Abstract

A constitutive model based on the combination of damage mechanics and plasticity is developed to analyse the failure of concrete structures. The aim is to obtain a model, which describes the important characteristics of the failure process of concrete subjected to multiaxial loading. This is achieved by combining an effective stress based plasticity model with a damage model based on plastic and elastic strain measures. The model response in tension, uni-, bi- and triaxial compression is compared to experimental results. The model describes well the increase in strength and displacement capacity for increasing
confinement levels. Furthermore, the model is applied to the structural analyses of tensile and compressive failure.

Keywords: concrete; constitutive model; plasticity; damage mechanics; fracture; mesh dependence

1 Introduction

Concrete is a strongly heterogeneous material, which exhibits a complex nonlinear mechanical behaviour. Failure in tension and low confined compression is characterised by softening which is defined as decreasing stress with increasing deformations. This softening response is accompanied by a reduction of the unloading stiffness of concrete, and irreversible (permanent) deformations, which are localised in narrow zones often called cracks or shear bands. On the other hand, the behaviour of concrete subjected to high confined compression is characterised by a ductile hardening response; that is, increasing stress with increasing deformations. These phenomena should be considered in a constitutive model for analysing the multiaxial behaviour of concrete structures.

There are many constitutive models for the nonlinear response of concrete proposed in the literature. Commonly used frameworks are plasticity, damage mechanics and combinations of plasticity and damage mechanics. Stress-based plasticity models are useful for the modelling of concrete subjected to triaxial stress states, since the yield surface corresponds at a certain stage of hardening to the strength envelope of concrete (Leon,
1935; Etse and Willam, 1994; Willam and Warnke, 1974; Pramono and Willam, 1989; Menétrey and Willam, 1995; Pivonka, 2001; Grassl et al., 2002; Papanikolaou and Kappos, 2007; Červenka and Papanikolaou, 2008; Folino and Etse, 2012). Furthermore, the strain split into elastic and plastic parts represents realistically the observed deformations in confined compression, so that unloading and path-dependency can be described well. However, plasticity models are not able to describe the reduction of the unloading stiffness that is observed in experiments. Conversely, damage mechanics models are based on the concept of a gradual reduction of the elastic stiffness (Kachanov, 1980; Mazars, 1984; Ortiz, 1985; Resende, 1987; Mazars and Pijaudier-Cabot, 1989; Carol et al., 2001; Tao and Phillips, 2005; Voyiadjis and Kattan, 2009). For strain-based isotropic damage mechanics models, the stress evaluation procedure is explicit, which allows for a direct determination of the stress state, without an iterative calculation procedure. Furthermore, the stiffness degradation in tensile and low confined compressive loading observed in experiments can be described. However, isotropic damage mechanics models are often unable to describe irreversible deformations observed in experiments and are mainly limited to tensile and low confined compression stress states. On the other hand, combinations of isotropic damage and plasticity are widely used for modelling both tensile and compressive failure and many different models have been proposed in the literature (Ju, 1989; Lee and Fenves, 1998; Jason et al., 2006; Grassl and Jirásek, 2006; Nguyen and Houlsby, 2008; Nguyen and Korsunsky, 2008; Voyiadjis et al., 2008; Grassl, 2009; Sánchez et al., 2011; Valentini and Hofstetter, 2012).

One popular class of damage-plastic models relies on a combination of stress-based plas-
ticity formulated in the effective (undamaged) stress space combined with a strain based damage model. The combined damage-plasticity model recently developed by Grassl and Jirásek (2006); Grassl and Jirásek (2006) belongs to this group. This model, called here Concrete Damage Plasticity Model 1 (CDPM1), is characterised by a very good agreement with a wide range of experimental results of concrete subjected to multiaxial stress states. Furthermore, it has been used in structural analysis in combination with techniques to obtain mesh-independent results and has shown to be robust (Grassl and Jirásek, 2006; Valentini and Hofstetter, 2012). However, CDPM1 is based on a single damage parameter for both tension and compression. This is sufficient for monotonic loading with unloading, but is not suitable for modelling the transition from tensile to compressive failure realistically. When the model was proposed, this limitation was already noted and a generalisation to isotropic formulations with several damage parameters was recommended. In the present work, CDPM1 is revisited to address this issue by proposing separate damage variables for tension and compression. The introduction of two isotropic damage variables for tension and compression was motivated by the work of Mazars (1984); Ortiz (1985); Fichant et al. (1999). Secondly, in CDPM1, a perfect plastic response in the nominal post-peak regime is assumed for the plasticity part and damage was determined by a function of the plastic strain. For the nonlocal version of CDPM1 presented in Grassl and Jirásek (2006), this perfect-plastic response resulted in mesh-dependent plastic strain profiles, although the overall load-displacement response was mesh-independent. Already in Grassl and Jirásek (2006), it was suggested that the plastic strain profile could be made mesh-independent by introducing hardening in the plasticity model for the nominal
post-peak regime. In the present model, the damage functions for tension and compres-
sion depend on both plastic and elastic strain components. Furthermore, hardening is
introduced in the nominal post-peak regime. With these extensions, the damage laws can
be analytically related to chosen stress-inelastic strain relations, which simplifies the cal-
ibration procedure. The extension to hardening is based on recent 1D damage-plasticity
model developments in Grassl (2009), which are here for the first time applied to a 3D
model. The present damage-plasticity model for concrete failure is an augmentation of
CDPM1. Therefore, the model is called here CDPM2. The aim of this article is to
present in detail the new phenomenological model and to demonstrate that this model
is capable of describing the influence of confinement on strength and displacement ca-
pacity, the presence of irreversible displacements and the reduction of unloading stiffness,
and the transition from tensile to compressive failure realistically. Furthermore, it will
be shown, by analysing structural tests, that CDPM2 is able to describe concrete failure
mesh independently.

2 Damage-plasticity constitutive model

2.1 General framework

The damage plasticity constitutive model is based on the following stress-strain relation-
ship:

\[ \sigma = (1 - \omega_t) \bar{\sigma}_t + (1 - \omega_c) \bar{\sigma}_c \]  

(1)
where \( \sigma_t \) and \( \sigma_c \) are the positive and negative parts of the effective stress tensor \( \bar{\sigma} \), respectively, and \( \omega_t \) and \( \omega_c \) are two scalar damage variables, ranging from 0 (undamaged) to 1 (fully damaged). The effective stress \( \bar{\sigma} \) is defined as

\[
\bar{\sigma} = D_e : (\varepsilon - \varepsilon_p)
\]

where \( D_e \) is the elastic stiffness tensor based on the elastic Young’s modulus \( E \) and Poisson’s ratio \( \nu \), \( \varepsilon \) is the strain tensor and \( \varepsilon_p \) is the plastic strain tensor. The positive and negative parts of the effective stress \( \bar{\sigma} \) in (1) are determined from the principal effective stress \( \bar{\sigma}_p \) as \( \bar{\sigma}_{pt} = \langle \bar{\sigma}_p \rangle_+ \) and \( \bar{\sigma}_{pc} = \langle \bar{\sigma}_p \rangle_- \), where \( \langle \rangle_+ \) and \( \langle \rangle_- \) are positive and negative part operators, respectively, defined as \( \langle x \rangle_+ = \max (0, x) \) and \( \langle x \rangle_- = \min (0, x) \).

