Abstract

In this paper we propose an artificial intelligence imaging solution to support archaeologists in the classification task of Roman commonware potsherds. Usually, each potsherd is represented by its sectional profile as a two dimensional black-white image and printed in archaeological books related to specific archaeological excavations. The partiality and handcrafted variance of the fragments make their matching a challenging problem: we propose to pair similar profiles via the unsupervised hierarchical clustering of non-linear features learned in the latent space of a deep convolutional Variational Autoencoder (VAE) network. Our contribution also include the creation of a ROman COmmonware POTtery (ROCOPOT) database, with more than 4000 potsherds profiles extracted from 25 Roman pottery corpora, and a MATLAB GUI software for the easy inspection of shape similarities. Results are commented both from a mathematical and archaeological perspective so as to unlock new research directions in both communities.

1. Introduction

Our ability to interpret an archaeological site rests on our capacity to recognise the material culture found in it, ranging from fixed structures to movable objects. Archaeological finds from any site do in fact contribute to defining its chronology, function and place within a broader network of relationships with other sites. Thanks to their relative resilience against decay combined with their specific underlying patterns of production, distribution and consumption, ceramic vessels (pottery) – whether fragmented (i.e. potsherds) or intact – represent some of the most common finds recovered during archaeological fieldwork. Individual pots and potsherds are usually recorded as 2D profiles and, in consideration of their morphological features (e.g. shape of the rim or the base), gathered in systematic catalogues (corpora), where patterns of similarity are used to establish relationships, in terms of function, chronology or both [1].

Within Roman archaeology specifically (albeit not exclusively), fundamental significance has been ascribed to those ceramic classes more closely associated with long-distance trade and contact, namely trade containers (amphorae) and high-quality tableware pots (finewares). However, these were middle-range commodities that did not reach all levels of the society in the same way, and, furthermore, their supply varied enormously over space and time. Indeed, some sites might have had limited or no access to this range of objects, and such notable absence in the archaeological record might indicate their abandonment at a time when they were in full occupation (i.e. reduced archaeological visibility). In contrast, ordinary table– and kitchen–ware (commonwares, also referred to as coarsewares) were considerably cheaper and mainly supplied within a local/regional network of distribution. As a result, they almost invariably constitute the bulk of pottery finds at almost every Roman site. Even though one would expect them to provide a most effective baseline for the dating (and more general interpretation) of Roman sites anywhere, their huge range of forms, poorly defined chronologies and scattered provenance have made their study so challenging (and so little promising) that many have favoured the analysis of the far more standardised
and easily recognisable finewares and amphorae.

Nevertheless, when a special effort is made to include a comprehensive study of commonware sherds, resulting interpretations can dramatically change. This was neatly shown by a recent analysis of the chronological distribution of potsherds recovered from the Roman town of Interamna Lirenas and from across its surrounding countryside (Central Italy) [2]. Whereas traditional reliance on finewares and amphorae had outlined a trajectory of precocious demographic decline (already in progress by the late 1st century BC), the widespread presence of commonwares shows a considerably more gradual process of growth, in fact peaking in the course of the 1st century AD, with little or no sign of decline until about two centuries later, see Figure 1. There can be no doubt that the study of commonwares should be a priority within (Roman) material culture studies. However, this does not make the obstacles which archaeologists have to face any less real. What is indeed needed is to improve and expand our classification of this vast and varied body of evidence in a way which is considerably more effective and less time-consuming than it currently is.

![Percentage of fine ware (straight) and common ware (dashed) potsherds: urban (blue) vs. rural (red) environment.](image)

**Figure 1:** Percentage of fine ware (straight) and common ware (dashed) potsherds: urban (blue) vs. rural (red) environment.

**Contributions.** The contribution of this paper is twofold. Firstly, we create the Roman Commonware Pottery (ROCOPOT) database containing two-dimensional black-white imaging profiles of commonware potsherds attested in Central Tyrhenian Italy, with metadata extrapolated from different corpora and excavation sites. Secondly, we propose an unsupervised workflow for matching and hierarchically clustering the potsherds profiles by comparing their latent representation learned in a deep convolutional Variational Autoencoder (VAE) network, and supported by a MATLAB GUI software for the easy inspection of the results on the field.

**Scope.** Our research aims to support archaeologists in the classification task of Roman commonware potsherds by unveiling new similarity patterns between individual profiles as featured in relevant corpora, especially those for which no match has so far been proposed. The resulting clustering patterns will highlight new morphological relationships and serve as an additional tool for archaeologists in order to improve their understanding of chronology, distribution, function and development of Roman commonwares over time. Whereas other similar projects have attempted to develop automated procedures for the correct identification of potsherds (i.e. establishing a relationship between what is newly found and the published 2D profiles), we aim to improve the internal consistency of the database itself and facilitate the archaeological classification workflow. On top of that, our workflow is fully scalable, meaning that once new profiles are available as black-white images, the learned representation features will unlock additional matches. The complete pipeline, from archaeological fieldwork to our contributions, is reported in Figure 2.

