We investigate the imprint of dark energy on the kinetic Sunyaev-Zel’dovich (kSZ) angular power spectrum on scales of $\ell = 1000$ to 10000, and find that the kSZ signal is sensitive to the dark energy parameter $w$, which is the ratio of its pressure to the energy density. The time dependence of EoS can be used to classify a range of DE models. The accumulating observational data, including observations of the cosmic microwave background radiation (CMB), Type-Ia supernovae (SN) and baryon acoustic oscillation (BAO) have set up strong constraints on the EoS of dark energy. Assuming the dark energy EoS is a constant, then recent observation from Wilkinson Microwave Anisotropy Probe (WMAP) gives the constraint $w = -1.073 \pm 0.180$ (95% confidence level), WMAP9+extra CMB data $^1$ +BAO+$H_0$, $^2$ and observation from Planck satellite gives $w = -1.24^{+0.18}_{-0.19}$ (95% CL from Planck+$H_0$+WMAP polarization data, $^3$). However, allowing time evolution of $w$, the results of constraints become comparatively looser. For example, parameterizing dark energy EoS as $w(a) = w_0 + w_a (1-a)$ then the constraints from WMAP9+extra CMB data +BAO+SN+$H_0$ is $w_0 = -1.34 \pm 0.36$ and $w_a = 0.85 \pm 0.94$ (95% CL, see table 10 of $^3$), and from Planck+$H_0$+WMAP polarization data it is $w_0 = -1.04^{+0.72}_{-0.65}$ and $w_a < 1.32$ at (95% CL). Therefore, the data slightly favor the model with $w_0 < -1$ and $w_a > 0$ while large uncertainties of parameters still exist in the recent observational constraints.

In the spirit of exploring more phenomena associated with dark energy, we would like to investigate how the dark energy affects the growth of structure and clustering properties of galaxies. The kinematic Sunyaev-Zel’dovich (hereafter kSZ, or kinetic SZ) effect is one of the important phenomena that relates the galaxy’s peculiar motion with the temperature fluctuations of the CMB. The effect can arise during two processes, i.e. consisting of the “inhomogeneous patchy reionization” and the post-reionization signals.

In models of inhomogeneous reionization (or “patchy reionization”), where different regions of the Universe were ionized at different times, the bulk motion of bubbles of free electrons around the UV emitting sources may cause the temperature anisotropy on the CMB $^5$. It has been demonstrated $^6$ that the magnitude of the kSZ power from patchy reionization is related to the duration of reionization. Hence, one can set a constraint on the duration of reionization ($\Delta z_{rei}$) once the optical depth to reionization can be measured $^7$. After reionization, the “secondary anisotropy” of CMB can also be generated from the peculiar motion of galaxy clusters. Thus by measuring the kSZ effect one can have a good handle on the peculiar velocity of galaxies and therefore infer the growth rate of large scale structure. The growth rate of the large scale structure is affected by the dark energy EoS, because the dark energy negative pressure can drive the accelerated expansion of the Universe and therefore halt the growth of structure at late times. Therefore, it is necessary to investigate the effect of dark energy on growth of structure and the “imprint” of dark energy on the kSZ effect. This research is particularly useful since many ongoing CMB experiments, such as South Pole Telescope (SPT and SPTPol $^8$) and Atacama Cosmology Telescope (ACT and ACTPol $^9$) are going to measure the kSZ effect to a high precision.

The effect of clustering can be reflected in three dif-

$^3$ This “extra CMB data” refers to the band-power spectra data from 150GHz South Pole Telescope (SPT) $^11$ and 148GHz Atacama Cosmology Telescope (ACT) $^12$.  

---

I. INTRODUCTION

Dark energy (DE), the energy source that drives our Universe accelerating, has remained a mystery since it was discovered in 1998 $^1$, $^2$. The key feature of dark energy is encoded in its equation of state (hereafter EoS) parameter $w$, which is the ratio of its pressure to the energy density. The time dependence of EoS can be used to classify a range of DE models. The accumulating observational data, including observations of the cosmic microwave background radiation (CMB) $^3$, $^4$, Type-Ia supernovae (SN) data $^5$, $^6$ and baryon acoustic oscillation (BAO) from galaxy surveys $^7$, $^8$ have set up strong constraints on the EoS of dark energy. Assuming the dark energy EoS is a constant, then recent observation from Wilkinson Microwave Anisotropy Probe (WMAP) gives the constraint $w = -1.073 \pm 0.180$ (95% confidence level), WMAP9+extra CMB data $^1$ +BAO+$H_0$, $^3$ and observation from Planck satellite gives $w = -1.24^{+0.18}_{-0.19}$ (95% CL from Planck+$H_0$+WMAP polarization data, $^4$). However, allowing time evolution of $w$, the results of constraints become comparatively looser. For example, parameterizing dark energy EoS as $w(a) = w_0 + w_a (1-a)$ then the constraints from WMAP9+extra CMB data +BAO+SN+$H_0$ is $w_0 = -1.34 \pm 0.36$ and $w_a = 0.85 \pm 0.94$ (95% CL, see table 10 of $^3$), and from Planck+$H_0$+WMAP polarization data it is $w_0 = -1.04^{+0.72}_{-0.65}$ and $w_a < 1.32$ at (95% CL). Therefore, the data slightly favor the model with $w_0 < -1$ and $w_a > 0$ while large uncertainties of parameters still exist in the recent observational constraints.

In the spirit of exploring more phenomena associated with dark energy, we would like to investigate how the dark energy affects the growth of structure and clustering properties of galaxies. The kinematic Sunyaev-Zel’dovich (hereafter kSZ, or kinetic SZ) effect is one of the important phenomena that relates the galaxy’s peculiar motion with the temperature fluctuations of the CMB. The effect can arise during two processes, i.e. consisting of the “inhomogeneous patchy reionization” and the post-reionization signals.

