{round}\left(\frac{\text{clip}(x, \alpha)}{s}\right) \cdot s,$$

where $\text{clip}(x, \alpha) = \min(\max(x, -\alpha), \alpha)$, $\bar{x}$ is the de-quantized value of $x$, $\text{round}(\cdot)$ rounds its input to the nearest integer and $s = 2^{2^{b-1}}$ is the scaling factor that projects a floating-point number to a fixed-point integer. An appropriate $\alpha$ is crucial to the quantization performance since it not only eliminates outlier but refers to retaining details in the reconstructed images.

3.2 Our Insights

Despite the progress, the performance of earlier low-bit SR quantization methods [23,11,41] remains an open issue when quantizing the full-precision counterpart to ultra-low precision with a layer-wise quantizer. After an in-depth analysis, we attribute the poor performance to the contradiction between the layer-wise symmetric quantizer and the asymmetric activation distribution in SR models.
Concretely, we observe the activations from different SR models. Fig. 1 shows the histograms, maximum and minimum of activations collected from the pre-trained EDSR [24] and RDN [47]. From the first column of Fig. 1, we realize that the activations of SR models are highly asymmetric in an irregular state. For example, the magnitude of the minimum activation is almost twice that of the maximum activation in EDSR. A similar phenomenon can be observed in RDN. Furthermore, as the second and third columns of Fig. 1 shows, the maximum and minimum of activations also vary drastically for different samples. Such an asymmetric activation distribution mostly results from the removal of BN layers in modern SR networks since BN reduces the scale information of images which however is crucial to SR tasks. Despite some studies retain BN layers, however, other remedies have to be taken to regain the performance. For example, SRResNet [22] propagates outputs of the first layer to the outputs of all following blocks, which causes asymmetric distributions as well. It is natural that the symmetric quantizer in existing studies cannot well fit the symmetric activation distributions, which we term as “quantization unfitness” in this paper.

To be specific, using only one clipping bound fails to handle the symmetric activations, whatever the value of $\alpha$. To demonstrate this, we quantize the activations of RDN [47] to 3-bit using the quantizer in Eq. (1). As shown in Fig. 2(a), the lack of activations along the negative axis direction causes a waste of two quantization levels if $\alpha$ is set to a large value such as the maximum of the activation magnitude. The wastes are more severe as the bit-width goes down. Taking the activations in Fig. 2(a) as an example, we observe 37.5% are wasted in 3-bit quantization, while it increases sharply to 50% in 2-bit quantization. When it comes to a small $\alpha$ such as the absolute value of the minimum of activation magnitude, as illustrated in Fig. 2(b), though avoiding the waste on quantization levels, only the small-magnitude activations are covered, leading to large quantization error since many high-magnitude activations are quantized to a small quantization level, i.e., $\alpha$. Recall that SR models are sensitive to the scale information of images. Consequently, representing the large full-precision activations with a small quantization level inevitably brings about detail loss in the reconstructed high-resolution images, leading to significant quality degradation. Similar observations can be found if the same clipping bound is applied to all the input images since the maximum and minimum activations over different images also drastically vary as illustrated in Fig. 1. Thus, an appropriate quantizer is vital to the performance of quantized SR models.

3.3 Our Solutions

In the following, we first detail dynamic dual trainable bounds (DDTB) specifically designed to quantize activations of SR models. Then, we elaborate on our initializer for DDTB. Finally, we describe the quantizer for weights. The overall computational graph is presented in Fig. 3(a).

**Activation Quantization.** Our DDTB consists of two parts: 1) A layer-wise quantizer with a trainable upper bound and a trainable lower bound; 2) A dynamic gate controller with adaptive upper and lower bounds to the inputs.
Dynamic Dual Trainable Bounds (DDTB)

Fig. 3. (a) Computational graph in the $l$-th quantized convolutional layer. (b) Structure of the dynamic gate controller.

Dual trainable bounds: As mentioned in Sec. 3.2, only using one clipping variable to clamp the asymmetric activations leads to the “quantization unfitness” problem. To address this, we introduce two trainable clipping variables of $\alpha_u$ and $\alpha_l$ to respectively determine the upper bound and the lower bound of the activations. Equipped with these two dual trainable clipping variables, the quantized integer $q$ for the input $x$ can be obtained as:

$$q = \text{round}\left(\frac{\text{clip}(x, \alpha_l, \alpha_u)}{s}\right) + Z,$$