**Related works.** Shape recognition, classification and matching of complete or partial data, are well-established problems in the computer vision and mathematical communities but for settled databases of thousands of images or shapes, e.g. [3, 4, 5]. In recent years, “Cultural Heritage Imaging Science” became an increasing popular research field bringing together experts from museum institutions, history of art, physics, chemistry, computer vision and mathematics departments for tackling cross-discipline challenging applications; however, few dedicated databases emerged in the literature, mainly related to collection of paintings and associated tasks, e.g. for object or people detection [6, 7, 8], style recognition [9] and many more, see [10].

Relevant works for matching 2D shapes are based on similarities of boundaries [11, 12] or skeletons [13], homeomorphic transformations based on size functions [14], geodesic calculus for image morphing [15], axiomatic criteria for deformable shapes [16] or comparison of invariant image moments [17, 18, 19, 20]. In particular, invariant shape descriptors are detailed in [21] for clustering together similar shapes while the meaningfulness of the obtained clusters is still an open question. For 3D surfaces (with triangular meshes) or volumes (with voxels), remarkable results are obtained via scale invariant descriptors based on the eigen-decomposition of the Laplace–Beltrami operator, e.g. the Heat Kernel Signature and its variants [22, 23, 24].

For the targeted application of this paper, even fewer databases are publicly available [25, 26, 27], with focus on their automatic digitisation, shape extraction and visual presentation [28] or the clustering of a priori manually selected geometric shape features into similar classes, e.g. by comparing curve skeletons [29], shape
boundaries [30], shape descriptors [31] or employing Generalised Hough Transform distance measures (in the case of petroglyphs, a dataset that shares similarity with our images) [32] and other topological features (e.g. pixels height and width, area, circularity, rectangularity, diameters or steepness indexes) [33, 34] or comparison with template primitives [35]. In [36] fragments and nodal points are also extracted from complete 3D models in view of a supervised deep learning approach starting from complete profiles. Recently, it is worth mentioning the deep-learning approach based on convolutional neural networks (CNNs) proposed in [37], which targeted the imaging classification of decorative styles in Tusayan White Ware (Northeast Arizona).

In contrast, our deep-learning approach is not biased by the selection of a-priori shape features, allowing for their unsupervised extraction by means of a deep convolutional Variational Autoencoder (VAE) network. Here, we force the VAE latent space to follow a prior probability distribution close to a standard Gaussian. Such regularisation has many advantages for unsupervised tasks mainly related to the easy reparametrisation of the variational lower bound and backpropagation through the stochastic layers [38]. Our approach is motivated by the high availability of fragments and the generative process of VAE, allowing us to extend the learned model to unseen data for extracting their shape features.

In pattern recognition, hierarchical clustering is a non-parametric yet versatile unsupervised approach for unveiling inherent structures in data, ordered in a tree called dendrogram [39]. The method is based on the recursive partitioning of the VAE features into clusters of (increasing or decreasing) cardinality, based on the minimisation of a certain cost function that promotes the separability of the data features [40]. Hierarchical clustering methods are easy to implement and they are often tuned to the application at hand, with an external evaluation of the results by the experts in the applied field [41].

Specifically to Roman pottery profiles, our approach for an unsupervised hierarchical clustering is in line with the promising works in [34, 42, 30, 32, 43], with the additional automatisation of the cluster merging rule based on the best cophenetic coefficient score [44]. Finally, we leave the check of the deeper clusters in the produced dendrograms to specialist archaeologists, who can effectively assess the performances of the proposed workflow.

Organisation of the paper. The paper is organised as follows: in Section 2 we introduce the Roman Commonware POTtery (ROCOPOT) database; in Section 3 we detail about the deep variational autoencoder (VAE) network for extracting the potsherds features and the hierarchical clustering algorithm (with appendix on computations in Section 6); in Section 4 we discuss the results obtained by our workflow.

2. The ROCOPOT Database

The Roman Commonware POTtery (ROCOPOT) database, downloadable from [45], comprises of more than 4000 black-white images, consisting of two-dimensional representation of the section (profile) of Roman commonware vessels. These profiles are featured in a series of archaeological corpora [46, 47, 48, 49, 50, 51, 52, 53, 54, 55, 56, 57, 58, 59, 60, 61, 62, 63, 64, 65, 66, 67, 68, 69, 70] which provide a representative sample of a wide array of vessel-forms attested across the Tyrrhenian side of the Italian peninsula in the Roman period (from Liguria to Campania). In this work we present the version 1.0 of our database (future extensions are planned). All these images are scanned at 300dpi from the archaeological corpora: these are saved in the lossless .png format with an identification string filename of the form...
IDCAT-PAGNUM.FIGID.png, where IDCAT identifies the catalogue while PAGENUM and FIGID are the page and the figure identification numbers of the printed profile in the corpora, respectively. This labelling convention is suitable for a fast inspection of the results described in Section 4: by assuming similar shapes are presented closely in each catalogue (as is normally the case), we can quickly look at filenames to evaluate potential matches.