In models of inhomogeneous reionization (or “patchy reionization”), where different regions of the Universe were ionized at different times, the bulk motion of bubbles of free electrons around the UV emitting sources may cause the temperature anisotropy on the CMB $^5$. It has been demonstrated $^6$ that the magnitude of the kSZ power from patchy reionization is related to the duration of reionization. Hence, one can set a constraint on the duration of reionization ($\Delta z_{rei}$) once the optical depth to reionization can be measured $^7$. After reionization, the “secondary anisotropy” of CMB can also be generated from the peculiar motion of galaxy clusters. Thus by measuring the kSZ effect one can have a good handle on the peculiar velocity of galaxies and therefore infer the growth rate of large scale structure. The growth rate of the large scale structure is affected by the dark energy EoS, because the dark energy negative pressure can drive the accelerated expansion of the Universe and therefore halt the growth of structure at late times. Therefore, it is necessary to investigate the effect of dark energy on growth of structure and the “imprint” of dark energy on the kSZ effect. This research is particularly useful since many ongoing CMB experiments, such as South Pole Telescope (SPT and SPTPol $^8$) and Atacama Cosmology Telescope (ACT and ACTPol $^9$) are going to measure the kSZ effect to a high precision.

The effect of clustering can be reflected in three dif-
ferent channels. First, the dark energy can freeze the growth of structure at late times, the larger the density is, the earlier it will take over the cosmic budget. Thus by counting the number of galaxy clusters from SZ effect one can set up constraints on the dark energy EoS \[12\]. Since the thermal SZ effect is sensitive to the structure growth rate, another channel is to measure the growth rate by cross-correlating the thermal SZ effect with the galaxy clusters \[14\]. Finally, due to the change of the structures’ growth rate, dark energy can effectively change the shape and amplitude of power spectrum. In Section III, we explore different phenomena of dark energy effect on kSZ signal. Thus by computing the kSZ power spectrum, one can directly measure the effect of dark energy from different \( \ell \) of kSZ power spectrum. Providing such an investigation on how much dark energy effect on kSZ signal is the main aim of this paper. Such detail modeling of post-reionization signal is particularly meaningful as more precise CMB observations are measuring the arcmin scale fluctuations. This is because once the astrophysics of post-reionization era is known better, it is possible to separate the post-reionization signal from the total signal, and thus obtain a reliable constraint on patchy reionization signal \[17\].

This paper is organized as follows. In Section III we provide an overview of the kSZ effect, and describe our model of the kSZ power spectrum, and discuss the baryon gaseous pressure and patchy reionization effect that may affect the shape and amplitude of power spectrum. In Section III we explore different phenomena of dark energy, by investigating how the different EoS functions \( w(z) \) can affect the the structure growth function and power spectrum. Then in Section IV we put together the time evolution of dark energy and kSZ models and investigate how the evolution of dark energy affect the 3D power spectrum of kSZ and therefore affects its angular power spectrum. We then compare our theoretical calculation with the current observational constraints on kSZ, and discuss its relation to patchy reionization signal. Our conclusion is presented in the last section.

Except when referring to specific models with particular parameters, throughout the paper we adopt a spatially flat, ΛCDM cosmology as our fiducial model with \( \Omega_b = 0.0425, \Omega_c = 0.221, \Omega_\Lambda = 0.737, n_s = 0.961, H_0 = 72.3 \text{ km s}^{-1} \text{ Mpc}^{-1}, \) and \( \sigma_8 = 0.834 \). This set of parameter was derived using a joint dataset of WMAP9 + SPT + ACT + BAO + \( H_0 \) \[2\].

II. KINETIC SZ POWER SPECTRUM MODELING

A. The kSZ effect

While traveling from the last scattering surface to us, a fraction of CMB photons are rescattered by free electrons with a coherent motion of peculiar velocity along the line-of-sight. The temperature fluctuations generated by such rescattering is \[30, 31, 36\]

\[
\frac{\Delta T}{T_0}(\hat{n}) = \sigma_T \int_0^{z_{rei}} \frac{dz}{(1 + z)H(z)} n_{e,i}(z)e^{-\tau(z)}(\vec{v} \cdot \hat{n}),
\]

where \( T_0 \approx 2.725 \text{ K} \) is the average temperature of CMB, \( \sigma_T \) is the Thomson cross-section for an electron, \( H(z) \), \( \tau(z) \) and \( n_{e,i}(z) \) are the Hubble parameter, optical depth and the ionized-free-electron number density respectively, and \( \vec{v} \cdot \hat{n} \) is the peculiar velocity of electrons along the line-of-sight. We choose the upper limit of the integral to be \( z_{rei} = 10 \) since we mainly focus on the kinetic SZ effect after the reionization, which happens at \( z = 10 \) in our fiducial cosmological model used in this analysis. Later we will see that the exact kSZ signal is not very sensitive to this upper limit as long as \( z \gtrsim 10 \).

The optical depth at redshift \( z \) is \[30, 31, 36\]

\[
\tau(z) = \sigma_T \int_0^{z} \frac{c n_{e,i}(z')}{(1 + z')H(z')} dz',
\]

where \( n_{e,i}(z) \) is the mean ionized free-electron number density. If we assume that at \( z < z_{rei} \) the hydrogen is completely ionized, then \[30, 31, 36\]

\[
\bar{n}_{e,i} = \frac{\chi \rho_e(z)}{\mu_e m_p},
\]

where \( \rho_e(z) = \rho_{e,0}(1 + z)^3 \) is the mean gas density at redshift \( z \), \( \mu_e = 1.14 \) is the mean mass per electron, and

\[
\chi = \frac{1 - Y_p(1 - N_{H_e}/4)}{1 - Y_p/2},
\]

is the fraction of ionized electrons. \( Y_p = 0.24 \) is the primordial helium abundance, and \( N_{H_e} \) is the number of helium electron ionized. We leave the derivation of Eq. \( 3 \) in Appendix A.