For instance, for a combined tensile and compressive stress state with principal effective stress components \( \bar{\sigma}_p = (-\bar{\sigma}, 0.2\bar{\sigma}, 0.1\bar{\sigma})^T \), the positive and negative principal stresses are \( \bar{\sigma}_{pt} = (0, 0.2\bar{\sigma}, 0.1\bar{\sigma})^T \) and \( \bar{\sigma}_{pc} = (-\bar{\sigma}, 0, 0)^T \), respectively.

The plasticity model is based on the effective stress, which is independent of damage. The model is described by the yield function, the flow rule, the evolution law for the hardening variable and the loading-unloading conditions. The form of the yield function is

\[
f_p (\bar{\sigma}, \kappa_p) = F (\bar{\sigma}, q_{h1}, q_{h2})
\]

where \( q_{h1} (\kappa_p) \) and \( q_{h2} (\kappa_p) \) are dimensionless functions controlling the evolution of the
size and shape of the yield surface. The flow rule is

$$\dot{\varepsilon}_p = \dot{\lambda} \frac{\partial g_p}{\partial \bar{\sigma}} (\bar{\sigma}, \kappa_p)$$

where $\dot{\varepsilon}_p$ is the rate of the plastic strain, $\dot{\lambda}$ is the rate of the plastic multiplier and $g_p$ is the plastic potential. The rate of the hardening variable $\kappa_p$ is related to the rate of the plastic strain by an evolution law. The loading-unloading conditions are

$$f_p \leq 0, \quad \dot{\lambda} \geq 0, \quad \dot{\lambda} f_p = 0$$

A detailed description of the individual components of the plasticity part of the model are discussed in Section 2.2.

The damage part of the model is described by the damage loading functions, loading unloading conditions and the evolution laws for damage variables for tension and compression. For tensile damage, the main equations are

$$f_{dt} = \dot{\varepsilon}_t (\bar{\sigma}) - \kappa_{dt}$$

$$f_{dt} \leq 0, \quad \dot{\kappa}_{dt} \geq 0, \quad \dot{\kappa}_{dt} f_{dt} = 0$$

$$\omega_t = g_{dt} (\kappa_{dt}, \kappa_{dt1}, \kappa_{dt2})$$

For compression, they are

$$f_{dc} = \alpha_c \dot{\varepsilon}_c (\bar{\sigma}) - \kappa_{dc}$$
\[ f_{dc} \leq 0, \quad \dot{\kappa}_{dc} \geq 0, \quad \dot{\kappa}_{dc} f_{dc} = 0 \]  \hspace{1cm} (10)

\[ \omega_c = g_{de} \left( \kappa_{dc}, \kappa_{dc1}, \kappa_{dc2} \right) \]  \hspace{1cm} (11)

Here, \( f_{dt} \) and \( f_{dc} \) are the loading functions, \( \tilde{\varepsilon}_t(\bar{\sigma}) \) and \( \tilde{\varepsilon}_c(\sigma) \) are the equivalent strains and \( \kappa_{dt}, \kappa_{dt1}, \kappa_{dt2}, \kappa_{dc}, \kappa_{dc1} \) and \( \kappa_{dc2} \) are damage history variables. Furthermore, \( \alpha_c \) is a variable that distinguishes between tensile and compressive loading. A detailed description of the variables is given in Section 2.3.

2.2 Plasticity part

The plasticity part of the model is formulated in a three-dimensional framework with a pressure-sensitive yield surface, hardening and non-associated flow. The main components are the yield function, the flow rule, the hardening law and the evolution law for the hardening variable.

2.2.1 Yield function

The yield surface is described in terms of the cylindrical coordinates in the principal effective stress space (Haigh-Westergaard coordinates), which are the volumetric effective stress

\[ \bar{\sigma}_V = \frac{I_1}{3} \]  \hspace{1cm} (12)
the norm of the deviatoric effective stress

\[ \bar{\rho} = \sqrt{2J_2} \]  \hspace{1cm} (13)

and the Lode angle

\[ \bar{\theta} = \frac{1}{3} \arccos \left( \frac{3\sqrt{3} \ J_3}{2 \ J_2^{3/2}} \right) \]  \hspace{1cm} (14)

The foregoing definitions use the first invariant

\[ I_1 = \bar{\sigma} : \delta = \bar{\sigma}_{ij}\delta_{ij} \]  \hspace{1cm} (15)

of the effective stress tensor \( \bar{\sigma} \), and the second and third invariants

\[ J_2 = \frac{1}{2} \bar{s} : \bar{s} = \frac{1}{2} \bar{s}^2 : \delta = \frac{1}{2} \bar{s}_{ij}\bar{s}_{ij} \]  \hspace{1cm} (16)

\[ J_3 = \frac{1}{3} \bar{s}^3 : \delta = \frac{1}{3} \bar{s}_{ij}\bar{s}_{jk}\bar{s}_{ki} \]  \hspace{1cm} (17)

of the deviatoric effective stress tensor \( \bar{s} = \bar{\sigma} - \delta I_1/3 \).

The yield function

\[
f_p(\bar{\sigma}_V, \bar{\rho}, \bar{\theta}; \kappa_p) = \left\{ \left[ 1 - q_{h1}(\kappa_p) \right] \left( \frac{\bar{\rho}}{\sqrt{6f_c}} + \frac{\bar{\sigma}_V}{f_c} \right)^2 + \sqrt{\frac{3}{2}} \frac{\bar{\rho}}{f_c} \right\}^2 \]

\[ + m_0 q_{h1}^2(\kappa_p) q_{h2}^2(\kappa_p) \left[ \frac{\bar{\rho}}{\sqrt{6f_c}} r(\cos \bar{\theta}) + \frac{\bar{\sigma}_V}{f_c} \right] - q_{h1}^2(\kappa_p) q_{h2}^2(\kappa_p) \]  \hspace{1cm} (18)

depends on the effective stress (which enters in the form of cylindrical coordinates) and on the hardening variable \( \kappa_p \) (which enters through the dimensionless variables \( q_{h1} \) and \( q_{h2} \)).
Parameter $f_c$ is the uniaxial compressive strength. For $q_{h2} = 1$, the yield function is identical to the one of CDPM1.

The meridians of the yield surface $f_p = 0$ are parabolic, and the deviatoric sections change from triangular shapes at low confinement to almost circular shapes at high confinement. The shape of the deviatoric section is controlled by the function

$$r(\cos \bar{\theta}) = \frac{4(1 - e^2) \cos^2 \bar{\theta} + (2e - 1)^2}{2(1 - e^2) \cos \bar{\theta} + (2e - 1) \sqrt{4(1 - e^2) \cos^2 \bar{\theta} + 5e^2 - 4e}}$$

proposed by Willam and Warnke (1974). The calibration of the eccentricity parameter $e$ is described in Jirásek and Bažant (2002) and in section 5. The friction parameter $m_0$ is given by

$$m_0 = \frac{3 (f_c^2 - f_t^2)}{f_c f_t} \frac{e}{e + 1}$$

where $f_t$ is the tensile strength. The shape and evolution of the yield surface is controlled by the variables $q_{h1}$ and $q_{h2}$ (Figs. 1 and 2). If the two variables $q_{h1}$ and $q_{h2}$ in (18) are set equal to one and the resulting yield function is set equal to zero, the failure surface

$$\frac{3 \rho^2}{2 f_c^2} + m_0 \left[ \frac{\rho}{\sqrt{6} f_c} r(\cos \bar{\theta}) + \frac{\bar{\sigma}}{f_c} \right] - 1 = 0$$

is obtained, which was originally proposed by Menétrey and Willam (1995).
Figure 1: The evolution of the meridional section of the yield surface during hardening.

