Surg J (NY) 2022;8:e22–e27.

Maxillofacial trauma can lead to both acute and more long-term symptoms, such as vision disturbance and enophthalmos, jaw-related problems, malocclusion, and sensibility disturbance. In addition, maxillofacial injuries can be associated with cosmetically disturbing facial deformities and scars and can have a negative psychological impact.1–4

For many decades, research within the field of maxillofacial trauma has focused mostly on surgical outcome measured objectively or assessed by a doctor/surgeon. However, over the last years there is an increasing amount of studies taking the patients’ experience into account using patient-reported outcome (PRO) instruments to evaluate symptoms and health-related quality of life (HRQL) after facial trauma.5–8

In several fields of medical research the introduction of PRO instruments has revealed differences in the patients’ and the doctors’ point of view regarding symptom burden and treatment outcomes.9 As a case in point, the prevalence of

Abstract

Background  The aim of this study was to assess patient-reported symptoms and health-related quality of life, 12 to 24 months after injury in patients with midfacial fractures.

Methods  Patients diagnosed with midfacial fractures were assessed regarding symptoms related to the fracture as well as assessment of the patients overall health-related quality of life using the Gothenburg Trismus Questionnaire (GTQ), the Folkestad facial trauma questionnaire, and EuroQol five-dimensional (EQ-SD). Questionnaires were distributed to the study patients 12 to 24 months after the trauma. Medical records were retrospectively surveyed for age, gender, trauma etiology, date of injury, fracture classification, treatment regimen, and time of surgery.

Results  Sixty-seven percent of the study group reports sensibility disturbance in the face 12 to 24 months after trauma and 52% reported cosmetic consequences related to the trauma. Numbness in the face was the symptom reported to be most disturbing for the patients. Few of the patients reported severe jaw-related problems, problems with muscular tension, or eating limitation according to the validated questionnaire GTQ.

Conclusion  Sensibility disturbance remains a significant and common symptom 12 to 24 months after midfacial trauma. There is a need for a validated patient-reported outcome instrument for facial trauma that covers multiple aspects of facial trauma such as vision disturbance and diplopia, jaw-related problems, and facial pain as well as sensibility disturbance and cosmetic consequences.

Abstract

Background  The aim of this study was to assess patient-reported symptoms and health-related quality of life, 12 to 24 months after injury in patients with midfacial fractures.

Methods  Patients diagnosed with midfacial fractures were assessed regarding symptoms related to the fracture as well as assessment of the patients overall health-related quality of life using the Gothenburg Trismus Questionnaire (GTQ), the Folkestad facial trauma questionnaire, and EuroQol five-dimensional (EQ-SD). Questionnaires were distributed to the study patients 12 to 24 months after the trauma. Medical records were retrospectively surveyed for age, gender, trauma etiology, date of injury, fracture classification, treatment regimen, and time of surgery.

Results  Sixty-seven percent of the study group reports sensibility disturbance in the face 12 to 24 months after trauma and 52% reported cosmetic consequences related to the trauma. Numbness in the face was the symptom reported to be most disturbing for the patients. Few of the patients reported severe jaw-related problems, problems with muscular tension, or eating limitation according to the validated questionnaire GTQ.

Conclusion  Sensibility disturbance remains a significant and common symptom 12 to 24 months after midfacial trauma. There is a need for a validated patient-reported outcome instrument for facial trauma that covers multiple aspects of facial trauma such as vision disturbance and diplopia, jaw-related problems, and facial pain as well as sensibility disturbance and cosmetic consequences.