Since the free-electron number density is related to its mean value by \( n_{e,i} = \bar{n}_{e,i}(1 + \delta) \), and we define the density averaged peculiar velocity as the “momentum field” \[2 \] \( \vec{\eta} = \vec{\xi}(1 + \delta) \) (\( \delta = (\rho - \bar{\rho})/\bar{\rho} \) is the density contrast), then Eq. \( 1 \) becomes

\[
\frac{\Delta T}{T_0}(\hat{n}) = \left( \frac{\sigma_T \rho_{e,0}}{\mu_e m_p} \right) \int_0^{z_{rei}} \frac{(1 + z)^2}{H(z)} \chi e^{-\tau(z)}(\vec{\eta} \cdot \hat{n}) dz,
\]

Expanding Eq. \( 1 \) onto spherical harmonics and calculating the angular power spectrum \( C_\ell \) of the expansion coefficients \( a_{\ell m} \), one can obtain the kSZ angular power spectrum \[29, 31\] under the Limber approximation \[27\],

\[
C_\ell = \frac{8 \pi^2}{(2\ell + 1)^3} \left( \frac{\sigma_T \rho_{e,0}}{\mu_e m_p} \right)^2 \int_0^{z_{rei}} (1 + z)^4 
\times \chi^2 \Delta^2_b(\ell/x, z)e^{-2\tau(z)} \frac{x(z)}{cH(z)} dz,
\]

\[\text{This definition is widely used in many previous literatures, e.g.}\ 15, 21]
Thus Eq. (7) becomes

\[
\Delta^2_h(k, z) = \frac{k^3}{2\pi^2} \int \frac{d^3 \vec{k}'}{(2\pi)^3} \left(1 - \mu^2) P_{\delta\delta}(|\vec{k} - \vec{k}'|, z) P_{vv}(k', z) - \frac{(1 - \mu'^2) k'}{|k - k'|} P_{\delta v}(|\vec{k} - \vec{k}'|) P_{\delta v}(k') \right),
\]

where \(P_{\delta\delta}(P_{vv})\) is the linear density (velocity) power spectrum and \(P_{\delta v}\) is the density-velocity cross spectrum. \(\mu = \vec{k} \cdot \vec{k}'\) is the cosine angle between vectors \(\vec{k}\) and \(\vec{k}'\).

In the linear theory regime, the continuity equation indicates that the Fourier space velocity field \(\hat{v}(\vec{k})\) is related to density field through \(\hat{v}(\vec{k}) = i f \hat{\delta}(\vec{k}) \frac{\vec{k}}{|\vec{k}|^2}\),

\[
\hat{v}(\vec{k}) = i f \hat{\delta}(\vec{k}) \frac{\vec{k}}{|\vec{k}|^2}.
\]

\(f = d \log D / d \log a\), and \(D\) is the linear growth factor. Therefore the peculiar velocity power spectrum and density-velocity cross-spectrum are related to the linear density power spectrum as \(\hat{v}(\vec{k})\).

\[
P_{vv}(k) = \left(\frac{\dot{\bar{u}}}{\bar{u}}\right)^2 P_{\delta\delta}(k); \quad P_{\delta v}(k) = \left(\frac{\dot{\bar{u}}}{\bar{u}}\right) P_{\delta\delta}(k).
\]

Therefore Eq. (7) becomes

\[
\Delta^2_h(k, z) = \frac{k^3}{2\pi^2} (\dot{\bar{u}} f)^2 \int \frac{d^3 \vec{k}'}{(2\pi)^3} P_{\delta\delta}(|\vec{k} - \vec{k}'|) \\
\times P_{\delta\delta}(k') I(k, k'),
\]

(10)

where

\[
I(k, k') = \frac{k (2 k' \mu) (1 - \mu^2)}{k^2 (k + k' - 2 k' \mu)}.
\]

(11)

is the kernel function that couples linear velocity field with density field.

Therefore by substituting Eq. (11) into Eq. (10) and combining with Eq. (9), one can obtain the power spectrum of kinetic SZ effect, aka Ostriker-Vishniac effect (hereafter OV effect) \[33\], which corresponds to the case where the CMB photons are rescattered by linear structure of galaxy clusters through the linear velocity modes (such as the bulk motion).

On the other hand, the nonlinearity of the structure formation can affect the kSZ power spectrum significantly on scales of \(l > 1000\). Refs. \[31, 32, 33\] demonstrate that the full kSZ effect is determined by the non-linear matter density field \(P_{\delta\delta}^{NL}\) cross-correlating with the linear velocity field. One can correct for the nonlinearity by replacing the linear matter power spectrum \(P_{\delta\delta}\) in Eq. (10) with non-linear matter power spectrum \(P_{\delta\delta}^{NL}\), \[31\], i.e.,

\[
\Delta^2_h(k, z) = \frac{k^3}{2\pi^2} (\dot{\bar{u}} f)^2 \int \frac{d^3 \vec{k}'}{(2\pi)^3} P_{\delta\delta}^{NL}(|\vec{k} - \vec{k}'|) \\
\times P_{\delta\delta}(k') I(k, k').
\]

(12)

In addition, there is no need to replace linear velocity field with non-linear velocity field. This is because velocity power spectrum has an extra \(1/k^3\) factor than the matter power spectrum, so there is more weight on larger scales than the matter power spectrum. Therefore it turns out that this extra factor make the velocity field rather insensitive to the small scale non-linear behavior \[30\].

