(Dated: March 2, 2018)

We propose a tight-binding (TB) model, that includes spin-orbit coupling (SOC), to describe the electronic properties of methyl-substituted germanane (GeCH₃). This model gives an electronic spectrum in agreement with first principle results close to the Fermi level. Using the Z₂ formalism, we show that a topological phase transition from a normal insulator (NI) to a quantum spin Hall (QSH) phase occurs at 11.6% biaxial tensile strain. The sensitivity of the electronic properties of this system on strain, in particular its transition to the topological insulating phase, makes it very attractive for applications in strain sensors and other microelectronic applications.

I. INTRODUCTION

Topological insulators (TIs) are a new state of matter that have attracted a lot of interest within the condensed matter physics community [1–6]. It is now well established that TIs are promising candidates for future advanced electronic devices. They possess a bulk insulating gap and conducting edge states. The edge states are protected by time-reversal symmetry (TRS) against backscattering and this property makes them robust against disorder and nonmagnetic defects. Consequently, the edge channels normally possess very high carrier mobility.

Among TI materials two-dimensional (2D) van der Waals systems have attracted a lot of attention during the past decade [7]. The interest in these systems originates from the discovery of graphene, which has a very high carrier mobility (200 000 cm²/(Vs)), thermal conductivity, and mechanical strength [8, 9]; however, its zero electronic band gap has severely limited its applicability in electronic devices. Also, the proposal for the existence of a topological insulating phase in graphene by Kane and Mele was shown to be unrealistic, because of its extremely small SOC strength [10, 11]. Hence, extensive efforts have been devoted to open a band gap and increase the effective SOC in graphene or find other 2D systems with favorable SOC, carrier mobility, and appropriate band gap.

Other 2D materials such as single- or few-layer transition metal dichalcogenides (TMDs), boron nitride, silicene, germanene, phosphorene, stanene and MXene, have been extensively explored [7, 12].

Another important issue for applications in electronic industry is the compatibility of the material with current silicon-based electronic technology. Therefore, the group IV elements with honeycomb structure are more favorable for this purpose.

One method for tuning the electronic band structure of 2D systems is the use of surface functionalization. Functionalization of graphene with hydrogen, the so-called hydrogen-terminated graphene or graphane, opens a sizeable band gap, but its carrier mobility decreases dramatically to 10 cm²/(Vs) [13]. Silicene and germanene the other analogues of graphene have also attracted much attention. However, the small band gap of these systems and mobility issues have limited their application for electronics. Functionalized germanene provide enhanced stability and tunable properties [14]. Compared with bulk Ge, surface functionalized germanene possess a direct and large band gap depending on the surface ligand. These materials can be synthesized via the topotactic decalination of layered Zintl phase precursors [14, 15]. In contrast to TMDs, the weaker interlayer interaction allows for direct band gap single layer properties such as strong photoluminescence that are readily present without the need to exfoliate down to a single layer. Bianco et al. [16] produced experimentally hydrogen-terminated germanene, GeH (also called, germanane). Recently the new material GeCH₃ was synthesized [14], that exhibit an enhanced thermal stability. GeCH₃ is thermally stable up to 250 °C which compares to 75 °C for GeH. The electronic structure of GeCH₃ has been shown to be very sensitive to strain, which makes it very attractive for strain sensor applications [17–19]. It has also a high carrier mobility and pronounced light absorption which makes it attractive for light harvesting applications [18, 19].

At present there exist already a few first-principle studies of GeCH₃ that also include the effect of SOC [14, 17–19]. To fully understand the physics behind the electronic band structure close to the Fermi level, we propose a TB model. Our TB model is fitted to the density functional theory (DFT) results both for the case with and without SOC. In the next part of this work we applied biaxial tensile strain to examine the effect of strain on the electronic properties of this system and compare our results with DFT calculations. The possibility of a topological phase transition in GeCH₃ under biaxial tensile strain is also examined. Our finding that there is a transition to the QSH phase is further corroborated by the fact that

normal direction to the plane of the monolayer GeCH. The buckling height, C bond lengths are 2.415 Å and 1.972 Å, respectively \[17\].

