A population of monocytes, known as Ly6C\textsuperscript{lo} monocytes, patrol blood vessels by crawling along the vascular endothelium. Here we show that endothelial cells control their origin through Notch signalling. Using combinations of conditional genetic deletion strategies and cell-fate tracking experiments we show that Notch2 regulates conversion of Ly6C\textsuperscript{hi} monocytes into Ly6C\textsuperscript{lo} monocytes \textit{in vivo} and \textit{in vitro}, thereby regulating monocyte cell fate under steady-state conditions. This process is controlled by Notch ligand delta-like 1 (Dll1) expressed by a population of endothelial cells that constitute distinct vascular niches in the bone marrow and spleen \textit{in vivo}, while culture on recombinant DLL1 induces monocyte conversion \textit{in vitro}. Thus, blood vessels regulate monocyte conversion, a form of committed myeloid cell fate regulation.

Monocytes are myeloid leukocytes that circulate through blood vessels and patrol the vascular endothelium or differentiate into mononuclear phagocytes. Mouse monocytes consist of two distinct subsets that differ in behaviour and function, which can be discriminated by expression of the Ly6C antigen and Cx3CR1 chemokine receptor in combination with additional surface markers. So called classical or Ly6Chi monocytes are characterized by Ly6C^hiCX3CR1^hi and constitute the more prevalent subset. They develop from the recently identified common monocyte progenitor (cMoP)^5,6. Under steady-state conditions, Ly6Chi monocytes circulate in the blood for short periods of time and are the definitive precursors of certain tissue-resident mononuclear phagocytes, for example in the gut, skin and spleen. When recruited to sites of inflammation through interaction with subsets of activated vascular endothelial cells (ECs), Ly6Chi monocytes give rise to macrophages and dendritic cells, producing inflammatory mediators and orchestrating the inflammatory response. Based on functional and genetic expression studies, these monocytes correspond to a subset of ‘classical’ human monocytes.

There is a second subtype of monocytes that interacts closely and constitutively with blood vessels. They display a Ly6C^loCX3CR1^hi signature and hence are called Ly6Clo monocytes. In the steady-state, Ly6Clo monocytes are long-lived and remain mostly within blood vessels, where they crawl along the luminal side of EC to monitor blood vessels and scavenge microparticles, a feature shared with the human CD16^lo monocytes. After endothelial injury in the kidney, Ly6Clo monocytes orchestrate EC necrosis and clearance. Moreover, Ly6Clo monocytes also mediate IgG-dependent effector functions and are involved in immune complex-mediated disease. Ly6Clo monocytes were also suggested to contribute to ischemic tissue repair.

The cellular and molecular context of Ly6C^lo monocyte development is far from clear. Mice deficient for the transcription factor Nur77 (Nr4a1), an orphan nuclear receptor, show reduced frequency and survival of Ly6C^lo monocytes. Recent findings further suggest that in the steady state, Ly6C^lo monocytes develop from Ly6C^hi monocytes. Grafted MDP and cMoP sequentially give rise to Ly6C^hi monocytes followed by Ly6C^lo monocytes. After adoptive transfer of Ly6C^hi monocytes, Ly6C^lo monocytes are detected in the blood and bone marrow (BM) of recipients, suggesting that Ly6C^hi monocytes convert to Ly6C^lo monocytes in the circulation. However, the tissues and molecular events regulating monocyte conversion are unknown.

Notch signalling is a cell to cell contact-dependent signalling pathway regulating cell fate decisions and inflammatory responses in the immune system. Activation of Notch receptors (Notch1–4 in mammals) is controlled by membrane-bound Notch ligands of the jagged (Jag) and Delta-like (Dll) gene families, which show different Notch receptor binding affinities and tissue expression patterns, thereby controlling specific Notch signalling outcomes. The cellular interactions required for Notch signalling often occur in local tissue microenvironments, or niche, in the BM and spleen. Vascular EC are a specialized component of the niche that maintain and regulate stem cells and their immune cell progeny by providing instructive paracrine cues, known as angiocrine factors, in part through expression of Notch ligands. In the BM niche ECs trigger self-renewal and repopulation of progenitor cells through Notch ligand Jag1 activating Notch1/Notch2 receptors in stem cells. Similarly, expansion and aggressiveness of B-cell lymphomas is induced by an angiocrine mechanism involving endothelial Jag1 activating Notch2 in malignant lymphoma cells. Specialized vascular niches are also found in secondary lymphoid organs, such as the marginal zone (MZ) of the spleen, which constitutes an EC interface between lymphoid follicles and the red pulp. Development of MZ B cells and Esam^hi dendritic cell in the splenic niche is dependent on Notch ligand delta-like 1 (Dll1)-Notch2 signalling. Monocytes, which are resident in BM and spleen, express Notch1 and Notch2, and their cell fate is influenced by Dll1 in vitro.