Maxillofacial trauma can lead to both acute and more long-term symptoms, such as vision disturbance and enophthalmos, jaw-related problems, malocclusion, and sensibility disturbance. In addition, maxillofacial injuries can be associated with cosmetically disturbing facial deformities and scars and can have a negative psychological impact.1–4

For many decades, research within the field of maxillofacial trauma has focused mostly on surgical outcome measured objectively or assessed by a doctor/surgeon. However, over the last years there is an increasing amount of studies taking the patients’ experience into account using patient-reported outcome (PRO) instruments to evaluate symptoms and health-related quality of life (HRQL) after facial trauma.5–8

In several fields of medical research the introduction of PRO instruments has revealed differences in the patients’ and the doctors’ point of view regarding symptom burden and treatment outcomes.9 As a case in point, the prevalence of
sensory disturbance after maxillofacial trauma has differed substantially (7–64%) depending on research methodology and methods of assessment.10,11 Thus, illustrating the need for PRO in clinical trials and also in clinical practice to enable direct input from the patients in a systematic manner.

To our experience there are no existing validated PRO instrument addressing and covering the different symptoms after facial trauma. In this study, we have introduced the validated Gothenburg Trismus Questionnaire (GTQ) earlier used in patients with facial trauma and orbital floor fractures, as well as the HRQL instrument Euro-Qol five-dimensional (Eq. 5D).

**Aim**

The aim of this study was to assess patient-reported symptoms and HRQL, 12 to 24 months after injury in patients with midfacial fractures.

**Material and Methods**

**Study Protocol and Data Collection**

Patients diagnosed with midfacial fractures at the ear, nose, and throat department at a tertiary referral center in Sweden during 2014 were identified using the International Statistical Classification of Diseases and Related Health Problems 10th Revision (ICD-10) diagnose coding system, from the outpatient registry.12

**Inclusion and Exclusion Criteria**

Inclusion criteria were: age > 18 years, midfacial fractures according to ICD-10 (including the following; S02.0 Fracture of vault of skull, S02.3 Fracture of orbital floor, S02.4 Fracture of malar and maxillary bones, S02.7 Multiple fractures involving skull and facial bones, S02.8 Fractures of other skull and facial bones and, S02.9 Fracture of skull and facial bones, part unspecified). Exclusion criteria were: isolated skull base fractures, nasal bone fractures, and fractures of the mandible.

Medical records were retrospectively surveyed for age, gender, trauma etiology, date of injury, fracture classification, treatment regimen, and time of surgery. Surgical approach as well as surgical method and any orbital floor implant and/or osteosynthesis material used was noted in the study protocol.

**Fracture Classification**

Fractures were classified based on the computed tomography scans as follows:

I. Isolated zygomatic arch fracture
   (a) Not displaced (< 3 mm)
   (b) Displaced (> 3 mm)
II. Orbital floor fracture
III. Medial orbit fracture
IV. Le Fort fracture
V. Zygomaticomaxillary fractures

(a) Not displaced (< 3 mm)
(b) Displaced (> 3 mm)
(c) Multifragment

**Patient-Reported Outcome**

Questionnaires regarding symptoms related to the midfacial fracture as well as assessment of the patients’ overall HRQL were distributed to the study patients 12 to 24 months after the trauma. All nonresponders were reminded once.

**Folkestad Facial Trauma Questionnaire**

This is a facial trauma-specific questionnaire including items assessing vision disturbance, cosmetic consequence from injury, sensibility disturbance, and jaw-related problems after facial trauma. The questionnaire has earlier been used and described in studies on orbital floor fractures.13,14

**Gothenburg Trismus Questionnaire**

The GTQ is a validated, symptom-specific questionnaire focusing on trismus, facial pain, jaw-related problems, and muscular tension in HNC. The GTQ consists of 21 items and 3 main domains (jaw-related problems, eating limitations, and muscular tension). GTQ score ranges from 0 to 100, where 100 indicates the maximal amount of symptoms, and 0 indicate no symptoms. The GTQ has been previously used for patients with HNC and patients with temporomandibular disorder (TMD).15

**EQ-5D**

The EQ-5D is a well-known and widely used questionnaire assessing HRQL. EQ-5D evaluates five dimensions of health and an overall rating of the patient’s experience of health.16,17

**Ethics**

The study was approved by the Regional Ethical Review Board at Gothenburg University and performed in accordance with the Declaration of Helsinki. All study subjects gave their informed consent to participate.