Since the original profiles can be composed of multiple (rarely intact) parts, we refined the database identifying a total of 407 bases (B), 450 handles (H), 3678 rims\(^1\) (R) and 451 rims with handles (RH), as well as the original shapes (O). The archaeologists identified such parts out of each original profile depending on its grade of completeness. Potential outliers like one of a kind profiles were removed. Details about the number of profiles in our database are summarised in Table 1 (see also the map in Figure 5), where for each catalogue we highlight the bibliographic reference, the publication year, the chronology and location of the archaeological site. For the rest of this work we focused only on the rims as they are assumed to carry out the most significant geometric information of the handcrafted material.

All the rims require a further polishing step so as to make them uniformly represented in the imaging space and before processing them into the deep learning algorithm. This is due to different presentation/editorial styles adopted across the corpora. For example, in Figure 3 we report common situations when identifying the rim, e.g. its separation from the template and cutting of the elongated slope as well as mirroring (Figure 3a), the fill in of relevant portions with a black colour with a possible rotation of the profile (Figure 3b), the cleaning of scanned contours from ageing phenomena and the removal of undesired handles (Figure 3c and 3d). Furthermore, based on the convert script from Imagemagick\(^2\), we converted the extracted rims from .png format to a .svg format so as to remove pixelisation errors (density 1200 and 1500 × 1500 pixels). All the rims are then resized to 256 × 256 pixels, without losing the aspect ratio, for the purpose of data normalisation in the deep learning network described in the rest of the paper, see Figure 4 for a full display of rims in our database.

3. Proposed approach

After preprocessing the ROCOPOT database and with the rim profiles at our disposal, we proceed with modelling the manifold of profiles by learning non-linear features associated to them. Such features will be used for the hierarchical clustering of the dataset. Note that the combination of these two approaches makes our workflow totally unsupervised, a key assumption for unveiling hidden or new clustering patterns in existing archaeological corpora.

3.1. Variational Autoencoders.

Our workflow is based on the learning of probabilistic features associated with profiles, able to ease the profile matching problem in a low-dimensional feature space. Instead of fixing a-priori qualitative profile features (e.g. the diameter, the ballness, the elongation, the area, the perimeter and many more), we fix the dimension \(k > 0\) of the latent space and maximise the probability that profiles, generated from a stochastic sampling process in the latent space, match with the profiles in our database. In this sense, deep learning convolutional Variational Autoencoders (VAEs) are powerful tools that can be interpreted as a generative non-linear version of the principle component analysis (PCA).

\(^1\)the rim usually refers to a rounded moulding on the lip of a jar, bowl, or dish, both to add strength and assist in handling [71].

Vanilla convolutional *Autoencoders* (AEs) are artificial neural networks designed for replicating the input at its output by means of back-propagating the reconstructed result with a single layer strategy [72]. Here, the representation of the input is learned via the minimisation of a *loss* function, composed by a reconstruction error measure and a regulariser, in a low-dimensional latent space. Any AE is composed by an *encoder*, which reduces the dimension of the input to the latent space, and a *decoder*, which reconstructs the output from the latent space. More advanced *Stacked Sparse Autoencoders* (SSAEs) [73] networks concatenate multiple vanilla AE, where each latent space is the input of the subsequent AE. Here, the sparsity assumption forces the neurons to specialise on few high-level features [74]. However, both AE and SSAE are limited by their (possibly) discontinuous latent space, making thus impossible the interpolation between multiple input data and leading to the *overfitting* phenomenon. This is a limitation for scaling-up the approach when processing unseen data.

In contrast, *Variational Autoencoders* (VAEs) [38, 75] are generative deep learning convolutional neural networks able to learn a continuous probabilistic representation of the global potsherds features in the latent space. The loss function in the network is composed by a regulariser term plus a reconstruction term:

\[
L(x, \bar{x}) = \beta_e L_{KL}(x, z) + L_c(x, \bar{x}),
\]

where \(\beta_e > 0\) is a weighting parameter varying according to the learning epoch \(e\), \(L_{KL}(x, z)\) is the loss function accounting for the reverse Kullback-Leibler (KL) divergence \(D_{KL}\) on the latent space, see (5) in the Appendix 6 and Figure 6, while \(L_c(x, \bar{x})\) is a sigmoid cross-entropy energy with logits loss, see (6) in Appendix.
6. By acting as regulariser, \( L_{KL}(x, z) \) ensures that the potsherds distribution generated from the learned latent space is as close as possible to the target one, while \( L_c(x, \bar{x}) \) measures the probability error of reconstructing black-white pixels in a potsherd image, similarly to a labelling task. More details about our chosen structure of the VAE network and technical parameters for the training process are given in Section 4.