Because of the intricate relationship of Ly6C^lo monocytes with EC we reasoned that blood vessels might be involved in monocyte conversion through a Notch-dependent mechanism. We here show that Notch2 signalling regulates conversion of Ly6C^hi monocytes into Ly6C^lo monocytes, which is controlled by Notch ligand Dll1 expressed by a population of EC present in haematopoietic niches of the BM and spleen. Thus, blood vessels regulate monocyte conversion, a form of committed myeloid cell fate regulation.

**Results**

**Monocyte populations and lineage relationships.** Our aim was to study the regulation of Ly6C^lo monocytes. To discriminate monocyte subsets and monocyte progenitor populations in mice we concurrently characterized MDP, cMoP, Ly6C^hi and Ly6C^lo monocytes in BM, spleen and peripheral blood (PB) with common and discriminating markers of monocyte types based on known expression profiles. This approach was tested in Cx3cr1^GFP^ reporter mice, in which monocyte subsets express distinct intensities of green fluorescent protein (GFP), but also in wild-type mice (Fig. 1a, Supplementary Fig. 1a,b and Supplementary Table 1). In addition, monocyte subpopulations were also validated in Nrg4a1-GFP reporter mice, which demonstrated selective GFP expression in Ly6C^lo monocytes (Supplementary Fig. 2a,b). These studies confirmed the proto-typical flow cytometry and gene expression profiles reported for Ly6C^hi and Ly6C^lo monocytes (Fig. 1b,c). Ly6C^lo monocytes are reported to derive from Ly6C^hi monocytes under steady-state conditions, based on characteristic changes of two markers, CX3CR1 and Ly6C, observed after adoptive transfer of Ly6C^hi monocytes. To confirm and extend these findings we performed adoptive transfer studies with Ly6C^hi monocytes that were isolated from CD45.2^Cx3cr1^GFP^ reporter mice (Supplementary Fig. 3a,b). Cell fate of donor cells, distinguished from recipient by expression of GFP and congenic CD45, was analysed by flow cytometry and gene expression profiles. When analysed by GFP and Ly6C expression, transferred Ly6C^hi monocytes progressively and uniformly switched to a Ly6C^lo monocyte phenotype displaying upregulation of GFP and downregulation of Ly6C (Fig. 1d, Supplementary Fig. 3c). An extended marker analysis demonstrated more complex phenotypic changes involving the progressive acquisition of CD11c and CD43 while maintaining low expression levels of major histocompatibility complex (MHC)-II, consistent with conversion into Ly6C^lo monocytes. These changes occurred over a period of 4 days and were observed in BM and spleen (Fig. 1d). Thus, an extended phenotypic analysis confirms conversion of Ly6C^hi monocytes into Ly6C^lo monocytes.

**Notch2 regulates Ly6C^lo monocytes in vivo.** To evaluate a potential role of Notch signalling in monocyte subset regulation we sorted Ly6C^hi and Ly6C^lo monocytes from the BM and analysed Notch-related gene-expression patterns. Compared with Ly6C^hi monocytes, Ly6C^lo monocytes had lower expression of Notch1 but comparable Notch2 expression in messenger RNA and protein (Fig. 2a,e,f). Furthermore, Notch-regulated genes, Hey2...
and Hes1, were markedly induced in Ly6C<sup>lo</sup> monocytes, indicating recent or on-going activation of Notch signalling in this subset (Fig. 2a)<sup>3,30</sup>. We next wanted to confirm these findings on corresponding human monocyte subsets. Analysis of the human CD16<sup>+</sup> monocytes, which are considered equivalents of mouse Ly6C<sup>lo</sup> monocytes, revealed higher expression of HES1 compared with the classical CD14<sup>+</sup> monocytes (Fig. 2b).

We next asked whether Notch deficiency influences monocyte subpopulations. To generate mice with conditional deletions of Notch receptors in monocytes we crossed mice bearing floxed

alleles of Notch1, Notch2 or Notch1/Notch2 (refs 17,31) with a myeloid specific Cre-recombinase strain, LysM-Cre (ref. 32). Strains were also back-crossed onto the Cx3cr1GFP/+ reporter strain (Supplementary Table 2). This targeting strategy was characterized in detail. LysM reporter analysis in LysM-Cre mice confirmed low LysM promoter activity in progenitor populations, but high promoter activity in Ly6C hi and Ly6C lo monocytes (Supplementary Fig. 4a)33. In addition, crossing the LysMCre strain to a Cre-dependent YFP reporter strain revealed selective mature myeloid targeting, which was partial in Ly6C hi monocytes, and more efficient for Ly6C lo monocytes and granulocytes (Fig. 2c, Supplementary Fig. 4b), confirming previous reports34.