Figure 2: The evolution of the deviatoric section of the yield surface during hardening for a constant volumetric stress of $\bar{\sigma}_V = -f_c/3$. 
2.2.2 Flow rule

In the present model, the flow rule in (4) is non-associated, which means that the yield function \(f_p\) and the plastic potential \(g_p\) do not coincide and, therefore, the direction of the plastic flow \(\partial g_p/\partial \bar{\sigma}\) is not normal to the yield surface. The plastic potential is given as

\[
g_p(\bar{\sigma}_V, \bar{\rho}; \kappa_p) = \left\{ [1 - q_{h1}(\kappa_p)] \left( \frac{\bar{\rho}}{\sqrt{6f_c}} + \frac{\bar{\sigma}_V}{f_c} \right)^2 + \left( \frac{\bar{\sigma}_V}{f_c} \right)^2 \right\} \]

\[+ q_{h1}^2(\kappa_p) \left( \frac{m_0\bar{\rho}}{\sqrt{6f_c}} + \frac{m_g(\bar{\sigma}_V, \kappa_p)}{f_c} \right) \]  

where

\[
m_g(\bar{\sigma}_V, \kappa_p) = A_g(\kappa_p) B_g(\kappa_p) f_c \exp \frac{\bar{\sigma}_V - q_{h2}(\kappa_p) f_t/3}{B_g(\kappa_p) f_c} \]

is a variable controlling the ratio of volumetric and deviatoric plastic flow. Here, \(A_g(\kappa_p)\) and \(B_g(\kappa_p)\), which depend on \(q_{h2}(\kappa_p)\), are derived from assumptions on the plastic flow in uniaxial tension and compression in the post-peak regime.

The derivation of these two variables is illustrated in the following paragraphs. Here, the notation \(m \equiv \frac{\partial g}{\partial \bar{\sigma}}\) is introduced. In the principal stress space, the plastic flow tensor \(m\) has three components, \(m_1, m_2\) and \(m_3\) associated with the three principal stress components. The flow rule (4) is split into a volumetric and a deviatoric part, i.e., the gradient of the plastic potential is decomposed as

\[
m = \frac{\partial g}{\partial \bar{\sigma}} = \frac{\partial g}{\partial \bar{\sigma}_V} \frac{\partial \bar{\sigma}_V}{\partial \bar{\sigma}} + \frac{\partial g}{\partial \bar{\rho}} \frac{\partial \bar{\rho}}{\partial \bar{\sigma}} \]

12
Taking into account that $\partial \bar{\sigma} V / \partial \bar{\sigma} = \delta / 3$ and $\partial \bar{\rho} / \partial \bar{\sigma} = \bar{s} / \bar{\rho}$, restricting attention to the post-peak regime (in which $q_{h1} = 1$) and differentiating the plastic potential (22), we rewrite equation (24) as

$$m = \frac{\partial g}{\partial \bar{\sigma}} = \frac{\partial m_{g}}{\partial \bar{\sigma}V} \frac{\delta}{3f_{c}} + \left( \frac{m_{0}}{\sqrt{6\bar{\rho}}} \right) \frac{\bar{s}}{f_{c}}$$  \hspace{1cm} (25)$$

Experimental results for concrete loaded in uniaxial tension indicate that the strains perpendicular to the loading direction are elastic in the softening regime. Thus, the plastic strain rate in these directions should be equal to zero ($m_{2} = m_{3} = 0$). Under uniaxial tension, the effective stress state in the post-peak regime is characterised by $\bar{\sigma}_{1} = f_{t}q_{h2}$, $\bar{\sigma}_{2} = \bar{\sigma}_{3} = 0$, $\bar{\sigma}_{V} = f_{t}q_{h2}/3$, $\bar{s}_{1} = 2f_{t}q_{h2}/3$, $\bar{s}_{2} = \bar{s}_{3} = -f_{t}q_{h2}/3$ and $\bar{\rho} = \sqrt{2/3}f_{t}q_{h2}$. Substituting this into (25) and enforcing the condition $m_{2} = m_{3} = 0$, we obtain an equation from which

$$\frac{\partial m_{g}}{\partial \bar{\sigma}V} |_{\bar{\sigma}V = f_{t}q_{h2}/3} = \frac{3f_{t}q_{h2}}{f_{c}} + \frac{m_{0}}{2}$$  \hspace{1cm} (26)$$

In uniaxial compressive experiments, a volumetric expansion is observed in the softening regime. Thus, the inelastic lateral strains are positive while the inelastic axial strain is negative. In the present approach, a constant ratio $D_{f} = -m_{2}/m_{1} = -m_{3}/m_{1}$ between lateral and axial plastic strain rates in the softening regime is assumed. The effective stress state at the end of hardening under uniaxial compression is characterised by $\bar{\sigma}_{1} = -f_{c}q_{h2}$, $\bar{\sigma}_{2} = \bar{\sigma}_{3} = 0$, $\bar{\sigma}_{V} = -f_{c}q_{h2}/3$, $\bar{s}_{1} = -2f_{c}q_{h2}/3$, $\bar{s}_{2} = \bar{s}_{3} = f_{c}q_{h2}/3$ and $\bar{\rho} = \sqrt{2/3}f_{c}q_{h2}$. Substituting this into (25) and enforcing the condition $m_{2} = m_{3} = -D_{f}m_{1}$, we get an
Substituting the specific expression for $\partial m_g/\partial \bar{\sigma}_V$ constructed by differentiation of (23) into (26) and (27), we obtain two equations from which parameters

$$A_g = \frac{3f_t q_{h2}}{f_c} + \frac{m_0}{2}$$

(28)

$$B_g = \frac{(q_{h2}/3) (1 + f_t/f_c)}{\ln A_g - \ln (2D_t - 1) - \ln (3q_{h2} + m_0/2) + \ln (D_t + 1)}$$

(29)

can be computed. The gradient of the dilation variable $m_g$ in (23) decreases with increasing confinement. The limit $\bar{\sigma}_V \to -\infty$ corresponds to purely deviatoric flow. As in CDPM1, the plastic potential does not depend on the third Haigh-Westergaard coordinate (Lode angle $\bar{\theta}$), which increases the efficiency of the implementation and the robustness of the model.