Electronic properties of monolayer GeCH is introduced in Sec. III, and the effect of strain on the electronic properties of monolayer GeCH is examined. This paper is organized as follows. In Sec. II, we introduce the crystal structure and lattice constants of monolayer GeCH. Our TB model with and without SOC is introduced in Sec. III, and the effect of strain on the electronic properties of monolayer GeCH is examined. In Sec. IV, using the \( \mathbb{Z}_2 \) formalism we demonstrate the existence of a topological phase transition in the electronic properties of monolayer GeCH when biaxial tensile strain is applied. The paper is summarized in Sec. V.

II. LATTICE STRUCTURE OF MONOLAYER GeCH

The hexagonal atomic structure of monolayer GeCH and its geometrical parameters are shown in Figs. 1(a-c). As shown in Figs. 1(a,b) it consists of three atomic layers where a buckled honeycomb sheet of Ge atoms is sandwiched between two outer methyl group layers. Each unit cell of monolayer GeCH consists of two Ge atoms and two CH3 groups. Previous DFT calculations gave for the lattice constant \( a = 3.954 \) Å, and the Ge-Ge and Ge-C bond lengths are 2.415 Å and 1.972 Å, respectively\[17\]. The buckling height, \( h \), indicating the distance between two different Ge sublattices, is 0.788 Å.

We have chosen the \( x \) and \( y \) axes along the armchair and zigzag directions, respectively. The \( z \) axis is in the normal direction to the plane of the monolayer GeCH. With this definition of coordinates, the lattice vectors are written as \( \mathbf{a}_1 = a/2(1, \sqrt{3}) \), \( \mathbf{a}_2 = a/2(-1, \sqrt{3}) \), where the corresponding hexagonal Brillouin zone of the structure (see Fig. 1(d)) is determined by the reciprocal vectors \( \mathbf{b}_1 = 2\pi/a(1, \sqrt{3}/3) \), \( \mathbf{b}_2 = 2\pi/a(-1, \sqrt{3}/3) \).

III. TIGHT-BINDING MODEL HAMILTONIAN

Electronic structure of monolayer GeCH3 has been obtained by using DFT calculations in Ref. \[17\]. It is shown that the low-energy electronic properties of this system are dominated by \( s \), \( p_x \) and \( p_y \) atomic orbitals of Ge atoms. DFT calculations including SOC interaction have shown that applying an in-plane biaxial tensile strain induces a topological phase transition in the electronic properties of monolayer GeCH3 \[17\]. Although such a DFT approach, provides valuable information regarding the electronic properties of such system, it is limited to small computational unit cells. For example, large nanoribbons consisting of hundreds of atoms and including disorder require very large super-cells which go beyond present day computational DFT capability. This motivated us to derive a TB model for monolayer GeCH3 that is sufficiently accurate to describe the low-energy spectrum and the electronic properties of this system.

In the following we will propose a low-energy TB model Hamiltonian that includes SOC for monolayer GeCH3. We show that our model is able to predict accurately the effect of strain on the electronic properties of the system.

A. Model Hamiltonian without SOC

We propose a TB model including \( s \), \( p_x \) and \( p_y \) atomic orbitals with principal quantum number \( n = 4 \) of Ge atoms to describe the low-energy spectrum of this system. The nearest-neighbor effective TB Hamiltonian without SOC in the basis of \( |s, p_x, p_y \rangle \) and in the second quantized representation is given by

\[
H_0 = \sum_{i,\alpha} E_{i\alpha} c_{i\alpha}^\dagger c_{i\alpha} + \sum_{(i,j),\alpha,\beta} t_{i\alpha,j\beta}(c_{i\alpha}^\dagger c_{j\beta} + \text{h.c}), \tag{1}
\]

where \( c_{i\alpha}^\dagger \) and \( c_{i\alpha} \) represent the creation and annihilation operators for an electron in the \( \alpha \)-th orbital of the \( i \)-th atom, \( E_{i\alpha} \) is the onsite energy of \( \alpha \)-th orbital of the \( i \)-th atom and \( t_{i\alpha,j\beta} \) is the nearest-neighbor hopping amplitude between \( \alpha \)-th orbital of \( i \)-th atom and \( \beta \)-th orbital of \( j \)-th atom. We will show that this effective model is sufficiently accurate to describe the low-energy spectrum of this system.

Note that the above Hamiltonian is quite different from the effective Hamiltonian that describes the electronic properties of pristine germanene \[20\]. In the pristine honeycomb structures of the group IV elements, the effective low-energy spectrum is described by the outer \( p_z \) atomic orbitals. However, in monolayer GeCH3, the \( p_z \) orbitals mainly contribute to the \( \sigma \)-bonding between Ge and C.