Mice with conditional deletion of Notch2 (GFP + N2AMY) had significantly reduced absolute and relative numbers of Ly6C lo monocytes in BM, PB and spleen (Fig. 2d, Supplementary Fig. 5a). The defect was only observed in Ly6C hi monocytes, since numbers of Ly6C hi monocytes, monocyte progenitor populations and neutrophils were unaffected, and occurred independent of the gfp reporter allele or the Cre deleter allele (Fig. 2d and Supplementary Fig. 5b–d). In contrast, mice with conditional deletion of Notch1 showed no alteration in monocyte subsets (Supplementary Fig. 5e), while combined deletion of Notch1/Notch2 phenocopied the single Notch2 mutants (Supplementary Fig. 5f). Altogether, these results demonstrate that monocyte Notch2 controls Ly6C lo monocyte numbers, suggesting a role in monocyte cell fate regulation.

To further investigate the selective reduction of Ly6C lo monocytes we next characterized Notch2 receptor expression by flow cytometry in control mice and conditional mutants. Notch2 was robustly expressed in MDP, cMoP, Ly6C hi and Ly6C lo monocytes in control mice (Fig. 2e,f). In GFP + N2AMY mice, Notch2 expression was not affected in MDPs and cMoP, but substantially reduced in Ly6C lo monocytes, consistent with partial Cre expression and activity in this population (Fig. 2e,f, Supplementary Fig. 4c and (ref. 34)). However, although Cre-mediated targeting is more effective in Ly6C lo monocytes (Fig. 2e,f, Supplementary Fig. 4b)34, most remaining Ly6C lo monocytes in Notch2 mutant mice retained normal Notch2 receptor expression, due to low expression of Cre (Fig. 2e,f and Supplementary Fig. 4c). This suggests that the remaining Ly6C lo monocytes in these mice develop from Notch2-expressing (Cre-negative) Ly6C hi monocytes (Supplementary Fig. 4c). Consistent with this idea, increasing the efficiency of Notch2 deletion in Ly6C hi monocytes, by using Notch2fl/+ mice carrying two alleles of LysMCre, increased the rate of Notch2 deletion in Ly6C hi monocytes but also lead to more strongly reduced levels of Ly6C lo monocytes (Fig. 2g,h), while Ly6C hi monocyte levels remained normal (Fig. 2g). Thus, loss of Notch2 at the level of Ly6C hi monocytes is compatible with generation of Ly6C lo monocytes, but incompatible with generation of Ly6C hi monocytes. Indeed, plotting Notch2 receptor levels on Ly6C lo monocytes against the frequency of Ly6C hi monocytes revealed that loss of Notch2 on Ly6C hi monocytes correlated strongly with loss of Ly6C lo monocytes (Fig. 2h). This also suggested that the fate of Ly6C lo monocytes is linked to Ly6C hi monocytes through Notch2.

We next wanted to test the effects of a more selective deletion of Notch 2 within the Ly6C hi population. To this end we used a conditional CD11c-Cre transgenic approach to delete Notch2 at early stages of Ly6C lo monocyte development, since CD11c is selectively upregulated in Ly6C lo monocytes at early stages of conversion (Fig. 1d, Fig. 5a). Loss of Notch2 partially reduced the number of Ly6C lo monocytes without affecting Ly6C hi monocytes (Fig. 2i, Supplementary Fig. 4d). Altogether, this demonstrates a requirement for Notch2 in the generation and maintenance of Ly6C lo monocytes.

Physiologic consequences of monocyte Notch2 deficiency. To study the consequences of Notch2 loss of function for monocyte patrolling behaviour in more detail we performed intravital microscopy of the cremaster muscle8,35. Under steady-state conditions, the number of rolling and adherent Ly6C hi monocytes was greatly reduced in GFP + N2AMY mice, which confirmed the results obtained by flow cytometry (Fig. 3a,b). Furthermore, while TNF-α treatment increased the rolling and adherence of Ly6C hi monocytes in control mice, this response was blunted in GFP + N2AMY mice (Fig. 3a,b), demonstrating a profound impairment of the Ly6C hi monocyte subpopulation with Notch2 loss of function. This result also ruled out the possibility that mutant Ly6C lo monocytes preferentially localize to blood vessel walls. In addition, the reduction of Ly6C hi monocytes in Notch2 mutant mice was accompanied by accumulation of an atypical cell population expressing high levels of MHC-II and CCR2 but low levels of CD11c, CD43 and CD11a (Fig. 3c–e), a phenotype not resembling a previously described MHC-II + monocyte population36.