3.2. Hierarchical clustering.

Once the VAE network is trained, we can associate to each profile a low-dimensional latent vector \( z \in \mathbb{R}^k \) with \( k > 0 \). From the reparametrisation trick discussed in (7) in Section 6.4, i.e. \( z = \mu + \sigma \odot \varepsilon \) where \( \varepsilon \in \mathbb{R}^k \) is a random vector, we concatenate the mean \( \mu \in \mathbb{R}^k \) and the variance \( \sigma \in \mathbb{R}^k \) in a vector of features \( \bar{z} \in \mathbb{R}^{2k} \). These features can now be used as a shape signature for the clustering task. Since popular clustering methods, like k-means, have the bottleneck of requiring as input the number of expected clusters (unknown for our database), we opted for an agglomerative hierarchical clustering approach so as to build a tree of nested clusters. Starting with a single class for each potsherd profile, we subsequently merge together profiles sharing similar features in a bottom-up hierarchical strategy according to a method for computing the distance between clusters and a metric between the observed features. In this way, we can inspect different levels of similarities and shape relations. In order to automatically identify the best cluster merging rule, we compute the cophenetic coefficient score [44] for each pair of methods (nearest distance [76], farthest distance [77], UPGMA [78], WPGMA [78], UPDMC [79], WPGMC [80] and ward [81]) and metrics (Euclidean, cityblock, Chebychev and cosine). Here, the cophenetic score [82] measures how faithfully the selected tree represents the dissimilarities among observation and the pair returning the highest value is selected as the best pair.

4. Network Parameters and Results

In this section we further discuss the parameters of our VAE network and the results produced by our workflow, when applied to the rims in our database. All the tests are performed on a GPU Nvidia Quadro P6000. The code is implemented in MATLAB 2020b.

4.1. Parameters and analysis of the VAE network.

Our VAE network is composed by multiple convolutional layers of filter size 3×3, concatenated with ad-hoc exponential linear unit (eLU) and dropout layers\(^3\) (with fixed dropout parameter equal to 0.25). With reference to Figure 6 where the VAE network used in this work is depicted, \( x \) is the original black-white profile (256×256 pixels) and \( \bar{x} \) is the output of the network. Note that \( \bar{x} \) is required for computing the reconstruction loss \( L_c \) in (1), while the output profile is obtained by \( \text{sig}(\bar{x}) \). Also, each convolutional layer is denoted by \( \text{conv}_{f_1, f_2, \ldots, s} \), where \( f_1 \) are the number of input channels, \( f_2 \) are the number of filters, \( n \) is the spatial size of the filters and \( s \) is the stride. In the network, parameters are set to \( f = 4 \), \( n = 3 \) and \( s = 1 \) while \( k = 128 \) is the dimension of the latent space.

We account for handcrafted details, printing or scanning artefacts by increasing the number of potsherds at our disposal 5 times via data augmentation, e.g. by adding variations of the original shapes obtained via image operations like erosion and dilation (of 3 pixels) and rotations (by -5 and +5 degrees). We trained our network on 90\% of the rims available, using the remaining 10\% as test data, and for a maximum number of 1000 epochs. The learned parameters are updated using the Adaptive Moment Estimation (ADAM) [83], with constant learning rate of 1e-06.

In order to avoid the so-called KL-vanishing phenomenon, related to the undesired vanishing of the regulariser during the optimisation, the regularisation term is weighted by a positive factor \( \beta_e \in (0, 1] \). Among different choices [84, 85] (applied to natural language processing challenges), we follow the cyclical annealing approach [86] with a periodical adjustment of the weight \( \beta_e \) of (1) in \( M \) cycles. For a fixed epoch \( e \), the weight \( \beta_e \) is computed according to the following rule:

\[
\beta_e = \begin{cases} 
\frac{\tau}{\tau_R} & \text{if } \tau_R \leq \tau < R, \\
1 & \text{otherwise}
\end{cases}
\]

for a linear function \( \tau_e = \tau_e / R \) and

\[
\tau_e = \text{mod}(e - 1, \lceil T / M \rceil) / (T / M),
\]

where \( T \) is maximum number of epochs, \( M \) is the number of cycles and \( R \) is the rate of which to increase \( \beta_e \) within a cycle. Thus, each cycle is composed by an annealing stage where \( \beta_e \) linearly increases from 0 to 1, and a fixing stage when \( \beta_e = 1 \). This strategy forces the model to behaves like AEs when starting each cycle with \( \beta_e = 0 \) and like standard VAEs when \( \beta_e = 1 \); in contrast, the model transits from a point estimate to a distribution estimate when linearly increasing \( \beta_e \) from 0 to 1. The cyclic repetition guarantees a progressive