where $\text{clip}(x, \alpha_l, \alpha_u) = \min(\max(x, \alpha_l), \alpha_u)$, $Z = \text{round}\left(\frac{-\alpha_l}{s}\right)$ is a zero-point integer corresponding to the real value 0. Accordingly, the scaling factor $s$ is calculated as: $s = \frac{\alpha_u - \alpha_l}{2^b - 1}$. Finally, the de-quantized value $\bar{a}$ is:

$$\bar{a} = (q - Z) \cdot s.$$  

Combining Eq. (2) and Eq. (3) completes our activation quantizer. As depicted in Fig. 2(c), the quantization levels generated by this quantization scheme well fit the activations when $\alpha_u$ and $\alpha_l$ are set to the maximum and minimum of activations, respectively. In order to accommodate samples with drastically varying ranges, we employ the stochastic gradient descent to adaptively learn $\alpha_u$ and $\alpha_l$ by minimizing the finally loss function. Denoting the clipped activations as $\tilde{a} = \min(\max(a, \alpha_l), \alpha_u)$, $\frac{\partial a}{\partial a}$ is set to 1 by using the straight-through estimator (STE) [4]. Then, the gradients of $\alpha_u$, $\alpha_l$ can be calculated as:

$$\frac{\partial \bar{a}}{\partial \alpha_u} = \frac{\partial \bar{a}}{\partial \tilde{a}} \frac{\partial \tilde{a}}{\partial \alpha_u} \approx \begin{cases} 1, & \alpha_u \geq \alpha_u \\ 0, & \alpha_u \leq \alpha_u \end{cases}, \quad \frac{\partial \bar{a}}{\partial \alpha_l} = \frac{\partial \bar{a}}{\partial \tilde{a}} \frac{\partial \tilde{a}}{\partial \alpha_l} \approx \begin{cases} 0, & \alpha \geq \alpha_l \\ 1, & \alpha \leq \alpha_l \end{cases}.$$  

With the dual $\alpha_l$ and $\alpha_u$, “quantization unfitness” can be alleviated. Note that, early study [16] also introduces two trainable parameters to determine the quantization range. This paper differs in: 1) [16] utilizes the center and radius of the quantization region to parameterize the quantization range while we explicitly introduce the upper and lower bounds. 2) [16] requires an expensive transformation to normalize activations to a fixed range before performing quantization.
3) Though trainable, the final quantization range is consistent with different inputs. Thus, we design a dynamic gate controller to provide an instance-wise quantization range adaptive to different inputs as illustrated in the next section.

**Dynamic gate controller:** Though the trainable upper and lower bounds partially alleviate the “quantization unfitness” problem, it is still suboptimal if only applying the same pair of \((\alpha_l, \alpha_u)\) for different inputs since their activation ranges also dramatically vary as shown in Fig. 1. To address this issue, we devise a dynamic gate controller to adapt \((\alpha_l, \alpha_u)\) to every input sample at runtime.

Fig. 3(b) depicts the structure of our gate controller, which is composed of a series of consequently stacked operators including two convolutional layers, a BN layer, a ReLU function, and a sigmoid function multiplied by 2. It takes the feature maps from the SR model as inputs and outputs two scaling coefficients \(\beta_l\) and \(\beta_u\) for each sample. Then, \(\beta_l\) and \(\beta_u\) are respectively used to re-scale the lower bound \(\alpha_l\) and the upper bound \(\alpha_u\), results of which serve as the final clipping bounds of the corresponding input images as shown in Fig. 3(a). Denoting the \(\alpha_u' = \beta_u \cdot \alpha_u\) and \(\alpha_l' = \beta_l \cdot \alpha_l\), the clipped activations \(\tilde{a}\) now can be reformulated as: \(\tilde{a} = \min(\max(a, \alpha_l'), \alpha_u')\). Similar to Eq. (4), the gradient is:

\[
\frac{\partial \bar{a}}{\partial \alpha_l'} = \frac{\partial \bar{a}}{\partial \alpha_u'} \approx \begin{cases} 1, & a \geq \alpha_u' \\ 0, & a < \alpha_u' \end{cases}, \quad \frac{\partial \bar{a}}{\partial \alpha_l'} = \frac{\partial \bar{a}}{\partial \alpha_l} \approx \begin{cases} 1, & a \geq \alpha_l' \\ 0, & a < \alpha_l' \end{cases}.
\]

Then, the gradients of \(\beta_u, \beta_l, \alpha_u, \alpha_l\) can be obtained by the chain rule.