Notch2 regulates Ly6C hi monocyte conversion in vivo. Ly6C hi monocyte deficiency could be due to increased cell death, as was shown in mice deficient for the transcription factor Nr4a1, which controls Ly6C lo monocyte numbers in part by regulating monocyte apoptosis13. We, therefore, tested the hypothesis that Notch2 regulates monocyte survival. However, neither the fraction of apoptotic cells, nor the fraction of dead cells was altered in each of the monocytes subsets in BM, PB or spleen in conditional Notch2 mutants (Fig. 4a,b).

To address the question whether conversion of Ly6C hi monocytes depends on Notch2 we isolated Ly6C hi monocytes from Cx3cr1GFP/+ control mice or conditional Notch2 mutants and analysed the cell fate after adoptive transfer into CD45.1 + congenic wild-type recipients. Four days after transfer the majority of recovered donor cells from control donors had converted into Ly6C lo monocytes, while few remained Ly6C hi monocytes. After transfer of cells from conditional mutants, however, the fraction of donor cells that had converted into

Ly6C<sup>lo</sup> monocytes was strongly reduced, while the fraction of recovered Ly6C<sup>hi</sup> monocytes was significantly increased (Fig. 4c,d, Supplementary Fig. 6). Similar results were obtained in experiments when peripheral Ly6C<sup>hi</sup> monocytes retrieved from PB and spleen were used for transfer (Supplementary Fig. 7), which also ruled out development of Ly6C<sup>lo</sup> monocytes from contaminating BM precursors. Thus, Ly6C<sup>hi</sup> monocytes deficient for Notch2 show impaired conversion into Ly6C<sup>lo</sup> monocytes, demonstrating regulation of monocyte cell fate by Notch2.

Dll1-Notch2 axis controls monocyte conversion in vitro. Notch receptors are differentially engaged by Notch ligands, and Notch2 is a preferred target of DLL1 (ref. 24). To define the Notch signalling components regulating monocyte conversion, and to provide proof-of-principle that Notch activation is sufficient for Notch2 signalling, we established an in vitro culture system to mimic the initial steps during monocyte conversion under defined conditions. We sorted Ly6C<sup>hi</sup> monocytes from BM of Cx3cr1<sup>GFP</sup>/<sup>+/−</sup> mice (Fig. 5a day 0) and cultured them in the presence of immobilized recombinant DLL1 protein, or control conditions (Fig. 5a and Supplementary Fig. 8). In culture, downregulation of Ly6C and upregulation of GFP occurred in all conditions over time, while cells remained uniformly CD115<sup>+</sup> (Fig. 5a, Supplementary Fig. 8b). However, conversion of Ly6C<sup>hi</sup> into Ly6C<sup>lo</sup> monocyte-like cells, detected by upregulation of CD43 and CD11c in MHC-II<sup>−</sup> cells, occurred to a significantly greater extent on DLL1 than in control cultures (Fig. 5a,b). Furthermore, in gene expression profiling, cells cultured on DLL1 showed significantly higher levels of Nr4a1 and Pou2f2 and significantly lower levels of Slfn5 compared with control culture (Fig. 5c), similar to a Ly6C<sup>lo</sup> monocyte phenotype.

The effect was specific for DLL1, since culture of Ly6C<sup>hi</sup> monocytes on another Notch ligand, JAG1, was much less effective in generating Ly6C<sup>lo</sup> monocyte-like cells, as were control conditions (Fig. 5d,e). Furthermore, DLL1-induced monocyte conversion was impaired by incubation with a γ-secretase inhibitor, N-(N-(3,5-difluorophenacetyl)-L-alanyl)-S-phenylglycine t-butyl ester (DAPT), which blocks the generation of the active intracellular Notch domain (ref. 37), thus indicating that DLL1-induced Notch receptor cleavage is required for this process (Fig. 6a,b). Importantly, DLL1-induced monocyte conversion was also severely impaired in Ly6C<sup>hi</sup> monocytes from Notch2 conditional mutants when compared with controls (Fig. 6c,d). These results demonstrate that a specific Dll1-Notch2 signalling axis controls conversion of Ly6C<sup>hi</sup> monocytes into Ly6C<sup>lo</sup> monocyte-like cells.