\(^3\)dropout layers are disable during the inference step.
learning, leading to a more meaningful latent space. In our experiments, we fixed \( T = 1000 \), \( M = 4 \) and \( R = 0.5 \), for a cycling annealing strategy as depicted in Figure 8a. Note that if \( \beta_e \gg 1 \) the loss would have related to the \( \beta \)-VAE extension, proposed by [75] and used for learning disentangled representation features in the latent space [87], but at the price of a reduced reconstruction quality [88].

Once our network is trained we are able to model the probability distribution of potsherds with \( z \in \mathbb{R}^k \) (\( k = 128 \) parameters), and to reconstruct the ROCOPOT dataset from Figure 4. We report in Figure 7 the confidence intervals of the pixel-wise mean squared error and the intersection over the union error as a distance [89],

defined for a shape \( s \) respectively as:

\[
\text{MSE}(x_s, \text{sig}(\hat{x}_s)) = \frac{\sum_{i,j=1}^{H,W} (x_{s,ij} - \text{sig}(\hat{x}_{s,ij}))^2}{H \cdot W},
\]

where \( H, W \) are the dimension of the image, sig is the sigmoid function, and

\[
\text{IoU}(x_s, \text{sig}(\hat{x}_s)) = 1 - \frac{2 \sum_{i,j=1}^{H,W} (x_{s,ij} \cdot \text{sig}(\hat{x}_{s,ij}))}{\sum_{i,j=1}^{H,W} (x_{s,ij})^2 + \sum_{i,j=1}^{H,W} \text{sig}(\hat{x}_{s,ij})^2}.
\]

In Figure 8b we display the loss function on both train and test data, individual terms (KL loss and cross-entropy reconstruction loss) and the Euclidean error through epochs, showing no overfitting during the training of the network. Both visual and quantitative results confirms that the shapes are reconstructed almost correctly, meaning that the neurons in the latent space are now specialised in modelling the probability distribution of the potsherds in our database.

Before using the \( 2k (= 256) \) features for the hierarchical clustering step, a natural question is to investigate the quality of the reconstruction and the robustness of the latent space to some perturbations.

4.2. Robustness of the learned features.

Our matching assumption is based on the fact that similar shapes share similar VAE latent space representation. Thus, it is worth to investigate if the shapes and the features in the latent space are robust to a series of perturbations that may occur with handcrafted data. In Figure 9 we report the reconstruction of a subset of potsherds in the ROCOPOT database under a range of perturbations on the input shape (erosion, dilation and...
(a) Cyclical annealing of $\beta$ ($T=1000, M=4, R=0.5$).

(b) ELBO loss in semi-logarithm scale along $y$-coordinate.

Figure 8: From top to bottom: Cosine decay of the learning rate; cyclical annealing of $\beta$ and ELBO loss (1) (train in blue and test in red, computed on randomly selected subsamples of 32 shapes, repeated 10 times and averaged).

4.3. Hierarchical clustering.

As said, our approach takes advantage of the learned features in the VAE’s latent space for the hierarchical clustering task. In our experiments the highest cophenetic score is obtained with the choice of the Unweighted Pair Group Method using arithmetic Averages (UPGMA, average) and the Euclidean metric for measuring the distance between clusters. We now restrict our focus on relevant types extracted from the metadata of our dataset. These are: domestic amphora, basin, beaker, bottle, bowl, censer, dish, dish-lid, dolium, jar, jug, knob, lid, mortarium, pan, pot and unguentarium. For all the potsherds profiles in each type, we extracted the relevant features with the VAE strategy described before, which are hierarchically clustered in view of extracting new similarity patterns. As an example, we report a portion of the hierarchical dendrogram for the type beaker in Figure 10a. For convenience, we call seed each of these pairs, corresponding to the paired leaves at the deepest level of the dendrogram. The same dendrogram can be produced also for each single catalogue if needed to inspect intra-catalogue similarities, see Figure 10b for CICI96 [47].

4.4. Unveiling hidden relations: the ROCOPOT App.

Given the cross-disciplinary nature of the challenge in this paper, we need a tool for visualising and inspecting the clusters in the dendrograms. To this end, we developed a MATLAB GUI 4 which is able to effectively support the onfield work of the archaeologists [91], see the screenshot in Figure 11.

4.5. Comments from the archaeological perspective

In order to test how effective our workflow is in recognising actual similarities between different profiles, we inspect the quality of the dendrograms via the MATLAB app.