Our gate controller enables the clipping bounds adaptive to each of the input samples, with which the gate outputs are dynamically correlated at runtime. However, the extra costs on computation and storage of the gate controller are expensive, causing a contradiction with our motive to reduce the complexity of SR models. Thus, we reduce the its complexity from two perspectives: 1) We quantize the weights and activations of the gate to a 2-bit using the quantizer defined by Eq. (2) and Eq. (3). The clipping bounds are set as the maximum and minimum of the weights/activations. We empirically find that such a simple setting is sufficient. During the inference phase, the BN layer in gate controller can be folded into the previous convolutional layer [41] and the extra floating-point operations are very cheap. 2) We choose to apply our dynamic gate controller to some layers of the SR model. Concretely, we define the dynamic intensity in the \(l\)-th layer as \(DI_l = V_{max}^l + V_{min}^l\), where \(V_{max}^l\) and \(V_{min}^l\) are variances of the maximum activations and minimum activations. The overhead is trivial as it forwards the training data to the full-precision network only once and can be completed offline. It is intuitive that a larger \(DI_l\) indicates a more dynamic activation range. Thus, we apply the dynamic gate to these layers with the top-\(P\)% largest dynamic intensity, where the gate ratio \(P\) is a hyper-parameter.

**DDTB Initializer.** One common way to initialize the \(\alpha_u\) and \(\alpha_l\) is to use the activation statistics such as the maximum and minimum values in the quantized network. However, for ultra-low bit cases, quantization error accumulates drastically, leading to unreliable statistics in deep layers. Instead, we derive the activation statistics by feeding a patch of images to the full-precision network, and then use the \(M\)-th and \((100 - M)\)-th percentiles of obtained activations to
initialize the $\alpha_u$ and $\alpha_l$, which are more stable even in the ultra-low bit situation since the full-precision network is not challenged by the quantization error issue.

In addition, we observe that the $\beta_u$ and $\beta_l$ are either too small or too large in the early training phase due to the random initialization of gate weights, which obstructs the learning of $\alpha_u$ and $\alpha_l$, and leads to inferior performance. Therefore, in the first $K$ training epochs, we do not apply $\beta_u$ and $\beta_l$ to scaling $\alpha_u$, $\alpha_l$, and the gate is trained individually to push its outputs close to 1 whatever the inputs. After $K$ epochs, we then apply $\beta_u$ and $\beta_l$ which start from a stable initial value, i.e., around 1. Then, the dynamic gate controller and the clipping variables are jointly trained to accommodate the drastically varying activation ranges. In all our experiments, we set $K = 5$.

**Weight Quantization.** The symmetric quantizer is also adopted to quantize weights in previous works. We suggest utilizing the asymmetric quantizer to quantize the weights. Similar to our activation quantization, an upper bound $w_u$ and a lower bound $w_l$ are used to clip the weight range: $\bar{w} = \min(\max(w, w_l), w_u)$. The quantized integer and de-quantized value can be obtained similar to Eq. (2) and Eq. (3). This quantization scheme is also compatible with the symmetric case when $w_u = -w_l$. In all our experiments, $w_u$ is set to the 99-th percentile and $w_u$ is set to 1-th percentile of the full-precision weights since we observe no performance gains if setting them to trainable parameters.

### 3.4 Training Loss

Following PAMS [23], we use $L_1$ loss and $L_{SKT}$ loss in all the experiments. Denoting $D = \{I_{LR}^i, I_{HR}^i\}_{i=1}^N$ as the training dataset with $N$ pairs of LR and HR images. The $L_1$ loss and $L_{SKT}$ loss are defined as:

$$L_1 = \frac{1}{N} \sum_{i=1}^{N} \|I_{LR}^i - I_{HR}^i\|_1,$$

(6)

$$L_{SKT} = \frac{1}{N} \sum_{i=1}^{N} \left\| \frac{F'_{S}(I_{LR}^i)}{\|F'_{S}(I_{LR}^i)\|_2} - \frac{F'_{T}(I_{LR}^i)}{\|F'_{T}(I_{LR}^i)\|_2} \right\|_2,$$

(7)

where $F'_{S}(I_{LR}^i)$ and $F'_{T}(I_{LR}^i)$ are structure features of $I_{LR}^i$ from the quantized network and the full-precision network, respectively. The structure feature can be calculated by $F'(I_{LR}^i) = \sum_{c=1}^{N} |F_c(I_{LR}^i)|^2 \in \mathbb{R}^{H \times W}$, where $F(I_{LR}^i) \in \mathbb{R}^{C \times H \times W}$ is the feature map after the last layer in the high-level feature extractor. Then, the overall loss function $L$ is:

$$L = L_1 + \lambda L_{SKT}.$$

(8)

where $\lambda = 1,000$ in all our experiments.