Throughout this paper, we calculate the linear and non-linear matter power spectrum using the public code CAMB \[37\] which automatically incorporates the HALOFIT \[41, 42\] prescription for the non-linear matter power spectrum.

B. Gaseous pressure

In the kSZ power spectrum calculations, it is commonly assumed that the density distribution of the baryonic gas follows exactly that of dark matter, so there is no “bias” in between \(\delta_{gas}\) and \(\delta_{DM}\) \[28, 30, 36\]. However, on small scales, a significant fraction of baryons are in form of gas, thus the thermal pressure of baryons can erase the density fluctuations in the gas distribution on small scales \[31\]. This “suppression” effect can be modeled as a window function \(W(k)\) such that \[31\].

\[
P_{\delta\delta}^{NL}(k, z) = W^2(k, z) P_{\delta\delta}^{NL}(k, z).
\]

(13)

Here we use the fitting formula of \(W(k)\) developed by \[31\].

\[
W^2(k, a) = \frac{1}{2} \left\{ e^{-k/k_i} + \frac{1}{1 + [1 + g(a) k/k_i]^{7/2}} \right\}
\]

(14)

---

3 Note that Eq. (10) only holds in the models where the growth is scale-independent. For more general cases in which the growth is scale-dependent, e.g. the models with massive neutrinos or the modified gravity models, one should leave the function \(f\), which is a function of \(k\) and \(z\), inside the integral.
where the filter scale \( k_t = 12.6/a + 6.3 \) and \( q(a) = 0.84/a \). This fitting formula is proved to provide a better fit to the gas density power spectrum than the analytic formula developed by Gnedin & Hui [43] through the comparison with “BolshoiNR and L60N” numerical simulations shown in [31]. Thus, by incorporating the gas pressure window function, the power spectrum \( \Delta^2(k, z) \) becomes [31],

\[
\Delta^2(k, z) = \frac{k^3}{2\pi^2} (\dot{a} f)^2 \int \frac{d^3k'}{(2\pi)^3} W^2(|\vec{k} - \vec{k}'|, z) \\
\times P_{\delta\delta}^N(|\vec{k} - \vec{k}'|) P_{\delta\delta}(k, k').
\]

Note that we assume that the velocity of gas follows exactly the velocity of dark matter, so there is no velocity bias between them.

In Fig. 1 we plot the kSZ angular power spectrum and gas window function in panels (a) and (b) respectively. In Fig. 1 (b), we can see that on the large scales, \( W(k) \approx 1 \) while on small scales \( W(k) \rightarrow 0 \) as \( k \) increases due to the gas thermal pressure force. The suppression is not very significant at the onset of the gravitational collapse (high \( z \)), but as structures gradually collapse, the suppression propagates progressively to larger and larger scales. In Fig. 1 (a), we plot the kSZ angular power spectrum \( D_k \equiv \ell(\ell + 1)C_\ell/2\pi \) as a function of \( \ell \). One can see that the linear OV effect only produces the signal peaking at \( \ell \sim 2000 \), and gradually decreases at higher \( \ell \). This is because the linear perturbation is sensitive to linear modes which are generically on large scales. One the other hand, using non-linear matter power spectrum instead (Eq. (12)) to calculate the full kSZ effect, one obtains the blue solid line, whose amplitude is about 3 times higher than that of the linear one on small scales. The \( D_k \) of the full kSZ power spectrum is about 3.066 \( \mu K^2 \) on scales of \( \ell \sim 3000 \). In addition, if we incorporate the window function to account for the fact that a fraction of density fluctuations will be suppressed by the gaseous pressure on small scales, i.e. to use Eq. (15), the total signal drops by a factor of 3%–10% on \( \ell \sim 2000 \) to 10000.

In order to see clearly how dark energy affects the kSZ signals, in the following analysis, we will adopt the full non-linear kSZ effect without gas pressure as our default model, and discuss the effect of dark energy on this full-kSZ signal. Of course, when using this model to compare with observations, one needs to consider the effect of gas pressure, which can only be well understood from numerical simulations.

### III. Dark Energy Imprints

In this section we shall first review how the dark energy EoS changes the comoving distance \( x(z) \), and then show how the time-varying dark energy affects the structure growth, and eventually we analyze how the kSZ power spectrum is affected by dark energy.

#### A. EoS \( w(z) \) and comoving distance \( x(z) \)

We adopt the Chevallier-Polarski-Linder (CPL) parametrization \[44 \ 15 \] of dark energy, i.e., \( w(a) = w_0 + w_a (1 - a) \) where \( w_0 \) and \( w_a \) are the two free parameters \[3 \]. In this parametrization form, the fractional matter density and dark energy density evolve as

\[
\Omega_m(z) = \Omega_m^0 (1 + z)^3,
\]

\[
\Omega_{DE}(z) = \Omega_{DE}^0 (1 + z)^{3(1 + w_0 + w_a)} \exp \left(- \frac{3w_a z}{1 + z} \right).
\]

where \( \Omega_m^0 = \Omega_m^0 + \Omega_h^0 \) and \( \Omega_{DE}^0 \) are the matter and dark energy density at present time and their values are set to be the default values in Sec. I. The we can substitute these two equations into the Friedmann equation \( H(z) = H_0 (\Omega_m(z) + \Omega_{DE}(z))^{1/2} \) to calculate the Hubble expansion and comoving distance \( x(z) \).
FIG. 2: Panel(a): Comoving distance \( x = \int_0^\infty (c/H(z'))dz' \) for seven dark energy models with different parameters of EoS. Panel (b): the evolution of EoS for seven dark energy models. The colour scheme of the two panels is shown on panel (a).