2.2.3 Hardening law

The dimensionless variables $q_{h1}$ and $q_{h2}$ that appear in (18), (22) and (23) are functions of the hardening variable $\kappa_p$. They control the evolution of the size and shape of the yield surface and plastic potential. The first hardening law $q_{h1}$ is

$$q_{h1}(\kappa_p) = \begin{cases} 
q_{h0} + (1 - q_{h0}) (\kappa_p^3 - 3\kappa_p^2 + 3\kappa_p) - H_p (\kappa_p^3 - 3\kappa_p^2 + 2\kappa_p) & \text{if } \kappa_p < 1 \\
1 & \text{if } \kappa_p \geq 1
\end{cases}$$

(30)
The second hardening law $q_{h2}$ is given by

$$q_{h2}(\kappa_p) = \begin{cases} 
1 & \text{if } \kappa_p < 1 \\
1 + H_p(\kappa_p - 1) & \text{if } \kappa_p \geq 1
\end{cases} \quad (31)$$

The initial inclination of the hardening curve $q_{h1}$ at $\kappa_p = 0$ is positive and finite, and the inclination of both $q_{h1}$ and $q_{h2}$ at $\kappa_p = 1$ is $H_p$, as depicted in Fig. 3. For $H_p = 0$, the hardening law reduces to the one proposed in Grassl and Jirásek (2006).

### 2.2.4 Hardening variable

The evolution law for the hardening variable,

$$\dot{\kappa}_p = \frac{\|\dot{\varepsilon}_p\|}{x_h(\sigma_V)} (2 \cos \bar{\theta})^2 = \frac{\dot{\lambda}\|m\|}{x_h(\sigma_V)} (2 \cos \bar{\theta})^2 \quad (32)$$
sets the rate of the hardening variable equal to the norm of the plastic strain rate scaled by a hardening ductility measure

\[
x_h(\bar{\sigma}_V) = \begin{cases} 
A_h - (A_h - B_h) \exp \left( -R_h(\bar{\sigma}_V)/C_h \right) & \text{if } R_h(\bar{\sigma}_V) \geq 0 \\
E_h \exp(R_h(\bar{\sigma}_V)/F_h) + D_h & \text{if } R_h(\bar{\sigma}_V) < 0
\end{cases}
\]  

(33)

For pure volumetric stress states, \( \bar{\theta} \) in (32) is set to zero. The dependence of the scaling factor \( x_h \) on the volumetric stress \( \bar{\sigma}_V \) is constructed such that the model response is more ductile under compression. The variable

\[
R_h(\bar{\sigma}_V) = -\bar{\sigma}_V \frac{1}{f_c} - \frac{1}{3}
\]  

(34)

is a linear function of the volumetric effective stress. Model parameters \( A_h, B_h, C_h \) and \( D_h \) are calibrated from the values of strain at peak stress under uniaxial tension, uniaxial compression and triaxial compression, whereas the parameters \( E_h \) and \( F_h \) are determined from the conditions of a smooth transition between the two parts of equation (33) at \( R_h = 0 \):

\[
E_h = B_h - D_h
\]  

(35)

\[
F_h = \frac{(B_h - D_h) C_h}{A_h - B_h}
\]  

(36)

This definition of the hardening variable is identical to the one in CDPM1 described in Grassl and Jirásek (2006), where the calibration procedure of the hardening variables is
Damage part

Damage is initiated when the maximum equivalent strain in the history of the material reaches the threshold $\varepsilon_0 = f_t/E$. For uniaxial tension only, the equivalent strain could be chosen as $\tilde{\varepsilon} = \tilde{\sigma}_t/E$, where $\tilde{\sigma}_t$ is the effective uniaxial tensile stress. Thus, damage initiation would be linked to the axial elastic strain. However, for general triaxial stress states a more advanced equivalent strain expression is required, which predicts damage initiation when the strength envelope is reached. This expression is determined from the yield surface ($f_p = 0$) by setting $q_{h1} = 1$ and $q_{h2} = \tilde{\varepsilon}/\varepsilon_0$. From this quadratic equation for $\tilde{\varepsilon}$, the equivalent strain is determined as

$$\tilde{\varepsilon} = \varepsilon_0 m_0 \left( \frac{\bar{\rho}}{\sqrt{6} f_c} r (\cos \theta) + \frac{\tilde{\sigma}_V}{f_c} \right) + \sqrt{\frac{\varepsilon_0^2 m_0^2}{4} \left( \frac{\bar{\rho}}{\sqrt{6} f_c} r (\cos \theta) + \frac{\tilde{\sigma}_V}{f_c} \right)^2 + \frac{3\varepsilon_0^2 \bar{\rho}^2}{2 f_c^2}} \quad (37)$$

For uniaxial tension, the effective stress state is defined as $\tilde{\sigma}_1 = \tilde{\sigma}_t$, $\tilde{\sigma}_2 = \tilde{\sigma}_3 = 0$, $\tilde{\sigma}_V = \tilde{\sigma}_t/3$, $\tilde{s}_1 = 2\tilde{\sigma}_t/3$, $\tilde{s}_2 = \tilde{s}_3 = -\tilde{\sigma}_t/3$, $\bar{\rho} = \sqrt{2/3} \tilde{\sigma}_t$ and $r(\cos \theta) = 1/e$. Setting this into (37) and using the definition of $m_0$ in (20) gives

$$\tilde{\varepsilon} = \varepsilon_0 \frac{\tilde{\sigma}_t}{f_t} = \tilde{\sigma}_t/E \quad (38)$$

which is suitable equivalent strain for modelling tensile failure. For uniaxial compression, the effective stress state is defined as $\tilde{\sigma}_1 = -\tilde{\sigma}_c$, $\tilde{\sigma}_2 = \tilde{\sigma}_3 = 0$, $\tilde{\sigma}_V = -\tilde{\sigma}_c/3$, $\tilde{s}_1 = -2/3 \tilde{\sigma}_c$, $\tilde{s}_2 = \tilde{s}_3 = -\tilde{\sigma}_c/3$, $\bar{\rho} = \sqrt{2/3} \tilde{\sigma}_c$ and $r(\cos \theta) = 1/e$. Setting this into (37) and using the definition of $m_0$ in (20) gives

$$\tilde{\varepsilon} = \varepsilon_0 \frac{\tilde{\sigma}_c}{f_c} = \tilde{\sigma}_c/E \quad (39)$$
\[ \bar{s}_2 = \bar{s}_3 = \frac{1}{3} \bar{\sigma}_c, \quad \bar{\rho} = \sqrt{\frac{2}{3} \bar{\sigma}_c}, \quad \text{and} \quad r(\cos \theta) = 1. \] Here, \( \bar{\sigma}_c \) is the magnitude of the effective compressive stress. Setting this into (37), the equivalent strain is

\[ \tilde{\varepsilon} = \frac{\bar{\sigma}_c \varepsilon_0}{f_c} = \frac{\bar{\sigma}_c f_t}{E f_c} \tag{39} \]

If \( \bar{\sigma}_c = (f_c/f_t) \bar{\sigma}_t \), the equivalent strain is again equal to the axial elastic strain component in uniaxial tension. Consequently, the equivalent strain definition in (37) is suitable for both tension and compression, which is very convenient for relating the damage variables in tension and compression to inelastic stress-strain curves.