B. Strain effects

Applying strain to a system modifies its electronic properties [23]. This is due to the fact that it changes both the bond lengths and bond angles leading to a modification of the hopping parameters that determine the electronic properties of the system.

An accurate prediction of the electronic properties of the system in the presence of different types of strain, is a stringent test of the accuracy of our TB model. To this end, we now first calculate the modification of the hopping parameters when biaxial tensile strain is applied to the plane of monolayer GeCH$_3$. Then we will study the modification of the energy spectrum in the presence of such a strain to show that our results agree very well with the DFT calculations. This particular type of strain noticeably simplifies our calculations. When biaxial tensile strain is applied in the plane of monolayer GeCH$_3$ leaves the honeycomb nature of its lattice intact and the initial lattice vectors $\mathbf{a}_1$ and $\mathbf{a}_2$ evolve to the deformed ones $\mathbf{a}_1$ and $\mathbf{a}_2$. Therefore, the vector $\mathbf{r}_0 = (x_0, y_0, z_0)$, in the presence of in-plane strain is deformed into $\mathbf{r} = (x, y, z) = [(1 + \epsilon_x)x_0, (1 + \epsilon_y)y_0, z_0]$, where $\epsilon_x$ and $\epsilon_y$ are the strain in the direction of the $x$ and $y$ axes, respectively. In the following, for simplicity we assume that the strengths of the applied biaxial strains in the two directions are equal, i.e., $\epsilon_x = \epsilon_y = \epsilon$. In the linear deformation regime, one can perform an expansion of the norm of $\mathbf{r}$ to first order in $\epsilon_x$ an $\epsilon_y$ which results in

$$ r \simeq (1 + \alpha_x \epsilon_x + \alpha_y \epsilon_y) \mathbf{r}_0 = [1 + (\alpha_x + \alpha_y)\epsilon] \mathbf{r}_0, $$

where $\alpha_x = (x_0/r_0)^2$ and $\alpha_y = (y_0/r_0)^2$ are coefficients related to the geometrical structure of GeCH$_3$.

FIG. 3. Variation of the buckling angle as a function of biaxial tensile strain. Symbols represent the DFT data for germanene [20] and the solid line is the fit to this data.

atoms to form the energy bands that are far from the Fermi level. Therefore, we will neglect the contribution of the $p_z$ orbitals of the Ge atoms and the other orbitals of the CH$_3$ molecule in our TB model.

With the above description, the hopping parameters of Eq. (1) can be expressed in terms of the standard Slater-Koster parameters as listed in the middle column of Table I, where $l = \cos \theta \cos \phi_0$ and $m = \sin \theta \cos \phi_0$ are, respectively, function of the cosine of the angles between the bond connecting two neighboring atoms with respect to $x$ and $y$ axes.

Using the Fourier transform of Eq. (1), and numerically diagonalizing the resulting Hamiltonian in $k$ space, one can fit to the ab-initio results in order to obtain the numerical values of the mentioned Slater-Koster parameters. The density functional calculation results [21] including the Heyd-Scuseria-Ernzerhof (HSE) functional approximation [22] are used to parametrize the TB model given by Eq. (1). We have listed the obtained numerical values of these parameters in Table II. The numerically calculated TB energy bands of monolayer GeCH$_3$ in the absence of strain, as shown in Fig. 2(a), are in excellent agreement with the ab-initio results. The direct band gap of monolayer GeCH$_3$ at the $\Gamma$ point is 1.82 eV.
TABLE I. The nearest neighbor hopping parameters between $s$ and $p$ orbitals are listed in the first column. The second column represents the hopping integrals as a function of the standard Slater-Koster parameters with direction dependent quantities. The third column are the nearest hopping parameters with the inclusion of applied strain.

| Hopping parameters | Without strain | With biaxial strain |
|--------------------|----------------|---------------------|
| $t_{ss}$           | $V_{ss}$       | $t^0_{ss} - 2\epsilon^2 \phi_0^0 \Delta \phi$ |
| $t_{sp}$           | $t^0_{sp}$     | $t^0_{sp} \Delta \phi$ |
| $t_{sp}$           | $t^0_{sp}$     | $t^0_{sp} \Delta \phi$ |
| $t_{p_{x}p_{x}}$   | $t_{p_{x}p_{x}}^0 \Delta \phi$ | $t_{p_{x}p_{x}}^0 \Delta \phi$ |
| $t_{p_{y}p_{y}}$   | $t_{p_{y}p_{y}}^0 \Delta \phi$ | $t_{p_{y}p_{y}}^0 \Delta \phi$ |