FIG. 3: Panel(a): Growth function \( f(z) = d\log(D)/d\log(a) \) for the five dark energy models with constant equation of state parameters. Panel (b): the fractional difference of power spectrum \( \Delta P_w(k)/P_{LCDM}(k) = (P_w(k) - P_{LCDM}(k))/P_{LCDM}(k) \) between dark energy models with four different \( w \) values and ΛCDM model. The colour scheme of the two panels is shown on panel (a).

FIG. 4: Panel(a): Growth function \( f(z) = d\log(D)/d\log(a) \) for the seven dark energy models with time-varying EoS parameters (\( w(z) = w_0 + w_z z/(1 + z) \)). Panel (b): the fractional difference of power spectrum \( \Delta P_w(k)/P_{LCDM}(k) = (P_w(k) - P_{LCDM}(k))/P_{LCDM}(k) \) between dark energy models with six different \( w(z) \) evolution and ΛCDM model. The colour scheme of the two panels is shown on panel (a).
In the following analyses, we take representative values of \( w_0 \) to be \(-0.8, -0.9, -1, -1.1, \) and \(-1.2, \) and \( w_a \) of \(-0.5, 0, \) and \( 0.5. \) All these models are allowed by the joint constraints using WMAP9+SPT+ACT+BAO+H0 \([46]\).

In Fig. 2 we plot the dark energy EoS in panel (b) and the corresponding comoving distance at redshift \( z \) in panel (a). One can see that the comoving distance increases as \( w_0 \) or \( w_a \) drops and vice versa. This is simply because a more negative \( w_0 \) or \( w_a \) means a smaller Hubble parameter in the past, thus a larger comoving distance. This is apparent in Fig. 2 (a).

This brings up the question of degeneracy. If \( w_0 \) is more negative but \( w_a \) is positive, this will produce the similar effect with a less negative \( w_0 \) but more negative \( w_a \). For instance, in Fig. 4, we can see that the \( x(z) \) function for \( w_0 = -0.8, w_a = -0.5 \) is very close to the model \( w_0 = -1.2, w_a = 0.5, \) and also close to the LCDM model \( w_0 = -1, w_a = 0 \). This is because the comoving distance is an integrated effect, although the evolution of \( w(z) \) are different for these models, their integrated effects are close to each other. This degenerates between the time-evolving EoS parameters is what we should be aware of when analyzing the kSZ effect signals.

### B. Growth function \( f(z) \)

In the 3D power spectrum of kSZ effect (Eq. (13)), \( \Delta_{be}(k, z) \) function depends on the evolution of structure growth function \( f(z) \), and also the (non)linear matter power spectrum. The growth function \( f(z) \) is the logarithmic derivative of the growth rate \( D(z) \) \( \equiv D(t) = D(t_0) \), i.e. \( f(z) = d \log(D)/d \log(a) \).

We use the numerical code CAMB \([37]\) to calculate the growth function \( f \) for various dark energy models in question. Since CAMB does not output growth function directly, we first modify its subroutine and output the density contrast as a function of redshift, and the calculate its logarithmic derivative to obtain the growth function. Note that we included the dark energy perturbation consistently in the calculation and pay particular attention to the quintom scenario \([38]\) in which \( w \) crosses \(-1 \) during evolution using the prescription in Ref. \([39]\).

In Fig. 3 (a), we vary the \( w_0 \) value from \(-0.8 \) to \(-1.2 \) while fixing \( w_a = 0 \), while in Fig. 4, we vary \( w_a \) as well. One can see that the \( f(z) \) function for various models converge at both ends, say, at \( z = 0 \) and \( z = 10 \). This is easy to understand since \( f(z) \) \( \simeq \Omega_m(z)^7 \) where \( \gamma \) has a weak dependence on \( w(z) \). At low \( z, \Omega_m(z) \approx \Omega_{m0} \) while at the high \( z \) end, \( \Omega_m(z) \approx 1 \). Therefore different values of \( w_0 \) or \( w_a \) mainly affect the evolution in the middle. A more negative \( w_0 \) or \( w_a \) makes dark energy less important in the past, which effectively gives structures more time to grow before diluted, thus a larger growth rate.

### IV. KSZ SIGNAL FOR DIFFERENT DARK ENERGY MODELS

#### A. 3D power spectrum of curl component of momentum field

To calculate the 3D curl momentum power spectrum \( \Delta_{be}(k) \) at different redshifts, we rewrite Eq. (12) as,

\[
\Delta_{be}^2(k, z) = \frac{k^3}{2\pi^2} (\hat{a}f)^2 \int \frac{d\kappa d\mu}{(2\pi)^2} P_{\delta\delta}^{NL}(\kappa - \kappa') \times P_{\delta\delta} \hat{I}(k, \kappa'),
\]

where \( \Delta_{be} \) is the curl component of momentum power spectrum, \( f \) is the growth function, \( \kappa \) is the comoving wave number, and \( \mu \) is the cosine of the angle between the wave vector and the line of sight. The term \( P_{\delta\delta}^{NL} \) is the nonlinear power spectrum, and \( P_{\delta\delta} \) is the linear power spectrum.
where 
\[
\tilde{I}(k, k', \mu) = \frac{((k/k')^2 - 2\mu(k/k'))(1 - \mu^2)}{1 + (k/k')^2 - 2\mu(k/k')},
\]  
(18)

is the reduced dimensionless kernel function. We plug in the calculation of \(f(z)\) and the linear and non-linear matter power spectrum (\(P_{\delta\delta}^L\) and \(P_{\delta\delta}^N\)) into Eq. (17), and integrate over the cosine angle of separation \(\mu = [-1, 1]\) and \(k'\), and then obtain the 3D curl component of momentum power spectrum. We also calculate the OV effect for comparison.