The damage variables \( \omega_t \) and \( \omega_c \) in (1) are determined so that a prescribed stress-inelastic strain relation in uniaxial tension is obtained. Since, the damage variables are evaluated for general triaxial stress states, the inelastic strain in uniaxial tension has to be expressed by suitable scalar history variables, which are obtained from total and plastic strain components. To illustrate the choice of these components, a 1D damage-plastic stress-strain law of the form

\[ \sigma = (1 - \omega) \bar{\sigma} = (1 - \omega) E (\varepsilon - \varepsilon_p) \tag{40} \]

is considered. Here, \( \omega \) is the damage variable. This law can also be written as

\[ \sigma = E \{\varepsilon - [\varepsilon_p + \omega (\varepsilon - \varepsilon_p)]\} = E (\varepsilon - \varepsilon_i) \tag{41} \]

where \( \varepsilon_i \) is the inelastic strain which is subtracted from the total strain. The geometrical interpretation of the inelastic strain and its split for monotonic uniaxial tension, linear
Figure 4: Geometrical meaning of the inelastic strain $\varepsilon_i$ for the combined damage-plasticity model. The inelastic strain is composed of reversible $\omega (\varepsilon - \varepsilon_p)$ and irreversible $\varepsilon_p$ parts. The dashed lines represent elastic unloading with the same stiffness as the initial elastic loading.

Hardening plasticity and linear damage evolution are shown in Fig. 4. Furthermore, the way how the hardening influences damage and plasticity dissipation has been discussed in Grassl (2009). The part $\omega (\varepsilon - \varepsilon_p)$ is reversible and $\varepsilon_p$ is irreversible. The damage variable is chosen, so that a softening law is obtained, which relates the stress to the inelastic strain, which is written here in generic form as

$$\sigma = f_s (\varepsilon_i)$$  \hspace{1cm} (42)

Setting (41) equal with (42) allows for determining the damage variable $\omega$. 

19
However, the inelastic strain $\varepsilon_i$ in (41) and (42) needs to be expressed by history variables, so that the expression for the damage variable can be used for non-monotonic loading. Furthermore, to be able to describe also the influence of multiaxial stress states on the damage evolution, the inelastic strain in (42) is replaced by different history variables than the inelastic strain in (41). The choice of the history variables for tension and compression is explained in sections 2.3.1 and 2.3.2.

### 2.3.1 History variables for tension

The tensile damage variable $\omega_t$ in (1) is defined by three history variables $\kappa_{dt}$, $\kappa_{dt1}$ and $\kappa_{dt2}$. The variable $\kappa_{dt}$ is used in the definition of the inelastic strain in (41), while $\kappa_{dt1}$ and $\kappa_{dt2}$ enter the definition of the inelastic strain in (42). The history variable $\kappa_{dt}$ is determined from $\tilde{\varepsilon}_t$ using (6) and (7). Here, $\tilde{\varepsilon}_t$ is given implicitly in incremental form by

$$\dot{\tilde{\varepsilon}}_t = \dot{\varepsilon}$$  \hspace{1cm} (43)

with $\varepsilon$ given in (37). For $\kappa_{dt1}$, the inelastic strain component related the plastic strain $\varepsilon_p$ is replaced by

$$\dot{\kappa}_{dt1} = \begin{cases} \frac{1}{x_s} \|\dot{\varepsilon}_p\| & \text{if } \dot{\kappa}_{dt} > 0 \text{ and } \kappa_{dt} > \varepsilon_0 \\ 0 & \text{if } \dot{\kappa}_{dt} = 0 \text{ or } \kappa_{dt} < \varepsilon_0 \end{cases}$$  \hspace{1cm} (44)
Here, the pre-peak plastic strains do not contribute to this history variable, since $\dot{\kappa}_{dt1}$ is only nonzero, if $\kappa_{dt} > \varepsilon_0$. Finally, the third history variable is related to $\kappa_{dt}$ as

$$\dot{\kappa}_{dt2} = \frac{\kappa_{dt}}{x_s}$$  \hspace{1cm} (45)

In (44) and (45), $x_s$ is a ductility measure, which describes the influence of multiaxial stress states on the softening response, see Sec. 2.3.4.

### 2.3.2 History variables for compression

The compression damage variable $\omega_c$ is also defined by three history variables $\kappa_{dc}$, $\kappa_{dc1}$ and $\kappa_{dc2}$. Analogous to the tensile case, the variable $\kappa_{dc}$ is used in the definition of the inelastic strain in (41), while $\kappa_{dc1}$ and $\kappa_{dc2}$ enter the definition of the equivalent strain in (42). In addition, a variable $\alpha_c$ is introduced which distinguishes tensile and compressive stresses. It has the form

$$\alpha_c = \frac{\sum_{i=1}^{3} \bar{\sigma}_{pci} (\bar{\sigma}_{pti} + \bar{\sigma}_{pci})}{\| \bar{\sigma}_p \|^2}$$  \hspace{1cm} (46)

where $\bar{\sigma}_{pti}$ and $\bar{\sigma}_{pci}$ are the components of the compressive and tensile part of the principal effective stresses, respectively, which were previously used for the general stress strain law in (1). The variable $\alpha_c$ varies from 0 for pure tension to 1 for pure compression. For instance, for the mixed tensile compressive effective stress state $\bar{\sigma}_p = \{-\bar{\sigma}, 0.2\bar{\sigma}, 0.1\bar{\sigma}\}$, considered in Sec. 2.1, the variable is $\alpha_c = 0.95$.

The history variable $\kappa_{dc}$ is determined from $\ddot{\varepsilon}_c$ using (9) and (10), where, analogous to
the tensile case, the $\varepsilon_c$ is specified implicitly by

$$\dot{\varepsilon}_c = \alpha_c \dot{\varepsilon}$$

(47)

The other two history variables are

$$\dot{\kappa}_d c_1 = \begin{cases} \frac{\alpha_c \beta_c}{x_s} \|\dot{\varepsilon}_p\| & \text{if } \kappa_{dt} > 0 \land \kappa_{dt} > \varepsilon_0 \\ 0 & \text{if } \kappa_{dt} = 0 \lor \kappa_{dt} < \varepsilon_0 \end{cases}$$

(48)

and

$$\dot{\kappa}_d c_2 = \frac{\dot{k}_{dc}}{x_s}$$

(49)

In (48), the factor $\beta_c$ is

$$\beta_c = \frac{f \sigma h_2 \sqrt{2/3}}{\bar{\rho} \sqrt{1 + 2D_i^2}}$$

(50)

This factor provides a smooth transition from pure damage to damage-plasticity softening processes, which can occur during cyclic loading, as described in section 2.3.5.

### 2.3.3 Damage variables for bilinear softening

With the history variables defined in the previous two sections, the damage variables for tension and compression are determined. The form of these damage variables depends on the type of softening law considered. For bilinear softening used in the present study, the
stress versus inelastic strain in the softening regime is

$$
\sigma = \begin{cases} 
  f_t - \frac{f_t - \sigma_1}{\varepsilon_{f1}} \varepsilon_i & \text{if } 0 < \varepsilon_i \leq \varepsilon_{f1} \\
  \sigma_1 - \frac{\sigma_1}{\varepsilon_f - \varepsilon_{f1}} (\varepsilon_i - \varepsilon_{f1}) & \text{if } \varepsilon_{f1} < \varepsilon_i \leq \varepsilon_f \\
  0 & \text{if } \varepsilon_f \leq \varepsilon_i 
\end{cases} \quad (51)
$$

where $\varepsilon_f$ is the inelastic strain threshold at which the uniaxial stress is equal to zero and $\varepsilon_{f1}$ is the threshold where the uniaxial stress is equal to $\sigma_1$ as shown in Fig. 5. Furthermore, $\varepsilon_1$ is the inelastic strain in the post-peak regime only. Since damage is irreversible, the inelastic strain $\varepsilon_1$ in (51) is expressed by irreversible damage history variables as