TABLE II. The values of the Slater-Koster parameters in units of eV as obtained from a fitting to the ab-initio results.

| $V_{ss}$ | $V_{sp}$ | $V_{pp}$ | $t_{pp}$ | $\epsilon_s$ | $\epsilon_p$ |
|----------|----------|----------|----------|--------------|--------------|
| -2.20    | 2.62     | 2.85     | -0.85    | -5.09        | 2.1          |

For the three nearest neighbor Ge atoms, one can write $t_{sp} = \alpha_{sp} + \eta_{sp} \phi_0$, where $\phi_0$ is the initial buckling angle. We note that in the presence of biaxial strain, the bond lengths and buckling angles are both altered. Thus, we consider their effects on the modification of the hopping parameters, simultaneously. Based on elasticity theory, we know that the main features of the mechanical properties in a covalent material are determined by the structure of the system and the strength of the covalent bonds. Therefore, one can expect that the change of the buckling angle in germanene [20] and GeCH$_3$ be akin. The variation of the buckling angle [20] as a function of biaxial strain can be fit to the linear form $\phi = \phi_0 - \eta \epsilon$ (see Fig. 3), where $\eta = -30$.

According to the Harrison rule [24], the standard Slater-Koster parameters related to $s$ and $p$ orbitals are proportional to the bond length $r$ as $V_{\alpha\beta\gamma} \propto 1/r^2$. Using Eq. (2), the modified parameters are given by

$$V_{\alpha\beta\gamma} = (1 - 2\epsilon \cos^2 \phi_0) V_{\alpha\beta\gamma}^0$$

One can then use the change of the buckling angle and the Slater-Koster parameters to obtain the modified hopping parameters as listed in the last column of Table I, where $t_{sp}^0$ represents the unstrained hopping parameters. For instance, the new hopping parameter $t_{sp}$ can be approximated by

$$t_{sp} = t_{sp}^0 + \left( \frac{\partial t_{sp}}{\partial r} \right)_{r_0} \Delta r + \left( \frac{\partial t_{sp}}{\partial \phi} \right)_{\phi_0} \Delta \phi$$

$$= t_{sp}^0 - 2 \cos \theta \cos \phi_0 V_{sp}^0 \frac{\Delta r}{r_0} - \cos \theta \sin \phi_0 V_{sp}^0 \Delta \phi.$$  

(4)

Substituting $\Delta r/r_0 = \epsilon \cos^2 \phi_0$ and $\Delta \phi = -\eta \epsilon$ into the above equation gives

$$t_{sp} = t_{sp}^0 [1 - \epsilon(2 \cos^2 \phi_0 - \eta \tan \phi_0)].$$  

(5)

In a similar way, one can obtain the other modified hopping parameters in order to study the evolution of the energy spectrum of monolayer GeCH$_3$ as a function of applied biaxial tensile strain.

Straightforward substitution of the new hopping parameters in Hamiltonian, Eq. (1), gives the Hamiltonian for the strained system. The calculated TB energy spectrum in the presence of biaxial tensile strain with strengths of 4%, 8%, and 12% are shown in Figs. 2(b), (c) and (d), which are in excellent agreement with the DFT results [17, 21]. We show in Fig. 4 the dependence of the band gap of GeCH$_3$ as function of biaxial tensile strain. Notice the good agreement between both DFT and TB approaches demonstrating the validity of our proposed TB model.

C. Spin-Orbit coupling

Spin-orbit interaction is a relativistic correction to the Schrödinger equation. It can significantly affect the electronic properties of systems that consists of heavier elements. In such systems, the major part of SOC originates from the orbital motion of electrons close to the atomic nuclei. In the Slater-Koster approximation, one
can assume an effective spherical atomic potential $V_i(r)$, at least in the region near the nucleus. Therefore, one can substitute $\nabla V_i(r) = (dV_i/dr)r/r$ and $s = h/2\sigma$ into the general form for the SOC term [25, 26]

$$H_{SOC} = -\frac{h}{4m_0^2c^2}(\nabla V \times p) \cdot \sigma,$$

(6)
to obtain the SOC in the form of

$$H_{SOC} = \lambda(r)L \cdot \sigma,$$

(7)
where $\lambda(r) = 1/2m_0^2c^2r(dV/dr)$ is a radial function whose value depends on the type of atomic species. In the above equations, $\hbar, m_0, c$ and $p$, are Plank constant, free mass of electron, speed of light, and momentum, respectively; and $\sigma, L$ and $s$ represent the Pauli matrices, angular momentum operator and electron spin operator, respectively.