**Statistical Methods**

Descriptive data are presented with mean and standard deviation when applicable. For comparison between study group and lost-to-follow-up group, the Fisher’s exact test (lowest one-sided p-value multiplied by 2) was used for dichotomous variables. The Mantel–Haenszel chi-square exact test was used for ordered categorical variables and chi-square exact test was used for nonordered categorical variables. The Mann–Whitney U test was used for continuous variables.

**Results**

**Study Group and Lost to Follow-Up**

A total of 132 patients were identified with midfacial fracture according to the ICD-10 during the study year. Out of
these, postal address was possible to identify in 120 patients to whom questionnaires was sent out to. Fifty-two patients responded and were available for further analysis (► Fig. 1).

Analysis of the lost to follow-up group revealed a significantly lower mean age among the nonresponders (p-value 0.038), furthermore, patients experiencing interpersonal violence were more likely to be nonresponders (p-value 0.044). We found no other significant differences between the groups.

**Patient and Fracture Characteristics**
A majority of the study patients were men, 62%. Zygomaticomaxillary complex fractures were the most common type of midfacial fracture in our material. Sixty-two percent of the fractures were displaced (>3 mm) or multifragment. Fall accidents were the dominating cause of accident followed by sports accident and bicycle accident (► Table 1).

Regarding surgical treatment subciliary incision was the most common approach for fracture treatment. Gillies incision as well as frontozygomatic suture incision was also commonly used. A majority (86%) of the patients who needed surgical reposition of fracture were treated within 14 days from the trauma. Osteosynthesis material was used in the majority of the surgically treated cases (► Table 2).

**Patient-Reported Outcome**
More than two-thirds, 67%, of the study group reports sensibility disturbance in the face 12 to 24 months after trauma and more than half of the investigated patients, 52%, reported cosmetic consequences related to the trauma. Among the cosmetic aspects after facial trauma a visual facial scar was the most disturbing complaint. Furthermore, sensibility disturbances in the teeth were reported by 40% of the study patients (► Table 3). Numbness in the face was the symptom reported to be most disturbing for the patients (► Fig. 2).

Rather few of the patients reported severe jaw-related problems, problems with muscular tension, or eating limitation according to the validated questionnaire GTQ. For reference, mean score for patients with TMD, patients with radiation-induced trismus, and healthy controls are presented in ► Table 4. Separate analysis with regards to jaw-related problems and trismus was performed excluding orbital floor fractures, since patients with orbital floor fractures are not expected to develop trismus. The analyses revealed very small differences and are therefore reported in text only.

For assessment of HRQL according to EQ-5D, 52% of the study group reported problem with pain or discomfort and 29% reported problem with anxiety or depression (► Table 5).

| Motor vehicle accident        | 1 (2)                 |

![Fig. 1](image-url) Study flowchart.
We found that long-term sequelae after facial trauma is common and that sensibility disturbance was rated as the most disturbing symptom for the patients in this study on patient-reported symptoms 1 to 2 years after midfacial trauma.

The most common cause of trauma was fall accident in this study. Causes of injury vary a lot between different countries and the impact of late sequelae on HRQL can vary depending on the cause of injury. Earlier studies have shown that violence as the cause of injury is a risk factor for a prolonged period of convalescence and a later return to work after trauma compared with other causes of injury, as well as an increased risk of depressive symptoms.18,19

In this study, patients who were lost to follow-up were younger and to a larger extent exposed to interpersonal violence or assault compared with the study patients. This suggests that the result of the present study might be an underestimation of the actual symptom burden.

A large European research project on zygomatic fractures and mandibular fractures revealed that assault was the most common cause of injury and that predominately men are affected by maxillofacial trauma.20,21

Patient who underwent surgery reported more problems with persistent symptoms after 1 to 2 years compared with patients with fractures that were treated conservatively in this study. This is in consistency with other studies. The reason for this is multifactorial and can partially be explained by the fact that most of the surgically treated patient suffered from more complex and dislocated fractures than those treated conservatively.22

**Patient-Reported Outcome**

We found that sensibility disturbance is a common long-term sequel for facial trauma patients, in this study reported by more than two-thirds of the patients. Sensibility disturbance was graded as the most disturbing symptom 1 to 2 years after trauma.