$$
\varepsilon_1 = \kappa_{dt1} + \omega_t \kappa_{dt2} \quad (52)
$$

Furthermore, the term $\varepsilon - \varepsilon_p$ in (40) is replaced by $\kappa_{dt}$, which gives

$$
\sigma = (1 - \omega_t) E \kappa_{dt} \quad (53)
$$
Setting (51) with (52) equal to (53), and solving for $\omega_t$ gives

$$\omega_t = \begin{cases} 
\frac{(E\kappa_{dt} - f_t)\varepsilon_{fi} - (\sigma_1 - f_t)\kappa_{dt1}}{E\kappa_{dt}\varepsilon_{fi} + (\sigma_1 - f_t)\kappa_{dt2}} & \text{if } 0 < \varepsilon_i \leq \varepsilon_{fi} \\
\frac{E\kappa_{dt} (\varepsilon_f - \varepsilon_{fi}) + \sigma_1 (\kappa_{dt1} - \varepsilon_i)}{E\kappa_{dt} (\varepsilon_f - \varepsilon_{fi}) - \sigma_1 \kappa_{dt2}} & \text{if } \varepsilon_{fi} < \varepsilon_i \leq \varepsilon_f \\
0 & \text{if } \varepsilon_f < \varepsilon_i 
\end{cases} \tag{54}$$

For the compressive damage variable, an evolution based on an exponential stress-inelastic strain law is used. The stress versus inelastic strain in the softening regime in compression is

$$\sigma = f_t \exp \left( -\frac{\varepsilon_i}{\varepsilon_{fc}} \right) \text{ if } 0 < \varepsilon_i \tag{55}$$

where $\varepsilon_{fc}$ is an inelastic strain threshold which controls the initial inclination of the softening curve. The use of different damage evolution for tension and compression is one important improvement over CDPM1 as it will shown later on when the structural applications are discussed.

### 2.3.4 Ductility measure

The history variables $\kappa_{dt1}$, $\kappa_{dt2}$, $\kappa_{dc1}$ and $\kappa_{dc2}$ in (44), (45), (48) and (49), respectively, depend on a ductility measure $x_s$, which takes into account the influence of multiaxial stress states on the damage evolution. This ductility measure is given by

$$x_s = 1 + (A_s - 1) R_s \tag{56}$$
where $R_s$ is

$$R_s = \begin{cases} 
-\frac{\sqrt{6}\bar{\sigma}_V}{\bar{\rho}} & \text{if } \bar{\sigma}_V \leq 0 \\
0 & \text{if } \bar{\sigma}_V > 0 
\end{cases} \quad (57)$$

and $A_s$ is a model parameter. For uniaxial compression $\bar{\sigma}_V/\bar{\rho} = -1/\sqrt{6}$, so that $R_s = 1$ and $x_s = A_s$, which simplifies the calibration of the softening response in this case.

### 2.3.5 Constitutive response to cyclic loading

The response of the constitutive model is illustrated by a quasi-static strain cycle (Fig. 6, solid line), before it is compared to a wide range of experimental results in the next section. The strain is increased from point 0 to point 1, where the tensile strength of the material is reached. Up to point 1, the material response is elastic-plastic with small plastic strains. With a further increase of the strain from point 1 to point 2, the effective stress part continues to increase, since $H_p > 0$, whereas the nominal stress decreases, since the tensile damage variable $\omega_t$ increases. A reverse of the strain at point 2 results in a reduction of the stress with an unloading stiffness, which is less than the elastic stiffness of an elasto-plastic model, but greater than the stiffness of an elasto-damage mechanics model, i.e. greater than the secant stiffness. At point 3, when the stress is equal to zero, a further reduction of the strain leads to a compressive response following a linear stress-strain relationship between the points 3 and 4 with the original Young’s modulus $E$ of the undamaged material. This change of stiffness is obtained by using two damage variables, $\omega_t$ and $\omega_c$. At point 3, $\omega_t > 0$, but $\omega_c = 0$. Up to point 5, no further plastic strains are generated, since the hardening from point 0 to 2 has increased the elastic
domain of the plasticity part, so that the yield surface is not reached. Thus, the softening from point 4 to 5 is only described by damage. Only at point 5, the plasticity surface is reached and a subsequent increase of strain results in hardening of the plasticity part, which corresponds to an increase of the effective stress. However, the nominal stress, shown in Fig. 6, decreases, since \( \omega_c \) increases. The continuous slopes of parts 4-5 and 5-6 are obtained, since the additional factor \( \beta_c \) in (48) is introduced. A second reversal of the strain direction (point 6) changes the stress from compression to tension at point 7, which is again associated with a change of the stiffness. The above response is very different from the one obtained with CDPM1 with only one damage parameter, which is also shown in Fig. 6 by a dashed line. With CDPM1, the compressive response after point 3 is characterised by both a reduced stiffness and strength which would depend on the amount of damage accumulated in tension. For the case of damage equal to 1 in tension, both the strength and stiffness in compression would be zero, which is not realistic for the tension-compression transition in concrete.

3 Mesh adjusted softening modulus

If the constitutive model described in the previous sections is straightaway used within the finite element method, the amount of dissipated energy might be strongly mesh-dependent. This mesh-dependence is caused by deformations in mesh-size dependent zones. The finer the mesh, the less energy would be dissipated. This is a well known limitation of constitutive laws with strain softening. One way to overcome this mesh-
dependence is to adjust the softening modulus with respect to the element size. For the present model, this approach is applied for the tensile damage variable by replacing in the tensile damage law in (54) the strain thresholds $\varepsilon_{f1}$ and $\varepsilon_f$ with $w_{f1}/h$ and $w_f/h$, respectively. Here, $w_{f1}$ and $w_f$ are displacement thresholds and $h$ is the finite element size. Thus, with this approach the damage variables for bilinear softening are

$$
\omega_t = \begin{cases} 
\frac{(E\kappa_{dt} - f_t)w_{f1} - (\sigma_1 - f_t)\kappa_{dt1}h}{E\kappa_{dt}w_{f1} + (\sigma_1 - f_t)\kappa_{dt2}h} & \text{if } 0 < h\varepsilon_i \leq w_{f1}h \\
\frac{E\kappa_{dt}(w_t - w_{f1}) + \sigma_1(\kappa_{dt1}h - w_t)}{E\kappa_{dt}(w_t - w_{f1}) - \sigma_1\kappa_{dt2}h} & \text{if } w_{f1} < h\varepsilon_i \leq w_t \\
0 & \text{if } w_t < h\varepsilon_i 
\end{cases}
$$

These expressions are used when the constitutive model is compared to experimental results in the next section. However, the evolution law for compressive damage is independent of the element size, as compressive failure is often accompanied by mesh-independent
zones of localised displacements.

4 Implementation

The present constitutive model has been implemented within the framework of the nonlinear finite element method, where the continuous loading process is replaced by incremental time steps. In each step the boundary value problem (global level) and the integration of the constitutive laws (local level) are solved.