Using the well known ladder operators $L_{\pm}$ and $S_{\pm}$, one can obtain the matrix representation of the SOC Hamiltonian in the basis set of $|s_1, p_{x1}, p_{y1}, s_2, p_{x2}, p_{y2}\rangle \otimes |\uparrow, \downarrow\rangle$ for monolayer GeCH$_3$ with matrix elements

$$\langle \alpha_i | H_{SOC} | \beta_i \rangle = \lambda_i < L \cdot \sigma >_{\alpha\beta},$$

(8)

where $\alpha_i$ and $\beta_i$ represent the atomic orbitals of $i$-th atom. Note that since the two atom basis in the unit cell of the monolayer GeCH$_3$ are the same, we have $\lambda_1 = \lambda_2 = \lambda$.

Thus, the representation of the SOC Hamiltonian in the above mentioned basis is

$$H_{SOC} = \begin{bmatrix} H_{SOC}^{\uparrow\uparrow} & H_{SOC}^{\uparrow\downarrow} \\ H_{SOC}^{\downarrow\uparrow} & H_{SOC}^{\downarrow\downarrow} \end{bmatrix},$$

(9)
whose elements are $6 \times 6$ matrices with $H_{SOC}^{\uparrow\downarrow} = H_{SOC}^{\downarrow\uparrow} = 0$, and

$$H_{SOC}^{\uparrow\uparrow} = \lambda \begin{bmatrix} 0 & 0 & 0 \\ 0 & 0 & -i\sigma_z \\ 0 & i\sigma_z & 0 \end{bmatrix}, \quad H_{SOC}^{\downarrow\downarrow} = \lambda \begin{bmatrix} 0 & 0 & 0 \\ 0 & 0 & i\sigma_z \\ 0 & -i\sigma_z & 0 \end{bmatrix}.$$  

(10)

The value of the strength $\lambda$ of the SOC should be chosen either in agreement with experiment or by fitting the TB bands to the ab-initio results near some $k$ points such that it gives the correct band gap. In order to evaluate the strength of the SOC for Ge atoms in monolayer GeCH$_3$, we fitted the spectrum obtained from our multi-orbital TB model to the one from density functional calculations within the local density approximation (LDA) for the exchange correlation in Ref. [17]. As shown in Fig. 5, there is excellent agreement between the TB spectrum and the DFT results for the SOC strength $\lambda = 0.096$ eV. We adopt this SOC strength in the following calculations of the TB spectrum when we use the hopping parameters from Table II.

The TB energy spectrum of monolayer GeCH$_3$ are shown in Figs. 6 (a) and (b) for 0% and 12.5% strain, respectively. Note that due to the presence of time reversal and inversion symmetry, each band in the energy spectrum of monolayer GeCH$_3$ is doubly degenerate. As shown in Fig. 7, by applying biaxial tensile strain, the global band gap located at $\Gamma$ gradually decreases and eventually a band inversion occurs at 11.6% strain. By further increasing strain, the induced band gap due to SOC, (see Figs. 6(b), and (c)) becomes indirect, and at a reasonable strength of 12.8% reaches the value of 115 meV.

One can use the TB spectrum of Figs. 6, to calculate the effective masses of electrons and holes near the conduction band minimum (CBM) and the valence band maximum (VBM). The results, in unit of free electron mass $m_0$, are listed in Table III for 0%, 6%, 9%, and 12.5% biaxial tensile strain. Note that, the electron and...
FIG. 7. The calculated band gaps of monolayer GeCH$_3$ as a function of biaxial strain at the Γ point, $E_\Gamma$, and the global gap $E_g$. The two distinct colored regions show the different trivial and band inverted phases.

TABLE III. The effective mass of electron and hole near the CBM and VBM in unit of free electron mass $m_0$. The electron and hole effective masses along the two directions of Γ-K and Γ-M are the same.

| Strain (%) | Effective mass ($m/m_0$) | Electron | Hole |
|-----------|--------------------------|----------|------|
| 0%        | 0.135                    | 0.157    |
| 6%        | 0.074                    | 0.105    |
| 9%        | 0.045                    | 0.058    |
| 12.5%     | 0.033                    | 0.316    |

Another way to test the validity of our TB model, is its ability to predict a possible topological phase transition in the electronic properties of monolayer GeCH$_3$. In the next section we will study the strain-induced topological phase in monolayer GeCH$_3$ using our TB model.