Dll1 is expressed in distinct endothelial niches. We wanted to corroborate the specific function of DLL1 for Ly6C<sup>lo</sup> monocyte development in vivo. In the adult mouse, DLL1 is selectively expressed in vascular endothelium of arteries, but not veins or capillaries, and in EC in the MZ of the spleen (ref. 24,37). We first characterized in more detail DLL1 expression in the two principle haematopoietic compartments, BM and spleen, using genetic reporter mice or immunostaining. In Dll1<sup>+/-lacZ</sup> reporter mice, in which one allele of Dll1 has been replaced by lacZ, specific reporter staining was observed in the splenic MZ, but not in the central artery of the splenic follicle (Fig. 7a). Immunofluorescence staining against CD31 and DLL1 and confocal microscopy revealed Dll1 expression in EC of the MZ and confirmed its absence in the central artery of the follicle (Fig. 7b). Interestingly, DLL1 staining in Cx3cr1<sup>GFP</sup>/<sup>+/−</sup> reporter mice demonstrated a...
close spatial relationship between DLL1 expression and GFP + cell populations in the MZ, suggesting a potential niche function (Fig. 7c). Co-staining with Ly6C or CD43 identified both monocyte subsets within the CD31 + and DLL1 + MZ area, while large GFP + macrophages reside in the borders of the MZ (Fig. 7d,e and Supplementary Fig. 9a,b). Furthermore, specific DLL1-reporter staining inDll1 +/lacZ mice was also observed in the BM, which appeared in a reticular pattern in the diaphysal area of the BM cavity, suggesting a vascular pattern (Fig. 7f). More importantly, the defect in Ly6C hi monocytes observed in Notch2 conditional mutants was recapitulated in haploinsufficient Dll1 mutant mice (Fig. 7g). This demonstrates a critical role for Dll1 in the regulation of Ly6C lo monocytes in vivo, and emphasizes the importance of a Dll1-Notch2 axis in the control of Ly6C lo.
monocyte development. Furthermore, these observations also suggest that distinct Dll1+ EC might form specialized niches for the generation of Ly6Clo monocytes.

Endothelial Dll1 controls Ly6Clo monocyte development. To test the hypothesis that endothelial Dll1 regulates Ly6Clo monocyte development we employed an endothelial-specific and inducible deletion strategy using the Cdh5(PAC)-CreERT2 strain, which shows EC-specific Cre activity in peripheral vessels and the BM cavity16,38. We first confirmed pan-endothelial, but EC-specific, targeting by generating Cre-dependent lacZ-reporter mice (lacZiEC), which demonstrated inducible EC staining in arteries, veins and capillaries after tamoxifen treatment, but also

(b,d) \( n = 3, \ast P < 0.05, \ast\ast P < 0.01, \ast\ast\ast P < 0.001; \) one-way ANOVA with Bonferroni’s Multiple comparison test. Error bars represent s.e.m.

We inducedDll1 deletion in arterial EC, which resulted in arterial EC-to-monocyte conversion (Supplementary Fig. 10a). In contrast to pan-endothelial deletion of Dll1, arterial EC-specific deletion of Dll1 did not affect relative or absolute numbers of Ly6C\textsuperscript{lo} monocytes (Fig. 8c), suggesting that Dll1 expressed in endothelial niches in the MZ or BM, and not in arterial endothelium, regulates monocyte conversion.

To further investigate the specificity of Dll1 effects on Ly6C\textsuperscript{lo} monocytes we mated the pan-endothelial and inducible Cre-transgenic strain to conditional alleles of the related Notch ligand Dll4 (refs 38,40). In contrast to deletion of Dll1, deletion of Dll4 did not lead to alterations in Ly6C\textsuperscript{lo} monocytes, or any other myeloid subset (Fig. 8d), which demonstrates specific effects of Dll1 in the regulation of Ly6C\textsuperscript{lo} monocytes.

To provide proof-of-principle that EC populations from the haematopoietic compartment regulate monocyte conversion we established an in vitro co-culture system. CD144\textsuperscript{+} ECs

were sorted from splenic tissue digests and cultured with Ly6Chi monocytes from Cx3cr1GFP\(^+\) reporter mice. We also confirmed Dll1 expression in this EC population (Fig. 8e). Compared with monocytes cultured alone, conversion of Ly6Chi monocytes into Ly6Clo monocyte-like cells was significantly increased on splenic EC, an effect that persisted over time (Fig. 8f,g). Altogether, these results suggest that distinct endothelial niches in the haematopoietic compartments regulate conversion of Ly6C\(^{hi}\) monocytes into Ly6C\(^{lo}\) monocytes via the Dll1-Notch2 axis.
Figure 8 | Endothelial deletion of Dll1 impairs Ly6C^lo monocyte development in vivo. (a) Inducible and endothelial-specific Cre-reporter mice (lacZiEC) showing specific β-galactosidase staining in splenic MZ (left) and BM (right) of the femur diaphysis after tamoxifen treatment; scale bars, 50 μm.