For the boundary value problem on the global level, the usual incremental-iterative solution strategy is used, in the form of a modified Newton-Raphson iteration method. For the local problem, the updated values \((\cdot)^{(n+1)}\) of the stress and the internal variables at the end of the step are obtained by a fully implicit (backward Euler) integration of the rate form of the constitutive equations, starting from their known values \((\cdot)^{(n)}\) at the beginning of the step and applying the given strain increment \(\Delta \varepsilon = \varepsilon^{(n+1)} - \varepsilon^{(n)}\). The integration scheme is divided into two sequential steps, corresponding to the plastic and damage parts of the model. In the plastic part, the plastic strain \(\varepsilon_p\) and the effective stress \(\bar{\sigma}\) at the end of the step are determined. In the damage part, the damage variables \(\omega_t\) and \(\omega_c\), and the nominal stress \(\sigma\) at the end of the step are obtained. The implementation strategy for the local problem, described in detail in Grassl and Jirásek (2006) for CDPM1, applies to the present model as well. To improve the robustness of the model, a subincerelementation scheme is employed for the integration of the plasticity part.
5 Comparison with experimental results

In this section, the model response is compared to five groups of experiments reported in
the literature. For each group of experiments, the physical constants Young’s modulus $E$,
Poisson’s ratio $\nu$, tensile strength $f_t$, compressive strength $f_c$ and tensile fracture energy
$G_{Ft}$ are adjusted to obtain a fit for the different types of concrete used in the experiments.
The first four constants are model parameters. The last physical constant, $G_{Ft}$, is directly
related to model parameters. For the bilinear softening law in section 2.3.3, the tensile
fracture energy is

$$G_{Ft} = f_t w_{t1}/2 + \sigma_1 w_t/2$$

(59)

For $\sigma_1/f_t = 0.3$ and $w_{t1}/w_t = 0.15$ (shown by Jirásek and Zimmermann (1998) to result
in a good fit for concrete failure), the expression for the fracture energy reduces to $G_{Ft} =
f_t w_t/4.444$. The compressive energy is $G_{Fc} = f_c \varepsilon_c l_c A_s$, where $l_c$ is the length in which
the compressive displacement are assumed to localise and $A_s$ is the ductility measure in
Sec. 2.3.4. If no experimental results are available, the five constants can be determined
using, for instance, the CEB-FIP Model Code (CEB, 1991).

The other model parameters are set to their default values for all groups. The eccentricity
constant $e$ that controls the shape of the deviatoric section is evaluated using the formula
in Jirásek and Bažant (2002), p. 365:

$$e = \frac{1 + \epsilon}{2 - \epsilon}, \text{ where } \epsilon = \frac{f_t f_{bc}^2 - f_c^2}{f_{bc} f_c^2 - f_t^2}$$

(60)
where \( f_{bc} \) is the strength in equibiaxial compression, which is estimated as \( f_{bc} = 1.16 f_c \) according to the experimental results reported in Kupfer et al. (1969). Parameter \( q_{h0} \) is the dimensionless ratio \( q_{h0} = \frac{\bar{f}_c}{f_c} \), where \( f_c \) is the compressive stress at which the initial yield limit is reached in the plasticity model for uniaxial compression. Its default value is \( q_{h0} = 0.3 \). For the hardening modulus the default value is \( H_p = 0.01 \). Furthermore, the default value of the parameter of the flow rule is chosen as \( D_f = 0.85 \), which yields a good agreement with experimental results in uniaxial compression. The determination of parameters \( A_h, B_h, C_h \) and \( D_h \) that influence the hardening ductility measure is more difficult. The effective stress varies within the hardening regime, even for monotonic loading, so that the ratio of axial and lateral plastic strain rate is not constant. Thus, an exact relation of all four model parameters to measurable material properties cannot be constructed. In Grassl and Jirásek (2006), it has been shown that a reasonable response is obtained with parameters \( A_h = 0.08, B_h = 0.003, C_h = 2 \) and \( D_h = 1 \times 10^{-6} \). These values were also used in the present study. Furthermore, the element size \( h \) in the damage laws in Section 3 was chosen as \( h = 0.1 \) m.

The first analysis is a uniaxial tensile setup with unloading. The model response is compared to the experimental results reported in Gopalaratnam and Shah (1985) (Fig. 7). The relevant model parameters for this experiment are \( E = 28 \) GPa, \( \nu = 0.2 \), \( f_c = 40 \) MPa, \( f_t = 3.5 \) MPa, \( G_{Ft} = 55 \) J/m\(^2\).

The next example is an uniaxial compression test with unloading, for which the model response is compared to experimental results reported in Karsan and Jirsa (1969) (Fig. 8). The model parameters are \( E = 30 \) GPa, \( \nu = 0.2 \), \( f_c = 28 \) MPa, \( f_t = 2.8 \) MPa. Further-
Figure 7: Uniaxial tension: Model response compared to experimental results in Gopalaratnam and Shah (1985).

more, the model constants for compression are $A_s = 5$ and $\varepsilon_{fc} = 0.0001$. The value of the tensile fracture energy $G_{Ft}$ does not influence the model response in compression, which also applies to all other compression tests considered in the following paragraphs. Therefore, only the compressive fracture energy is stated.

Next, the model is compared to uniaxial and biaxial compression tests reported in Kupfer et al. (1969). For these experiments, the model parameters are set to $E = 32$ GPa, $\nu = 0.2$, $f_c = 32.8$ MPa, $f_t = 3.3$ MPa. Furthermore, the model constants for compression are $A_s = 1.5$ and $\varepsilon_{fc} = 0.0001$. The comparison with experimental results is shown in Fig. 9 for uniaxial, equibiaxial and biaxial compression. For the biaxial compression case, the stress ratio of the two compressive stress components is $\sigma_1/\sigma_2 = -1/ -0.5$.

Furthermore, the performance of the model is evaluated for triaxial tests reported in Caner and Bažant (2000). The material parameters for this test are $E = 25$ GPa, $\nu = 0.2$,
Figure 8: Uniaxial compression: Model response compared to experimental results reported in Karsan and Jirsa (1969).

Figure 9: Uniaxial and biaxial compression: Model response compared to experimental results reported in Kupfer et al. (1969).

\[ f_c = 45.7 \text{ MPa}, \quad f_t = 4.57 \text{ MPa}. \]  

Furthermore, the model constants for compression are \( A_s = 15 \) and \( \varepsilon_{fc} = 0.0001 \). The model response is compared to experimental results presented in Figs. 10.
Figure 10: Confined compression: Model response compared to experiments used in Caner and Bažant (2000).

Next, the model response in triaxial compression is compared to the experimental results reported in Imran and Pantazopoulou (1996). The material parameters for this test are $E = 30$ GPa, $\nu = 0.2$, $f_c = 47.4$ MPa, $f_t = 4.74$ MPa. Furthermore, the model constants for compression are $A_s = 15$ and $\varepsilon_{fc} = 0.0001$.

Finally, the model response in hydrostatic compression is compared to the experimental results reported in Caner and Bažant (2000). The material parameters are the same as for the triaxial test shown in Fig. 10.

Overall, the agreement of the model response with the experimental results is very good. The model is able to represent the strength of concrete in tension and multiaxial compression. In addition, the strains at maximum stress in tension and compression agree well with the experimental results. The bilinear stress-crack opening curve that was used results in a good approximation of the softening curve in uniaxial tension and compres-
Figure 11: Confined compression: Model response compared to experiments reported in Imran and Pantazopoulou (1996).