IV. TOPOLOGICAL PHASE TRANSITION OF MONOLAYER GeCH$_3$ UNDER STRAIN

In the previous section, using the TB model including SOC, we showed that monolayer GeCH$_3$ is a NI. We also showed that one can manipulate its electronic properties by applying in-plane biaxial strain. It is clear from Eq. (8) that SOC preserves the TRS. Thus, the monolayer GeCH$_3$ can exhibit a QSH phase when its energy spectrum is manipulated by an external parameter that does not break TRS. The $Z_2$ classification is a well known approach to distinguish between the two different NI and TI phases [1, 2]. In the following, we briefly introduce the lattice version of the Fu-Kane formula [27], to calculate the $Z_2$ invariant. Then, we show numerically that by applying biaxial tensile strain, a change in the bulk topology of monolayer GeCH$_3$ occurs.

A. Calculation of the $Z_2$ invariant

The Fu-Kane formula [27], for the calculation of the $Z_2$ invariant is given by

$$Z_2 = \frac{1}{2\pi i} \left[ \oint_{\text{HBZ}} dk \cdot \mathbf{A}(k) - \int_{\text{HBZ}} d^2k F(k) \right] \pmod{2}, \quad (11)$$

where the integral is taken over half the Brillouin zone as denoted by HBZ. Here, the Berry gauge potential $\mathbf{A}(k)$, and the Berry field strength $F(k)$ are given by $\sum_n (u_n(k)|\nabla_n u_n(k))$, and $\nabla_k \times \mathbf{A}(k) |_z$, respectively; where $u_n(k)$ represents the periodic part of the Bloch wave function with band index $n$, and the summation in $\mathbf{A}(k)$ runs over all occupied states.

Note that, in this approach one has to do some gauge fixing procedure [28] to fulfill the TRS constraints and the periodicity of the $k$ points which are related by a reciprocal lattice vector $G$. Moreover, due to the TRS and the inversion symmetry in monolayer GeCH$_3$, each band is at least doubly degenerate. Therefore, one needs to generalize the definition of $\mathbf{A}$ and $F$ to non-Abelian gauge field analogies [29] constructed from the 2M dimensional ground state multiplet $|\psi(k)\rangle = (|u_1(k)\rangle, ..., |u_{2M}(k)\rangle)$, associated to the Hamiltonian $H(k)|u_n(k)\rangle = E_n(k)|u_n(k)\rangle$ [28, 29].

FIG. 8. Conversion of the equivalent (a) rhombus shape of the honeycomb Brillouin zone in $k$ space into a (b) unit square in $q$ space.

In order to compute the $Z_2$ invariant, a lattice version of Eq. (11) is more favorable for numerical calculations. To this end, one can simply convert the equivalent rhombus shape of the honeycomb Brillouin zone in $k$ space as shown in Figs. 8(a) and (b), into a unit square in $q$ space by the following change of variables

$$k_x = \frac{2\pi}{a} (q_x - q_y), \quad k_y = \frac{2\pi}{\sqrt{3}a} (q_x + q_y). \quad (12)$$
In the next subsection we examine the formation of topologically protected edge states in a typical nanoribbon with zigzag edges when the system is driven into the TI phase by applying biaxial tensile strain.