(b) Absolute and relative numbers of myeloid cell populations by flow cytometry after pan-endothelial deletion of Dll1 compared with littermate controls. Data are pooled from four experiments (n = 8). (c) Absolute and relative numbers of myeloid cell populations by flow cytometry after arterial-specific, endothelial deletion of Dll1 compared with littermate controls. Data are pooled from two experiments (n = 5/6). (d) Absolute and relative numbers of myeloid cell populations by flow cytometry after endothelial-specific deletion of Dll4 compared with littermate controls. Data are pooled from two experiments (n = 5). Representative flow cytometry plot from GFP^+ CD11b^+ gate (f) and frequency of Ly6C^lo monocyte-like cells (g) are shown (n = 3). *P < 0.05, **P < 0.01, ***P < 0.001; Student’s t-test (b–e) or one-way ANOVA with Bonferroni’s multiple comparison test (g). (b–e,g) Error bars represent s.e.m.
Discussion

We here define the molecular and cellular context that regulates monocyte conversion. Taken together, our results show that Notch2 regulates conversion of Ly6C\textsuperscript{hi} monocytes into Ly6C\textsuperscript{lo} monocytes, thereby regulating a specific developmental step in monocyte cell fate under steady-state conditions. This process is controlled specifically by Notch ligand Dll1 expressed by a population of EC that constitute distinct vascular niches in the BM and spleen. Thus, blood vessels regulate monocyte conversion, as a form of developmental cell fate regulation.

The origin and regulation of Ly6C\textsuperscript{lo} monocytes is still poorly understood. Recent findings have suggested that Ly6C\textsuperscript{lo} monocytes develop from Ly6C\textsuperscript{hi} monocytes. Adoptive transfer of cMØ\textsuperscript{lo} leads to the sequential appearance of Ly6C\textsuperscript{lo} monocytes followed by Ly6C\textsuperscript{hi} monocytes\textsuperscript{5}. Furthermore, Jung and colleagues have provided direct evidence that Ly6C\textsuperscript{hi} monocytes derive from Ly6C\textsuperscript{hi} monocytes by adoptive transfer experiments\textsuperscript{14}. Our experiments demonstrating monocyte conversion with isolated Ly6C\textsuperscript{hi} monocytes in vivo, and recapitulation of it in vitro, clearly support the notion of monocyte conversion as a mechanism regulating development of Ly6C\textsuperscript{lo} monocytes. However, while our data provide evidence for and insights into the mechanism of monocyte conversion, our findings do not exclude the existence of additional mechanisms to generate Ly6C\textsuperscript{lo} monocytes, for example from progenitor cells, as has been recently suggested\textsuperscript{41}.

So far, specific molecular or cellular regulators of monocyte conversion have remained elusive, and it has been speculated that monocyte conversion occurs spontaneously in the circulation\textsuperscript{2,14}. Our data demonstrating a requirement for the Dll1-Notch2 signalling axis for the conversion of Ly6C\textsuperscript{hi} monocytes into Ly6C\textsuperscript{lo} monocytes not only provides clear evidence for the regulated nature of monocyte conversion, but also shows that this process is under control of blood vessels through Notch ligand Dll1. The fact that conditional deletion of Dll4 has no impact on Ly6C\textsuperscript{lo} monocytes further emphasizes the specific nature of Dll1 actions. Although the precise location of monocyte conversion remains unknown, our data clearly demonstrate the existence, and functional importance, of distinct Dll1-expressing vascular niches in BM and spleen. This suggests that monocyte conversion happens, or is at least initiated, in these vascular niches under steady-state conditions. This is further supported by the fact that co-cultured EC from these niches promote monocyte conversion, while our in vivo data from mice with arterial-specific Dll1 deletion exclude the participation of arterial ECs in this process. However, given the dynamic nature of endothelial responses, it is conceivable that in certain situations, such as inflammation, the location, composition and extent of vascular niches might change, which, in turn, might influence monocyte conversion rates.