4 Experiments

4.1 Implementation Details

All the models are trained on the training set of DIV2K including 800 images [38], and tested on four standard benchmarks including Set5 [2], Set14 [22], BSD100 [31] and Urban100 [12]. Two upscaling factors of ×2 and ×4 are evaluated. The quantized SR models include EDSR [24], RDN [47], and SRResNet [22]. We quantize them to 4, 3, and 2-bit and compare with the SOTA competitors including DoReFa [49], Tensorflow Lite (TF Lite) [14], PACT [3], and PAMS [23]. The PSNR and SSIM [42] over the Y channel are reported.

The full-precision models and compared quantization methods are implemented based on their open-source code. For the quantized models, following PAMS [23], we quantize both weights and activations of the high-level feature extraction module. The low-level feature extraction and reconstruction modules are set to the full-precision1. The batch size is set to 16 and the optimizer is Adam [19] with $\beta_1 = 0.9$, $\beta_2 = 0.999$ and $\epsilon = 10^{-8}$. We set the initial learning rate to $10^{-3}$ and halve it every 10 epochs. For EDSR, the gate ratio $P$ is set to 30 and the initialization coefficient $M$ is 99. As for RDN, $P$ and $M$ are 50 and 95. For SRResNet, $P = 10$ and $M = 99$. The total training epochs are set to 60. The training images are pre-processed by subtracting the mean RGB. During

1 Results of fully quantized SR models are provided in the supplementary material.
Table 2. PSNR/SSIM comparisons between existing low-bit SR methods and our DDTB in quantizing RDN \cite{47} of scale 4 and scale 2 to the low-bit format. Results of the full-precision model are displayed below the dataset name.

4.2 Experimental Results

Table 1, Table 2, and Table 3 respectively show the quantitative results of EDSR, RDN, and SRResNet on different datasets. Details are discussed below.

**Evaluation on EDSR.** In the case of 4-bit, our DDTB outperforms the advanced PAMS by a large margin. For instance, for 4-bit EDSR \times 4, DDTB obtains 0.37dB PSNR gains on Urban100. More noticeable improvements can be observed when performing ultra-low bit quantization. For instance, our DDTB obtains performance gains by 0.94dB, 0.66dB, 0.36dB, and 0.70dB on Set5, Set14, BSD100, and Urban100 when quantizing EDSR \times 4 to 2-bit.

**Evaluation on RDN.** When quantizing the model to 4-bit, our DDTB slightly outperforms the existing SOTA of PACT. When it comes to ultra-low bit, the superior performance is in particular obvious. In detail, for 2-bit RDN \times 4, the performance gains of our DDTB are 0.64dB, 0.45dB, 0.26dB, and 0.51dB on Set5, Set14, BSD100, and Urban100 when quantizing EDSR \times 4 to 2-bit.

**Evaluation on SRResNet.** The results of SRResNet also manifest that the performance gains of our DDTB are more prominent with ultra-low precision. For 2-bit SRResNet \times 4, our DDTB improves the performance by 0.65dB, 0.47dB, 0.30dB, and 0.69dB on Set5, Set14, BSD100, and Urban100, while the performance gains are 1.15dB, 0.79dB, 0.67dB, and 1.80dB for 2-bit SRResNet \times 2.

training, random horizontal flip and vertical rotation are adopted to augment data. All experiments are implemented with PyTorch \cite{34}.
Table 3. PSNR/SSIM comparison between existing low-bit SR methods and our DDTB in quantizing SRResNet [22] of scale 4 and scale 2 to the low-bit format. Results of the full-precision model are displayed below the dataset name.

| Model         | Dataset | Bit | Dorefa [49] | TF Lite [14] | PACT [3] | PAMS [23] | DDTB (Ours) |

|               |         | 3   | 24.24/0.714 | 25.33/0.750 | 25.39/0.761 | 25.46/0.765 | 25.64/0.770 |
|               |         | 4   | 24.26/0.714 | 25.62/0.780 | 25.61/0.769 | 25.68/0.773 | 25.77/0.776 |

Qualitative Visualizations. Fig. 4 exhibits the qualitative visualizations of 2-bit EDSR\(^2\). Compared with others methods, the reconstructed HR image of our DDTB provides sharper edges and richer details.