B. Electronic properties of GeCH$_3$ nanoribbons under strain

The appearance of helical gapless states at the edge of a 2D topological insulator, is a crucial consequence of its nontrivial bulk topology. In the previous section, we showed that a jump from 0 to 1 in the $Z_2$ invariant for biaxial strain at $\epsilon > 11.6\%$ takes place, demonstrating a topological phase transition in the electronic properties of monolayer GeCH$_3$. As an example, in this subsection, we study the 1D energy bands of GeCH$_3$ nanoribbons with zigzag edges in the presence of biaxial tensile strain. Our TB model predicts the appearance of topologically protected edge states with increasing strain when the $Z_2$ invariant becomes 1. We denote the width of the zigzag GeCH$_3$ nanoribbon (z-GeCH$_3$-NR) by $N$, which is the number of zigzag chains across the ribbon width. To calculate the energy spectrum of a z-GeCH$_3$-NR with width $N$, we construct its supercell Hamiltonian ($H^{SC}$) in the basis of $|\psi\rangle \equiv |s_{H_0}, s_1, p_{x1}, p_{y1}, ..., s_{2N}, p_{x2N}, p_{y2N}, s_{H_1}\rangle \otimes |\uparrow, \downarrow\rangle$ where $s_i$, $p_{x,i}$, and $p_{y,i}$ represent the $s$, $p_x$, and $p_y$ orbitals of Ge atoms along the nanoribbon width. $|s_{H_0}\rangle$ and $|s_{H_1}\rangle$ represent the atomic orbitals of H atoms that are introduced to passivate the Ge atoms on each edge, respectively. We assume that the width of the nanoribbon is large enough that the interaction between the two edges is negligible, and one can safely neglect the tiny change of the hopping parameters due to the passivation procedure. Therefore, one can write the matrix elements of the nanoribbon Hamiltonian $H^{SC} = H^{SC}_{H} + H^{SC}_{SOC}$ as

$$M_{\alpha,i,i'}^{\sigma',\sigma} = \langle \psi | H^{SC} | \psi \rangle_{\alpha,i,i'}^{\sigma',\sigma} = E_{\alpha,i} \delta_{i,i'} + \delta_{\sigma,\sigma'} \sum_{n} t_{\alpha,i,i'}^{n} e^{i\mathbf{R}_{bn}} + \lambda_{i} \delta_{ij} < L \cdot \sigma >_{\alpha\beta}^{\sigma',\sigma},$$

(17)

where $i,j$ are the basis site indices in a supercell; $\alpha, \beta$ denote the atomic orbitals; $\sigma, \sigma'$ denote the spin degrees of freedom; and $\mathbf{R}_{bn}$ is the translational vector of the $n$-th supercell. The corresponding onsite energy of Ge atoms and the hopping parameters pertaining to the Ge-Ge bonds are substituted from Tables I and II. Moreover, one has to define the onsite energy $E_{H}^{\alpha}$ and the hopping parameters $t_{H,Ge}^{xy}$ and $t_{H,Ge}^{sp}$ in the above equation corresponding to the matrix elements related to the H-Ge bond. We adopt from the fitting procedure the numerical values $E_{H}^{\alpha} = -2.54$ eV, $t_{H,Ge}^{xy} = V_{H,Ge}^{x} = -4.54$ eV, and $t_{H,Ge}^{sp} = \pm V_{H,Ge}^{sp}$ with $V_{H,Ge}^{sp} = 0.5$ eV where the lower (upper) H-Ge edge bonds. One can diagonalize the corresponding TB Hamiltonian, Eq. (17), in or-
der to obtain the energy spectrum. By applying biaxial tensile strain we found that the band gap of the nanoribbon gradually decreases and eventually the metallic edge states protected by TRS appear for a strain value where a band inversion takes place in the TB energy spectrum of bulk monolayer GeCH$_3$. The numerically calculated energy bands of z-GeCH$_3$-NR with $N = 40$ in the presence of 9%, 11%, and 13% biaxial tensile strain are shown in Figs. 10(a), (b), and (c), respectively. This demonstrates a topological phase transition from the NI to the QSH phase in the electronic properties of monolayer GeCH$_3$.

V. CONCLUSIONS

To conclude, we have proposed an effective TB model with and without SOC for monolayer GeCH$_3$ including $s$, $p_x$, and $p_y$ orbitals per atomic site. Our model reproduces the low-energy spectrum of monolayer GeCH$_3$ in excellent agreement with ab-initio results. It also predicts accurately the evolution of the band gap in the presence of biaxial tensile strain. By including the SOC, this band gap manipulation leads to a band inversion in the electronic properties of monolayer GeCH$_3$, giving rise to a topological phase transition from NI to QSH. Our model predicts that this phase transition takes place for 11.6% biaxial tensile strain as verified by the $Z_2$ formalism. The topologically protected global bulk gap at a strain of 12.8% is 115 meV, which is much larger than the thermal energy at room temperature and makes monolayer GeCH$_3$ a promising candidate for future applications. We also showed the emergence of topologically protected edge states in a typical z-GeCH$_3$-NR in the presence of biaxial strain larger than 11.6%. This is an additional confirmation of the existence of the TI phase in the electronic properties of monolayer GeCH$_3$.