Recently, the instructive function of the vascular niche for self-renewal and regenerative capacity of HSCs has been defined, which, in part, is mediated by endothelial-specific expression of Notch ligand Jag1 (refs 20,21). Our finding that monocyte conversion is regulated by ECs extends the spectrum of niche regulation towards more committed steps of myeloid cell development and further supports the importance of the vascular niche in regulating cell fate. On the other hand, the finding that Notch2 signalling mediates conversion into Ly6C\textsuperscript{lo} monocytes, while Notch2 deletion leads to MHC-II\textsuperscript{hi} atypical monocytes. While the role and relevance of this atypical monocyte population observed in conditional mutants is currently unclear, it is important to note that, using different gating strategies and experimental approaches, subpopulations of MHC-II-expressing monocytes have recently been described, which acquire antigen for carriage to lymph nodes\textsuperscript{26}.

Currently, the molecular effectors of Notch2 in monocytes are unknown. Interestingly, the transcription factor Nr4a1, an orphan nuclear receptor, regulates the survival of Ly6C\textsuperscript{lo} monocytes\textsuperscript{13}. Although a role of Nr4a1 in monocyte conversion has not been investigated, mice with general or BM-restricted inactivation of Nr4a1 showed reduced Ly6C\textsuperscript{lo} monocytes numbers and increased rates of apoptosis. Although we did not observe a cell death phenotype in Notch2 mutant mice, we found DLL1-dependent regulation of Nr4a1 in vitro. Clearly, the molecular regulation of monocyte conversion requires further study.

Our study also describes the first steps towards an approach to recapitulate monocyte cell fate ex vivo. This might provide a setting to study and understand the molecular events driving monocyte conversion under defined conditions.

Methods

Mice. Mouse strains used in the study are listed in Supplementary Table 2. Cxcl3\textsuperscript{GFP/+}\textsuperscript{mice} (kindly provided by Steffen Jung), Ly6M\textsuperscript{GFP}\textsuperscript{mice}\textsuperscript{32}, Dll1\textsuperscript{+}\textsuperscript{lucZ}\textsuperscript{mice} (kindly provided by Achim Gossler), Notch1\textsuperscript{flkO}\textsuperscript{mice} and Notch2\textsuperscript{flkO}\textsuperscript{mice}, Cdh5(PAC)-CreERT2\textsuperscript{mice}\textsuperscript{43}, Bmsn(PAC)-CreERT2\textsuperscript{mice}\textsuperscript{44}, Dll4\textsuperscript{lox/lox}\textsuperscript{mice}, Dll4\textsuperscript{+}\textsuperscript{Cre}\textsuperscript{mice}, Ncr4\textsuperscript{lox/lox}\textsuperscript{mice}, Nr4a1-GFP\textsuperscript{mice}\textsuperscript{15}, Ly6M\textsuperscript{GFP}\textsuperscript{mice}\textsuperscript{33}, Ly6M\textsuperscript{eGFP}\textsuperscript{mice}\textsuperscript{34}, Ly6M\textsuperscript{ROSA}\textsuperscript{mice}\textsuperscript{35}. Currently, the molecular effectors of Notch2 in monocytes are unknown. Interestingly, the transcription factor Nr4a1, an orphan nuclear receptor, regulates the survival of Ly6C\textsuperscript{lo} monocytes\textsuperscript{13}. Although a role of Nr4a1 in monocyte conversion has not been investigated, mice with general or BM-restricted inactivation of Nr4a1 showed reduced Ly6C\textsuperscript{lo} monocytes numbers and increased rates of apoptosis. Although we did not observe a cell death phenotype in Notch2 mutant mice, we found DLL1-dependent regulation of Nr4a1 in vitro. Clearly, the molecular regulation of monocyte conversion requires further study.

Our study also describes the first steps towards an approach to recapitulate monocyte cell fate ex vivo. This might provide a setting to study and understand the molecular events driving monocyte conversion under defined conditions.

Tissue and cell preparation. For single cell suspension mice were killed and spleen, BM and blood were collected. Erythrocytes were removed by red blood cell lysis buffer (Biolegend) or by density centrifugation using Histopaque 1083 (Sigma-Aldrich). After extensive washing cells were resuspended in PBS containing 10% FCS and 2 mM EDTA kept on ice, stained and used for flow cytometry or for sorting.