The lack of a ground truth in matching potsherds, itself resulting from a degree of inherent subjectivity in the manual classification process, has a great impact on an automatic evaluation of the performances. Therefore the task of validating the matching accuracy of the dendrograms is assigned to archaeologists. Although, in principle, one could evaluate the coherence of each hierarchical group (of profiles) within the dendrogram, this task would involve a rather complex review of the results. Therefore, we asked archaeologists to concentrate on and validate the matching accuracy for each individual seed, expected to be the best match proposed by our unsupervised workflow.

Before proceeding, we acknowledge that a large number of profiles in our dataset may in fact represent somewhat unique vessels bearing little or no similarity

4Freely available at doi.org/10.5281/zenodo.5552265 and mach.maths.cam.ac.uk/software [90]
to any other. Roman commonwares consisted of ordinary pottery which was produced at a myriad of distinct workshops, the latter often coming into and going out of existence in the lapse of a generation. We should therefore expect the range of vessels produced, distributed and consumed, even within the same region and in the same period, to be considerably vast and varied. This otherwise unbridled drive towards a variety of forms was certainly directed - and to a degree tempered - by the practicalities of the production process.
(e.g. standardization) and the predominantly functional character of these objects. Of course, given the high levels of inter-connectivity and exchange achieved in the Roman world (and Central Tyrrenian Italy was certainly no exception!), local potters worked within productive traditions which were used to absorb, copy and rework types originally imported from elsewhere, and whose features may have appeared from time to time better suited to specific functions or even just the tastes of potential customers. Nevertheless, only a fraction of the whole dataset may have in fact featured any actual degree of close similarity.

Our workflow processes 3678 rim profiles as featured in 25 catalogues (R in Table 1) and identifies 1231 seeds (corresponding to 2462 profiles). The archaeologists looked at each seed by inspecting and comparing the paired profiles, thus assessing their similarity. They did not consider the overall shape of the vessel (even when known), but instead only concentrated on the overall combination of morphological features as presented by each individual rim (e.g. inclination, curve, lip design). This approach did not present any particular challenge to them as it was very much in keeping with standard practice in the analysis of (incomplete) potsherds as most commonly recovered through fieldwork. In light of the above archaeological considerations about the nature of the data itself, it is not surprising that only 500 out of 1231 seeds (41%) were eventually validated as a positive match. What is remarkable, however, is that out of those 500 positive seeds, only 147 (29%) had already been indicated as close matches in the relevant pottery corpora, whilst the remaining 353 (71%) are new. In other words, although some of these similarities have been in fact recognised and recorded when the pottery corpora were originally put together by their authors, our workflow is able to significantly expand this range of relationships. This goes far beyond a random matching of profiles, since the actual probability of pairing two similar profiles within the 2462 available is less than 0.001%.

It is certainly notable that our workflow was autonomously capable of establishing close similarity between profiles which were originally recognised as ‘similar’ by the original authors. This suggests that the workflow may have learned to look for the same combination of features which a pottery specialist normally looks for when classifying pottery. Although replicating such results may in itself be considered a notable achievement from a mathematical point of view, it is the fact that the range of similarities was expanded that matters a lot from an archaeological point of view. If one considers that each pottery catalogue is a reflection of relevant patterns of production, distribution and consumption within a given location in a given period, an improved understanding of their inter-relationship can truly contribute not only to refining chronologies (useful as this exercise may be), but also to mapping how (trade) contacts between different places were created and evolved over the Roman period. Even though such patterns are routinely reconstructed on the base of the distribution of finewares and amphorae, we already pointed out that these classes may not provide as comprehensive a view of the broader population as commonwares can.

In short, the proposed workflow is very promising, especially when considering its inherent scalability. As the dataset is expanded with the inclusion of new profiles from additional pottery corpora, the learning step will improve, thus increasing the chance of recognising more (and possibly qualitatively better) similarities. More than anything, the clustering step is capable of structuring in minutes the kind of dataset whose size would require months (or indeed years!) of manual reviewing a long list of disparate publications. In fact, although here applied to commonware pottery from Central Tyrrenian Italy, this workflow can be straightforwardly extended not only to Roman commonwares in general, but to any coherent pottery class from any time and/or period. Although this process is neither infallible or exhaustive, it is in fact meant not to replace, but rather to aid in the manual interpretation and classification of pottery profiles by unveiling additional relationships which the mass of data may render almost invisible to the human eye.