Figure 12: Hydrostatic compression: Model response compared to experiments reported in Caner and Bažant (2000).

With the above comparisons, it is demonstrated that CDPM2, provides, similar to CDPM1, a very good agreement with experimental results.
6 Structural analysis

The performance of the proposed constitutive model is further evaluated by structural analysis of three fracture tests. The main objective of this part of the study is to demonstrate that the structural response obtained with the model is mesh-independent. For constitutive models with softening stress-strain laws, it is known that mesh-dependent load-displacement curves might be obtained. This mesh-dependence is expected especially for tests in which tensile cracking is dominant. In these tests, the inelastic strains localise in mesh-size dependent regions. One way to avoid this mesh-dependence is to adjust the softening modulus to the mesh size. This technique is often called crack band approach and is described for the present model in section 3.

6.1 Three point bending test

The first structural example is a three-point bending test of a single-edge notched beam reported by Kormeling and Reinhardt (1982). The experiment is modelled by triangular plane strain finite elements with three mesh sizes. The geometry and loading set up is shown in Fig. 13. The input parameters are chosen as $E = 20$ GPa, $\nu = 0.2$, $f_t = 2.4$ MPa, $G_R = 100$ N/m, $f_c = 24$ MPa (Grassl and Jirásek, 2006). All other parameters are set to their default values described in section 5. For this type of analysis, local stress-strain relations with strain softening are known to result in mesh-dependent load-displacement curves. The capability of the adjustment of the softening modulus approach presented in section 3 to overcome this mesh-dependence is assessed with this test. The global response
Figure 13: Three point bending test: Geometry and loading setup. The out-of-plane thickness is 0.1 m. The notch thickness is 5 mm.

in the form of load-Crack Mouth Opening Displacement (CMOD) is shown in Fig. 14. The local response in the form of tensile damage patterns at loading stages marked in

![Graph showing load-CMOD curves for three mesh sizes and experimental bounds.](image)

Figure 14: Load-CMOD curves of analyses with three mesh sizes compared to the experimental bounds reported in Kormeling and Reinhardt (1982).

Fig. 14 for the three meshes is shown in Fig. 15.

Overall, the load-CMOD curves in Fig. 14 are in good agreement with the experimental results and almost mesh independent. On the other hand, the damage zones in Fig. 15 depend on the mesh size.
Figure 15: Tensile damage patterns for the coarse, medium and fine mesh for the three point bending test. Black indicates a tensile damage variable of 1.

### 6.2 Four point shear test

The second structural example is a four point shear test of a single-edge notched beam reported in Arrea and Ingraffea (1982). Again, the experiment is modelled by triangular plane strain finite elements with three different mesh sizes. The geometry and loading setup are shown in Fig. 16. The input parameters are chosen as $E = 30$ GPa, $\nu = 0.18$, $f_t = 3.5$ MPa, $G_{ft} = 140$ N/m, $f_c = 35$ MPa (Jirásek and Grassl, 2008). All other parameters are set to their default values described in section 5. The global responses of analyses and experimental results are compared in the form of load-Crack Mouth Sliding Displacement (CMSD) curves in Fig. 17. Furthermore, the damage patterns for the

![Four point shear test](image)

Figure 16: Four point shear test: Geometry and loading setup. The out-of-plane thickness is 0.15 m. A zero notch thickness is assumed.
Figure 17: Load-CMSD curves of analyses with three mesh sizes compared to the experimental bounds reported in Arrea and Ingraffea (1982).

The three meshes at loading stages marked in Fig. 17 are compared to the experimental crack patterns in Fig. 18.

Figure 18: Four point shear test: Tensile damage patterns for the coarse, medium and fine mesh compared to the experimental crack patterns reported in Arrea and Ingraffea (1982). Black indicates a tensile damage variable of 1.

The load-CMSD curves obtained with the three meshes are in good agreement with the experimental results. The coarse mesh overestimates the load levels obtained with the medium and fine mesh. However, the two finer meshes are in good agreement. Again, the width of the damaged zone depends on the element size. Furthermore, the damage zones
are influenced by the mesh orientation. In particular, for the fine mesh the damage zone follows the regular element arrangement, so that the crack is less curved than reported in the experiments. This is a well known behaviour of models using the adjustment of the softening modulus approach, which has been studied in more detail in Jirásek and Grassl (2008); Grassl and Rempling (2007).

6.3 Eccentric compression test

The third structural example studies the failure of a concrete prism subjected to eccentric compression, tested by Debernardi and Taliano (2001). The geometry and loading setup are shown in Figure 19a. The specimen with a relatively great eccentricity of 36.8 mm is modeled by a thin layer of linear 3D elements to reduce the computational time compared to a full 3D analysis. Three different mesh sizes with element lengths of 7.5, 5 and 2.5 mm were chosen (see Figure 19b for the coarse mesh).

The model parameters were set to $E = 30$ GPa, $\nu = 0.2$, $f_t = 4$ MPa, $f_c = 46$ MPa, $G_{Ft} = 100$ N/m, $A_s = 10$ and $\varepsilon_{fc} = 0.0001$. The model response in terms of the overall load versus the mean compressive strain of the compressed side obtained on the fine mesh is compared to the experimental result in Figure 20. The load capacity and the strain at peak are underestimated by the model. The overall behaviour, however, is captured well. The comparison of the load-compressive strain relations for the analyses run on meshes of different sizes indicates that the description of this type of compressive failure is nearly mesh-independent. The evolution of the damage zone for the analysis on the coarse mesh
Figure 19: a) Geometry and loading setup of the eccentric compression test. b) The coarse finite element mesh.

Figure 20: Comparison of the analysis of the eccentric compression test with the experiment.
Figure 21: Contour plots of the damage variable for the a) coarse, b) medium and c) fine mesh of the eccentric compression test.

is depicted in Figure 21 for the final stage of the analyses in Figure 20). On the tensile side several zones of localized damage form, whereas the failure on the compressive side is described by a diffuse damage zone.

7 Conclusions

The present damage plasticity model CDPM2, which combines a stress-based plasticity part with a strain based damage mechanics model, is based on an enhancement of an already exisiting damage-plasticity model called CDPM1 (Grassl and Jirásek (2006)). Based on the work presented in this manuscript, the following conclusions can be drawn on the improvements that this constitutive model provides:
1. The model is able to model realistically the transition from tensile to compressive failure. This is achieved by the introduction of two separate isotropic damage variables for tension and compression.

2. The model is able to reproduce stress inelastic strain relations with varying ratios of reversible and irreversible strain components. The ratio can be controlled by the hardening modulus of the plasticity part.

3. The model reproduces mesh-independent load-displacement curves for both tensile and compressive failure.

In addition, the model response is in good agreement with experimental results for a wide range of loading from uniaxial tension to confined compression.

**Acknowledgements**

This work have been performed partially within the project “Dynamic behaviour of reinforced concrete structures subjected to blast and fragment impacts”, which in turn is financially sponsored by MSB - the Swedish Civil Contigencies Agency. The first author would also like to thank Prof. Bohem Patzák of the Czech Technical University for kind assistance with his finite element package OOFEM (Patzák, 1999; Patzák and Bittnar, 2001).