Many studies have undertaken objective assessments for sensibility disturbance but the correlation with patient-reported symptoms are poor and risks to underestimate the problem.23 For example, Souyris et al investigated 1,394 cases of midfacial fractures and found the prevalence of sensibility disturbance to be 7.2% when assessed by the surgeon,11 whereas Sakavics et al found a prevalence of 64.4% when using both objective testing and patient-reported assessment.10 Folkestad and Granstrom compared the doctor’s assessment and patient’s experience of symptoms after facial trauma (using separate protocols for doctor and patient, at five occasions during 1 year) and showed that there is a discrepancy between the patients’ and the doctors’ experience above all when it comes to sensibility disturbance.14

All in all, the present study supports that the use of PRO is important in evaluation of sensibility disturbance and that sensibility disturbance is of great significance for the patients even though sometimes overlooked by clinicians and regarded as a mild symptom.

The second most common long-term sequel in this study was cosmetic impact from visual facial scar. More than half of the patients in the study confirmed symptoms with cosmetic impact. A study by Tebble et al showed that even smaller facial laceration can have a long-term impact on the patient and that the impact is related to both type of trauma and the patient’s level of emotional distress. Tebble et al showed that injuries caused by assault was associated with more problems with cosmetic consequences and psychological distress.24 Another study by Rahtz et al on appearance concern and trauma suggested in the same way that the cosmetic impact of trauma is correlated to the patient’s

general level of psychological distress and not specifically related to the location of the trauma.  

We found no differences in anxiety and depression compared with the norm population data according to the HRQL instrument EQ-5D as one could have expected given the facial trauma. Again, patients exposed to interpersonal violence were underrepresented in our material and might have revealed another picture.

In this study, the prevalence of trismus and jaw-related problems was low. When comparing the results from the study patients with HNC patients and TMD patients, patients with midfacial fractures scored very low and more in line with a healthy population. Very few studies have focused on trismus and jaw-related problems after midfacial trauma. Chang et al studied patients with zygomaticomaxillary complex fractures with and without involvement of the temporomandibular joint (TMJ) and found that trismus is very common preoperatively both when the joint is involved and not, but a majority of the patients improves after surgery. Folkestad and Granstrom found a significant difference between the doctor’s assessment and patient’s experience of restricted mouth opening both preoperatively and at

---

Fig. 2 Impact of patient-reported symptoms after midfacial trauma. How often symptoms are disturbing, Visual Analogue Scale (VAS) score in mm (0–100) where 0 means never disturbing and 100 means always disturbing. Mean and 95% confidence interval (CI).
1 month after surgery. There was no TMJ involvement in any of these cases.14

Facial trauma is described as one of the etiological factors to the development of TMD but it seems that that the risk of more longstanding jaw-related problems is evident primarily when the mandible joint or TMJ is directly involved in the fracture.27,28

Regarding the PRO instruments introduced in this study we conclude that the GTQ, which is a symptom-specific and validated instrument, could not as a whole detect the patients’ main problems especially with sensibility disturbances. The Folkestad facial trauma questionnaire that has earlier been used in studies on orbital floor fracture is relevant but needs validation and psychometric testing in a larger patient cohort.

**Study Limitations**

A limitation of this study is the cross-sectional design where baseline data and symptoms pre- and postoperatively cannot be assessed. The dropout rate was high in terms of non-responders to the questionnaires used in the study.

**Conclusion**

Sensibility disturbance remains a significant and common symptom 12 to 24 months after midfacial trauma. The use of PRO instrument is warranted but also challenging in this group of patients. There is a need for a validated PRO instrument for facial trauma that covers multiple aspects of facial trauma such as vision disturbance and diplopia, jaw-related problems, and facial pain as well as sensibility disturbance and cosmetic consequences.