5. Conclusions and Future Works

In this paper, we introduced the RoMan CoMMOnware PoTtery profiles (ROCOPOT) database and pro-
vided a workflow for unveiling close similarities between (Roman commonware) pottery profiles. That is based on the hierarchical clustering of Roman potsherds via latent features learned in a deep convolutional VAE network. Such features are proved to be robust to a number of perturbations mimicking the real scenario of the high shape variance due to handcrafted materials. The most obvious advantage provided by our approach rests in the ability to ease and speed up the processing and matching of a very large number of pottery profiles from different corpora within a coherent and unified analytical environment. This is achieved by presenting the pottery specialist with a selection of most likely matches in the companion software, thus providing invaluable pointers not only in the development of a comprehensive typology of Roman commonwares, but even in the future classification of potsherds coming from new excavations. These results are very encouraging and prompt us to pursue this research further. Firstly, we plan to increase the number of profiles available in our database; secondly we will develop a specific online tool which will aid in the classification of profiles of new commonware potsherds recovered by new archaeological projects (and thus increasing our knowledge on this pottery class whilst expanding its application in the field). Finally, we aim to train the network to include other parts of the vessels (bases, main body) in its similarity search and fully incorporate the feedback (validation) of the archaeologists in order to refine its analysis through iteration.

6. Appendix

Here we discuss the main concepts of variational autoencoders and the derivation of the loss function in Equation (1), by means of (5) and (6), see [38, 92].

We assume that the dataset consists of \( X = \{x_1, \ldots, x_n\} \) samples, with \( n > 0 \) (in our case \( n \) two-dimensional black-white images representing the profile of potsherds of size \( H \times W \) from the ROCOPOT database). We identify with \( x \in X \) one sample from the dataset and with \( Y \in Y \) the reconstruction of \( x \), where \( Y \) is the reconstruction of the space \( X \). Also, let \( g_\theta(\cdot) \) and \( f_\theta(\cdot) \) be the encoding and decoding functions, parametrised by \( \phi \) and \( \theta \), respectively. Moreover, \( q_\phi(z|x) \) represents the estimated posterior probability distribution (probabilistic encoder) for the latent code \( z \in \mathbb{R}^k \) given \( x \) and \( p_\theta(x|z) \) the likelihood of generating true data samples \( x \) given the latent code \( z \) (probabilistic decoder). Here \( k > 0 \) is the fixed dimension of the reduced latent space. In general, The Kullback-Leibler (KL) divergence \( D_{KL}(q \parallel p) \) is a non-symmetric relative entropy designed to quantify the discrepancy between two distributions \( q \) and \( p \) and how much information is lost if the distribution \( q \) is used to represent \( p \).

6.1. The Evidence Lower Bound Loss in VAE

In the AE scheme, the idea is to learn a low-dimensional representation \( z = g_\phi(x) \in \mathbb{R}^k \) of the data by means of learning the identity function such that \( \tilde{x} = f_\theta(g_\phi(x)) \). The overfitting and the impossibility to generate new samples are clear limits of this approach. Conversely, VAEs aim to learn the model underlying the data: the estimated posterior \( q_\phi(z|x) \) is designed to be close to the real posterior \( p_\theta(z|x) \) making possible to generate true samples. To that effect, the forward or reverse KL divergence could be used. The forward KL divergence \( D_{KL}(p_\theta(z|x) \parallel q_\phi(z|x)) \) tends to favour an approximate distribution \( q_\phi \) with an undesired mean effect; conversely the reverse KL divergence \( D_{KL}(q_\phi(z|x) \parallel p_\theta(z|x)) \) is better suited to approximate the distribution \( q_\phi \) within a mode of \( p_\theta \) and is preferred [93, 94, 95, 96]. The reversed KL divergence is equivalent to:

\[
D_{KL}(q_\phi(z|x) \parallel p_\theta(z|x)) = \int q_\phi(z|x) \log \frac{q_\phi(z|x)}{p_\theta(z|x)} \, dz
\]

\[
= \int q_\phi(z|x) \log \frac{q_\phi(z|x)p_\theta(x)}{p_\theta(z,x)} \, dz \\
= \int q_\phi(z|x) \left( \log p_\theta(x) + \log \frac{q_\phi(z|x)}{p_\theta(z,x)} \right) \, dz \\
= \log p_\theta(x) + \int q_\phi(z|x) \log \frac{q_\phi(z|x)}{p_\theta(z,x)} \, dz \\
= \log p_\theta(x) + \mathbb{E}_{z \sim q_\phi(z|x)} \left( \log \frac{q_\phi(z|x)}{p_\theta(z,x)} - \log p_\theta(x|z) \right) \\
= \log p_\theta(x) + D_{KL}(q_\phi(z|x) \parallel p_\theta(z)) \\
= \mathbb{E}_{z \sim q_\phi(z|x)} \log p_\theta(x|z),
\]
where in the above we used \( p_\theta(z | x) = p_\theta(z, x) / p_\theta(x) \), \( \int q_\phi(z | x) \, dz = 1 \) and \( p_\theta(x, z) = p_\theta(x | z) p_\theta(z) \). By rearranging the above equation, we have:

\[
\log p_\theta(x) - D_{KL}(q_\phi(z | x) \| p_\theta(z | x)) = \mathbb{E}_{z \sim q_\phi(z | x)} \log p_\theta(x | z) - D_{KL}(q_\phi(z | x) \| p_\theta(z))
\tag{2}
\]