In Fig. 6, we plot the power spectrum of momentum field of the fiducial \(\Lambda\)CDM model at different redshifts. It is obvious that more and more structures form as the universe evolves, therefore the amplitude of curl momentum power spectrum increases as redshift drops. At high \(z\), \(e.g., z = 6\), the nonlinearity has less effect on the kSZ \(\Delta_x\) on the concerning scales thus the linear OV approach is a good approximation. However, as the universe evolves, the rms of fluctuation exceeds unity on larger and larger scales, so structures become non-linear on comparatively larger scales. This makes the \(z = 0\) curl momentum power spectrum significantly different from the OV power spectrum on scales of \(k > 1 \, h\)Mpc\(^{-1}\).

Now we can compare \(\Delta_x(k)\) of \(w\)CDM cosmology to that of the \(\Lambda\)CDM cosmology. In Fig. 6 we plot the fractional difference of \(w\)CDM momentum power spectrum with the fiducial \(\Lambda\)CDM model, at four different redshifts, which are chosen as follows: \(z = 6\) as the onset of structure formation, \(z = 3\) as the typical epoch of gravitational collapse, \(z = 1\) as the era when dark energy becomes important, and \(z = 0\) represents the current epoch. For each panel, we choose \(w_0\) to be \([-1.2, -1.1, -1, -0.9, -0.8]\).

One can see that at \(z = 6\), there is little difference between \(w\)CDM prediction and the \(\Lambda\)CDM prediction, since in both scenarios the dark energy component is negligible. The dark energy effect kicks in at \(z = 1\), making the fractional difference reach 5% at this time. At even later time, this difference become more significant, and at present time this different is \(\sim 10\%\).

We show the fractional difference between CPL dark energy model and \(\Lambda\)CDM model in Fig. 6. One can see that the more negative \(w_0\) or \(w_a\) is, the higher the amplitude of curl momentum field is, and vice versa. This is natural since \(\Delta_x(k)\) increases as the matter power.

B. The total signal

Now we put together the factors of structure growth, comoving distance, and power spectrum of curl momentum field to analyze how dark energy affects the kSZ angular power spectrum.
FIG. 7: Fractional difference between the power spectrum of momentum field $\Delta_b(k)$ at four different redshifts. The colour scheme for seven different dark energy models with time-varying EoS is shown on the “$z=6$” panel.

FIG. 8: Panel (a): kSZ angular power spectrum ($D_\ell \equiv \ell(\ell + 1)C_{\ell}^{kSZ}/2\pi$) for five dark energy models with constant EoS. Panel (b): Same as panel (a) but for time-varying dark energy models. The horizontal bars with arrows show $D_{\ell=3000} \leq 8.6 \mu K^2$ (95% confidence level) from Atacama Cosmology Telescope (ACT) \cite{17} and $D_{\ell=3000} \leq 6.7 \mu K^2$ (95% CL) from South Pole Telescope (SPT1) \cite{23}. The black data point shows $D_{\ell=3000} = 2.9 \pm 1.5 \mu K^2$ (1$\sigma$ CL) also from South Pole Telescope (SPT2) while including bispectrum constraints \cite{48}.

Note that Eq. \cite{14} is an integral up to $z_{\mathrm{rei}} = 10$, so it is a projected effect of the velocity field along line of sight. Therefore, we need to count for all the observable modes of fluctuations at different redshifts. By calculating $d^2G/dz d\ln k$, Ref. \cite{21} shows (in their Fig. 1) that, 75% of the full kSZ power comes from redshifts in the range of $[0, 7]$ and $k$-mode in the range of $0.2-7.0 \ h \text{Mpc}^{-1}$ at $\ell = 3000$. This $\{k, z\}$ range is ideal to probe for the amplitude and even the time evolution of the dark energy EoS, thus the kSZ measurement can potentially facilitate a novel test of dark energy. Note that although in the following we plot the $C_{\ell}s$ up to $\ell \simeq 10000$, most of the constraining power related to cosmology comes from $\ell \simeq 3000$. 
FIG. 9: Panel (a): The ratio between $w$CDM and $\Lambda$CDM $C_\ell$ (i.e. ratio between model with $w_0 \neq -1$ and $w_0 = -1$) with the scaling law (Eqs. 13 and 20) marked as black lines. Panel (b): the ratio between $C_\ell$ with $w_a \neq 0$ and with $w_a = 0$ (note that this is not ratio between dynamical dark energy with $\Lambda$CDM model), the black lines correspond to the scaling law (Eqs. 21 and 22). The accuracy of the fit is within 1% over $\ell \simeq 3000$–10000.

| $D_\ell(\mu K^2)$ | $w_0 = -0.8$ | $w_0 = -0.9$ | $w_0 = -1$ | $w_0 = -1.1$ | $w_0 = -1.2$ |
|------------------|--------------|--------------|-------------|--------------|--------------|
| $\ell = 1000$   | 1.49         | 1.58         | 1.65        | 1.71         | 1.76         |
| $\ell = 2000$   | 2.19         | 2.37         | 2.51        | 2.62         | 2.70         |
| $\ell = 3000$   | 2.61         | 2.86         | 3.06        | 3.20         | 3.32         |
| $\ell = 4000$   | 2.92         | 3.20         | 3.43        | 3.62         | 3.77         |
| $\ell = 5000$   | 3.14         | 3.46         | 3.72        | 3.93         | 4.10         |
| $\ell = 6000$   | 3.32         | 3.67         | 3.95        | 4.17         | 4.35         |
| $\ell = 7000$   | 3.47         | 3.84         | 4.13        | 4.37         | 4.56         |
| $\ell = 8000$   | 3.59         | 3.98         | 4.28        | 4.53         | 4.73         |
| $\ell = 9000$   | 3.69         | 4.10         | 4.40        | 4.66         | 4.87         |
| $\ell = 10000$  | 3.78         | 4.20         | 4.51        | 4.77         | 4.98         |

**TABLE I:** The values of kSZ power spectrum $D_\ell = \ell(\ell + 1)C_\ell/2\pi [\mu K^2]$ of 10 multiples for five constant $w$ models.