Above results demonstrate the effectiveness of our DDTB and also verify the correctness of our motivation in designing an appropriate quantizer adaptive to the activation distribution. Moreover, it is worth noticing that DDTB provides stable improvements over different SR models and bit-widths. For example,

---

\(^2\) More qualitative visualizations are presented in the supplementary material.
Table 4. Complexity analysis. The number in brackets indicates the parameters in the high-level feature extraction module. We compute BOPs by generating a 1920×1080 image (upsampling factor ×4). Results of 2-bit are displayed and more can be found in the supplementary.

| Model            | Bit | Params   | Gate Params (ratio) | BOPs | Gate BOPs (ratio) |
|------------------|-----|----------|---------------------|------|-------------------|
| EDSR [24]        | 32  | 1.52M    | 0                   | 532T | 0                 |
| EDSR_DDTB        | 2   | 0.41M(0.08M) | 0.6%               | 219T | 0.0000013%        |
| RDN [47]         | 32  | 22.3M    | 0                   | 6038T| 0                 |
| RDN_DDTB         | 2   | 1.76M(1.42M) | 2.8%               | 239T | 0.0000066%        |
| SRResNet [22]    | 32  | 1.543M   | 0                   | 591T | 0                 |
| SRResNet_DDTB    | 2   | 0.44M(0.07M) | 0.1%               | 278T | 0.0000002%        |

PAMS obtains the best results among the compared methods when quantizing EDSR×4 to 4-bit, but it was outperformed by TF Lite in 3-bit and PACT in 2-bit. In contrast, DDTB achieves the best results in all these three bit-widths. Such stability further illustrates the advanced generalization of DDTB.

4.3 Model Analysis

To measure the complexity of the quantized network, we use the parameters and Bit-Operations (BOPs) [40] as the metric. BOPs are the number of multiplication operations multiplied by the bit-widths of two operands. As shown in Table 4, DDTB significantly reduces the model size and computation cost. And the extra computation cost and size of our dynamic gate controller are negligible. Note that, the full-precision low-level feature extraction and reconstruction modules occupy most of the memory and computation costs when quantizing the network to the case of ultra-low bit. Fig. 5(a) displays the $\beta_u$ values of 15 randomly selected test images. We select the results of 2-bit EDSR×4. It can be seen that the $\beta_u$ of different images varies a lot, which proves that the dynamic gate controller can well adjust the clipping bounds adaptive to the input images.

4.4 Ablation Study

This section conducts the ablation study of our DDTB. All experiments are conducted with 2-bit EDSR×4.
Table 5. Effect of different components in our methods. “DW”: dual bounds for weight quantization. “DI”: DDTB initializer. The PSNR/SSIM are reported.

| Components | Results |
|------------|---------|
|            | Set5 [22] | Set14 [22] | BSD100 [31] | Urban100 [2] |
| DDTB DW DI | 29.51/0.835 | 26.79/0.734 | 26.45/0.696 | 23.72/0.688 |
| ✓          | 30.00/0.853 | 27.15/0.741 | 26.62/0.702 | 23.98/0.702 |

| ✓ ✓ ✓ ✓     | 30.80/0.871 | 27.08/0.760 | 26.99/0.717 | 24.64/0.735 |
| ✓ ✓ ✓ ✓ ✓   | 30.97/0.876 | 27.87/0.764 | 27.09/0.719 | 24.82/0.742 |

Gate Parameters. Fig. 5(b) exhibits the results of different gate ratio $P$ on Set14 [22] dataset. The best result is observed when the $P$ is set to 30. Compared with the case without our gate controller, its PSNR increases by 0.16dB. Using more layers cannot bring improvements and even does slight damage to the performance. Moreover, using the full-precision gate does not provide better results, which indicates that a 2-bit gate is sufficient. To reduce search overhead, we find the best $P$ on the model of scale 4 and apply it to the corresponding model of scale 2. Though not optimal, it is sufficient to show SOTA performance.

Components. We use PAMS as the baseline to show the effect of different components including dynamic dual training bounds (DDTB) for activation quantization, dual bounds for weight quantization, and DDTB initializer (DI). Table 5 shows the experimental results. When DDTB and DW are individually added, the performance increases compared with the baseline. The DDTB significantly boosts the baseline which proves its ability to fit the asymmetric activation distribution. By combining the initializer, the performance continues to increase. When all of them are applied, the best performance can be obtained.

5 Conclusion

This paper presents a novel quantization method, termed Dynamic Dual Trainable Bounds (DDTB) to solve the asymmetric activation distribution in the DCNN-based SR model. Our DDTB introduces trainable upper and lower bounds, to which a dynamic gate controller is applied in order to adapt to the input sample at runtime. The gate is represented in a 2-bit format and only applied to part of the network to minimize the extra overhead. Moreover, we design a special DDTB initializer for stable training. Our DDTB shows its superiority over many competitors with different quantized SR models on many benchmarks, especially when performing ultra-low precision quantization.