Flow cytometry and cell sorting. Non-specific binding of antibodies by Fc-receptors was blocked with anti-mouse CD16/CD32 (TrueStain fcX from Biolegend) in single cell suspensions prepared from spleen, PB or BM. After subsequent washing step cells were labelled with primary and secondary antibodies and streptavidin-fluorochrome conjugates (Supplementary Table 3) and used for flow cytometry analysis (LSR-II, BD Biosciences) or sorting (FACSAria, BD Biosciences or MoFlo XDP, Beckman Coulter). Data were analysed by FlowJo software (TreeStar). Initially cells were identified based on forward scatter (FSC) and side scatter (SSC) characteristics. After exclusion of doublets (on the basis of
In vitro conversion studies. Ninety-six-well flat bottom plates were coated at room temperature for 3 h with IgG-Fc, JAG1-Fc or DLL1-Fc ligands (all from R&D) reconstituted in PBS. Sorted BM Ly6C<sup>+</sup> monocytes were cultured in coated plates in the presence of M-CSF (10 ng ml<sup>−1</sup>), thrombopoietin (TPO, 20 ng ml<sup>−1</sup>), stem cell factor (SCF, 10 ng ml<sup>−1</sup>), insulin-like growth factor (IGF)-II (20 ng ml<sup>−1</sup>), fibroblast growth factor (FGF)-I (10 ng ml<sup>−1</sup>) (all from Peprotech) and Hepatinit (25 U ml<sup>−1</sup>) at 37°C for 24 or 48 h. In experiments where the effect of Notch inhibition on conversion process was assessed, 6 μg of γ-secretase inhibitor, DAPT or dime-thylsulfoxide (DMSO) was applied to the cells prior to and 24 h after culture. In separate experiments BM Ly6C<sup>+</sup> monocytes were co-cultured with sorted splenic CD14<sup>+</sup> GFP<sup>+</sup> CD11b<sup>+</sup> EC. One or 2 days after culture, cells were harvested, stained and subjected to flow cytometry. Frequency of Ly6C<sup>+</sup> monocyte-like cells (CD11b<sup>+</sup> GFP<sup>+</sup> Ly6C<sup>-</sup>/C176 CD11c<sup>+</sup>MHC-II<sup>+</sup>/CD43<sup>+</sup>) in total live CD11b<sup>+</sup> GFP<sup>+</sup> cells served as an indicator of conversion efficiency and is shown in the graphs.

Adoptive cell transfer experiments. CD11b<sup>+</sup> Ly6C<sup>+</sup>GFP<sup>+</sup> monocytes were sorted from BM and injected into CD45.1<sup>+</sup> recipients intravenously (i.v.). Four days after transfer spleen, PB and BM were collected and single cell suspension was prepared. After blocking of Fc receptors using anti-mouse CD16/CD32 (TruStain FcX from Biolegend) cells were labelled with biotin-conjugated anti-CD45.1 antibody and analyzed using a BD LSRFortessa or a FACSCanto flow cytometer. One or 2 days after culture, cells were harvested, stained and subjected to flow cytometry. Frequency of Ly6C<sup>+</sup> monocyte-like cells (CD11b<sup>+</sup> GFP<sup>+</sup> Ly6C<sup>-</sup>/C176 CD11c<sup>+</sup>MHC-II<sup>+</sup>/CD43<sup>+</sup>) in total live CD11b<sup>+</sup> GFP<sup>+</sup> cells was calculated from live cell gate and normalized on SSC-W, SSC-A, relative frequency of each subpopulation from live cell gate or mean absolute number of each subset (calculated from live cell gate and normalized on SSC-W, SSC-A). Roche according to the manufacturer’s instructions, for normalization. Expression of each specific gene was normalized to expression of Rps9 and calculated by the comparative CT (2<sup>−ΔΔCT</sup>) method<sup>25</sup>.

In vivo targeting of EC and PCR analysis. Five to 6-weeks-old mice expressing EC-specific inducible Cre recombinase and Cre-negative littermate controls were treated with 500 μg tamoxifen for 5 consecutive days intraperitoneally (i.p.). Mice were killed after 4 weeks. Efficiency of Cre-dependent gene deletion was monitored by PCR and agarose gel-electrophoresis as described<sup>23</sup>.

Statistical analysis. Results are expressed as mean ± s.e.m. N numbers are biological replicates of experiments performed at least three times unless otherwise indicated. Significance of differences was calculated using unpaired, two-tailed Student’s t-test with confidence interval of 95%. For comparison of multiple experimental groups one-way analysis of variance (ANOVA) was used and Bonferroni’s multiple-comparison test was performed when the overall P value was <0.05. Data from intravital microscopy were analysed using two-way ANOVA and Bonferroni’s post-test. P values of less than 0.05 were considered to be significant.

Data availability. The authors declare that all the relevant data are available upon request.