In Fig. 8 (a), we plot the kSZ angular power spectrum $\ell(\ell + 1)C_\ell/2\pi$ as a function of the multipole $\ell$. We show the result for the various dark energy models with a constant EoS from $-0.8$ to $-1.2$. One can see that, since a more negative $w_0$ makes the comoving distance $x(z)$, growth function $f(z)$ and amplitude of curl momentum field $\Delta_0(k)$ coherently larger, the cumulative integral will eventually enhance the total signal $C_\ell$ significantly, and vice versa. On scales of $\ell \sim 3000$, $C_\ell(w = -0.8)$ is smaller than the $\Lambda$CDM value by a factor of 14.7%, while $C_\ell(w = -1.2)$ is larger than the $\Lambda$CDM value by a factor of 8.5%. So the total variation of signal given the allowed parameter space by WMAP observations [8] can reach nearly 23% on scales of $\ell = 3000$. On even smaller scales (larger $\ell$’s), the difference can be even more significant. We list the values of $C_\ell$’s of 10 multiples separated by $\Delta \ell = 1000$ in Table I. This is the most prominent effect of dark energy on kSZ power spectrum.

In addition, in Fig. 8 (b), we plot the kSZ power spectrum for dark energy models with a non-zero $w_a$, namely, $w_a$ from $-0.5$ to $0.5$. Note that this range of $w_a$ value is allowed by the joint constrained from WMAP9+SPT+ACT+BAO+$H_0$ [14]. We can see that with $w_0 = -0.8$ or $w_0 = -1.2$, if $w_a > 0$ the dark energy kicks in earlier than $w_a = 0$, so the structure growth will be suppressed and vice versa. Quantitatively, the change in $w_a$ by $\pm 0.5$ results in a change in the kSZ signal by a factor of 50 to 60% on scales of $\ell = 3000$, which is a significant effect manifesting the properties of dark energy. We list the 10 values of $C_\ell$’s for CPL dark energy model in Table I.

To use the kSZ measurements to constrain dark energy EoS, one needs to calculate the kSZ power spectra for a large numbers of cosmological models for the Markov Chain Monte Carlo (MCMC) process. This is computationally expensive so it is useful to develop accurate fitting formula for the practicality.

To understand the feature of kSZ spectrum, we plot the ratio of the spectrum between the constant-$w$ model and the $\Lambda$CDM in Fig. 9 (a) where dots in different colours represent different values of $w$. We can see that the trend of $C_\ell(w \neq -1)/C_\ell(w = -1)$ close to a power law shape, so we model the function as

$$
\frac{C_\ell(w \neq -1)}{C_\ell(w = -1)} = B \left( \frac{\ell}{1000} \right)^C,
$$

where the amplitude $B$ and the power index $C$ are to be determined. We first output the left-hand-side of Eq. (14) for each $\ell$, and then by assuming a form of $B$ and $C$ as $a_1 + a_2 \exp(w) + a_3 w$, we fit these parameters with the data $C_\ell(w \neq -1)/C_\ell(w = -1)$. We find that the follow-
TABLE II: The values of kSZ power spectrum $D_\ell = \ell(\ell+1)C_\ell/2\pi [\mu K^2]$ of 10 multiples for varying $w_a$ models.

| $D_\ell (\mu K^2)$ | $w_a = 0.5$ | $w_a = 0$ | $w_a = -0.5$ | $w_a = 0.5$ | $w_a = 0$ | $w_a = -0.5$ |
|---------------------|-------------|-----------|-------------|-------------|-----------|-------------|

| $\ell = 10000$      | 2.03        | 3.78      | 4.50        | 4.49        | 4.98      | 5.24        |

### C. Observational constraints

We now discuss what current and future observational constraints can be obtained on the kSZ power spectrum and its prospective to constrain dark energy. In [47], by using 148 GHz and 218 GHz Atacama Cosmology Telescope (ACT) data and fitting the template with contribution from thermal and kinetic SZ effects, infrared sources and radio sources, the 95% level upper limit is found to be $8.6\mu K^2$. In [22], the constraint on $D_{\ell=3000}$ is obtained by combining 95, 150 and 220 GHz channel data of SPT. By fitting the template of thermal SZ with the kinetic SZ signal, it is found that $D_{kSZ}^{3000} < 2.8\mu K^2$ at 95% CL. In addition, if considering the the correlation between thermal SZ effect with cosmic infrared background, this upper limit is loosed to $D_{kSZ}^{3000} < 6.7\mu K^2$ at 95% CL. Furthermore, by incorporating the bispectrum data from the same three channels of SPT, Ref. [48] finds that the derived constraints on kSZ amplitude at $\ell = 3000$ is $\langle D_{kSZ}^{3000} \rangle = 2.9 \pm 1.5\mu K^2$ at 1$\sigma$ confidence level (CL.), and $< 5.5\mu K^2$ at 95% CL. We place these upper limits and data point in the two panels of Fig. 8.

By comparing the constraints from [47], [22] and [48], we can see that although the constraints are not very strong at current situation, the SPT constraint with bispectrum (black data point on Fig. 8b) already tend to rule out the model with $(w_0 = -0.8, w_a = 0.5)$. In addition, the trend of tightening constraints of kSZ signal is quite obvious given many of the ongoing CMB surveys. In the future, if we can place both upper and lower limit on kSZ power spectrum, it can be used as a powerful tool to constrain EoS of dark energy. In reality, Herschel data can be used to separate the infrared and radio sources in the foreground, and thus improve the constraints on kSZ signal.