The left-hand-side of Equation (2) allows us to maximise the (log-)likelihood of generating real data, i.e. \( \log p_\theta(x) \), while minimising the difference between the real and estimated posterior distributions. Note that \( p_\theta(x) \) is fixed with respect to \( q_\phi(z | x) \). The negative of the left-hand-side in Equation (2) is defined as the Evidence Lower Bound (ELBO) loss function:

\[
\mathcal{L}_{ELBO}(\theta, \phi) = - \mathbb{E}_{z \sim q_\phi(z | x)} \log p_\theta(x | z) + D_{KL}(q_\phi(z | x) \| p_\theta(z)).
\tag{3}
\]

The optimal parameters are obtained by solving the following minimisation problem:

\[
(\theta^*, \phi^*) = \arg \min_{\theta, \phi} \mathcal{L}_{ELBO}(\theta, \phi).
\]

Being the reverse KL divergence always non-negative, \(-\mathcal{L}_{ELBO} = \log p_\theta(x) - D_{KL}(q_\phi(z | x) \| p_\theta(z | x)) \leq \log p_\theta(x)\), from Equation (2) we have:

\[
-\mathcal{L}_{ELBO} = \log p_\theta(x) - D_{KL}(q_\phi(z | x) \| p_\theta(z | x)) \leq \log p_\theta(x).
\]

### 6.2. Derivation of the KL divergence

The KL divergence in Equation (3) is a regulariser because it is a constraint on the form of the approximate posterior [97]. In general, the KL divergence of two multivariate Gaussian distributions \( q_\phi \) and \( p_\theta \) (of dimension \( n \)), i.e. \( q_\phi = N(\mu_\phi, \sigma_\phi) \) and \( p_\theta = N(\mu_\theta, \sigma_\theta) \), can be expressed in the following form:

\[
D_{KL}(q_\phi \| p_\theta) = \frac{1}{2} \left( \log \frac{|\sigma_\theta|}{|\sigma_\phi|} - n + \text{tr}(\sigma_\theta^{-1} \sigma_\phi) + (\mu_\theta - \mu_\phi)^T \sigma_\theta^{-1} (\mu_\theta - \mu_\phi) \right).
\tag{4}
\]

In VAE, \( q_\phi \) is the encoder distribution defined as \( q_\phi(z | x) = N(z | \mu(x), \sigma(x)) \) where \( \sigma = \text{diag}(\sigma_2^1, \ldots, \sigma_2^n) \) while \( p_\theta \) is the latent prior given by \( p_\theta(z) = N(0, I) \). Thus, from Equation (4) the reverse KL divergence \( D_{KL}(q_\phi(z | x) \| p_\theta(z)) \) is expressed as:

\[
D_{KL}(q_\phi(z | x) \| p_\theta(z)) = \frac{1}{2} \left( \log \frac{|\sigma_\theta|}{|\sigma_\phi(z | x)|} - n + \text{tr}(\sigma_\theta^{-1} \sigma_\phi) + (\mu_\theta - \mu_\phi)^T \sigma_\theta^{-1} (\mu_\theta - \mu_\phi) \right).
\tag{5}
\]

### 6.3. Reconstruction loss

The expectation in Equation (3) is a reconstruction loss. In our scenario, similar to a semantic segmentation problem with labels 0 and 1 due to the black-white nature of the data, it makes sense to use a sigmoid cross-entropy with logits energy term as reconstruction loss \( \mathcal{L}_r(x, \bar{x}) \), of the form

\[
-x \cdot \log(\text{sig}(\bar{x})) - (1 - x) \cdot \log(1 - \text{sig}(\bar{x})),
\]

where \text{sig} is the sigmoid function, reformulated for numerical stability and for avoiding overflows\(^5\) as

\[
\mathcal{L}_r(x, \bar{x}) = \max(\bar{x}, 0) - \bar{x} \cdot z + \log (1 + \exp(-\bar{x})).
\tag{6}
\]

### 6.4. Reparametrisation trick

The expectation term in Equation (3) requires generating samples from the latent space \( q_\phi(z | x) \). However, the sampling is a stochastic process, making impossible to backpropagating the gradient. The reparameterisation trick proposed in [38] (based on methods already introduced in [98, 99]) allows to overcome such difficulties by means of rewriting \( z \) as a sum of a deterministic part plus an independent random variable \( \varepsilon \sim N(0, I) \):

\[
z = \mu + \sigma \odot \varepsilon,
\tag{7}
\]

where \( \odot \) refers to element-wise product. With this trick in place, the mean \( \mu \) and the variance \( \sigma \) of the distribution are now learnable parameters.