### D. Relation to patchy reionization

What we modeled above is the homogeneous kSZ signal which comes from the era after reionization $z \lesssim 10$. The total signal of kSZ consists of both homogeneous kSZ signal and the patchy reionization signal with most...
of its contribution from reionization era. The magnitude of the kSZ power from the second component, i.e. patchy reionization, is strongly related to the process of reionization \[21, 23\], which detail is relatively unknown. For instance, it is unclear whether the reionization is an instantaneous reionization, or two-step reionization, or a double reionization \[24, 19\]. In addition, it is not clear how much contribution of the total kSZ signal from the patchy reionization era. For example, if reionization started at \(z = 14\) and ended at \(z = 6\), then it can generate roughly \(3\mu K^2\) of patchy kSZ power (at \(\ell \geq 3000\)), while the range \(z = [8, 12]\) would generate \(1.5\mu K^2\) \[21, 31\]. Therefore, in order to derive the patchy component of total kSZ signal, it is very important to have a good theoretical modeling of the homogeneous kSZ contribution as was laid out in this paper.

V. CONCLUSION

The nature of dark energy is a mystery in modern cosmology, and its property is characterized by its equation of state (EoS) parameter. Current CMB space-mission such as WMAP and Planck, ground-based CMB experiments such as ACT and SPT, as well as baryon acoustic oscillation experiments from SDSS can set up tight constraints on \(w\) parameter if assuming that \(w\) is a constant. However, if allowing \(w\) to vary, such as \(w(a) = w_0 + w_a(1 - a)\) (the CPL parametrization), the constraints become weaker while a large region of parameter space is allowed. 

In this paper we have calculated the kinetic Sunyaev-Zel’dovich signal for general dark energy models with both the constant-\(w\) case, and the CPL parametrization (time-varying \(w\) case). We first review the calculation of the kSZ signal for the \(\Lambda\)CDM model, and extend the analysis for the general dark energy model. We calculate the curl momentum power spectrum \(\Delta^\mu(k)\) at different redshifts, and find that dark energy can affect the amplitude and shape of the gravitational clustering at redshifts \(0-3\). Finally, we integrate the curl momentum field from redshift 0 till the reionization redshift \(z_{\text{rei}} = 10\), and find that if, for example, \(w_0 = -0.8\) the total signal of kSZ can be suppressed by a factor of \(\sim 14.7\%\) on scales of \(\ell = 3000\), while \(w_0 = -1.2\) the total signal of kSZ can be enhanced by a factor of \(\sim 8.5\%\) on the same scales. We then vary the parameter \(w_a\) and find that this parameter is more sensitive to the amplitude and shape of the kSZ signal, and in the range of \(w_a = \pm 0.5\) (1\(\sigma\) constrained parameters space by WMAP9+ACT+SPT+BAO+H0), the \(w_a\) can alter the amplitude of kSZ signal by nearly 60\%. Therefore, if kSZ signal can be precisely measured, it can be a sensitive test of dark energy.

Finally, in order to fast calculate the kSZ signal in a general dark energy model with a constant \(w\) or a time-varying \(w\), we model an empirical relation which can precisely recover the values of kSZ power spectrum from numerical calculation. Our fitting formulae (Eqs. \[19\]–\[22\]) work very precisely in a large region of parameter space \((w_0, w_a)\) and therefore can be useful in the fast computation of \(C^\text{kSZ}_\ell\).

Appendix A: Derivation of \(\chi\) and \(\mu_e\)

In Section \[11\] we define \(\chi\) as the fraction of the total number of electrons that are ionized. We assume that at \(z < z_{\text{rei}}\) the hydrogen is completely ionized, and the number of helium electrons ionized is \(N_{\text{He}}\), so \(N_{\text{He}}\) can take 0, 1 and 2 for neutral, singly and fully ionized helium respectively. In our fiducial model we assume \(N_{\text{He}} = 0\) at all redshifts. Thus \(\chi\) is the ratio between ionized and total number of electrons, i.e.

\[
\chi = \frac{\mu_{e,i}}{n_e} = \frac{n_{\text{H}} + n_{\text{He}} \cdot N_{\text{He}}}{n_{\text{H}} + 2n_{\text{He}}}, \quad (A1)
\]

The helium number density is

\[
n_{\text{He}} = \frac{Y_p}{4X_p}n_{\text{H}}, \quad (A2)
\]

where \(Y_p = 0.24\) and \(X_p = 1 - Y_p\) is the primordial helium and hydrogen abundance. Therefore substituting Eq. (A2) into Eq. (A1), we obtain

\[
\chi = \frac{1 - Y_p(1 - N_{\text{He}}/4)}{1 - Y_p/2}. \quad (A3)
\]

We now calculate the gas density as

\[
\rho_g = m_p n_{\text{H}} + m_{\text{He}} n_{\text{He}}, \quad (A4)
\]

since \(m_{\text{He}} \simeq 4m_p\), and by using Eq. (A2), we obtain

\[
n_{\text{H}} = \frac{\rho_g}{(1 + X_p)} m_{\text{H}}. \quad (A5)
\]

Since the total electron density is \(n_e = n_{\text{H}} + 2n_{\text{He}}\), by using Eq. (A2), we obtain

\[
n_e = \frac{\rho_g}{m_p \mu_e}, \quad \mu_e = \frac{1 + Y_p/X_p}{1 + Y_p/(2X_p)} = 1.14, \quad (A6)
\]
where $\mu_e$ is called mean electron weight. Then combining Eqs. (A1), (A3) and (A6), we obtain

$$n_{e,i} = \frac{\chi \rho_a}{m_p \mu_e}. \quad (A7)$$
