FRB 121102: A Repeatedly Combed Neutron Star by a Nearby Low-luminosity Accreting Supermassive Black Hole

Abstract

The origin of fast radio bursts (FRBs) remains mysterious. Recently, the only repeating FRB source, FRB 121102, was reported to possess an extremely large and variable rotation measure (RM). The inferred magnetic field strength in the burst environment is comparable to that in the vicinity of the supermassive black hole Sagittarius A* of our Galaxy. Here, we show that all of the observational properties of FRB 121102 (including the high RM and its evolution, the high linear polarization degree, an invariant polarization angle across each burst and other properties previously known) can be interpreted within the “cosmic comb” model, which invokes a neutron star with typical spin and magnetic field parameters whose magnetosphere is repeatedly and marginally combed by a variable outflow from a nearby low-luminosity accreting supermassive black hole in the host galaxy. We propose three falsifiable predictions (periodic “on/off” states, and periodic/correlated variation of RM and polarization angle) of the model and discuss other FRBs within the context of the cosmic comb model as well as the challenges encountered by other repeating FRB models in light of the new observations.

Key words: pulsars: general – radiation mechanisms: non-thermal – radio continuum: general

1. Introduction

Despite the rapid development in the observational front of fast radio bursts (FRBs; Lorimer et al. 2007; Thornton et al. 2013; Masui et al. 2015; Petroff et al. 2015a; Champion et al. 2016; DeLaunay et al. 2016; Keane et al. 2016; Spitler et al. 2016; Chatterjee et al. 2017), we still do not know how these mysterious bursts are generated. Out of about two dozen FRB sources currently known, only one source, FRB 121102, was observed to repeat (Scholz et al. 2016; Spitler et al. 2016; Law et al. 2017), and it was precisely localized in a star-forming region within a low-metallicity dwarf galaxy at $z = 0.193$ and is additionally associated with a persistent radio source (Bassa et al. 2017; Chatterjee et al. 2017; Marcote et al. 2017; Tendulkar et al. 2017).

Recently, Michilli et al. (2018) reported some new observational results of FRB 121102 that brought important clues to understand the origin of this source. These authors found that the radio emission of FRB 121102 is almost 100% linearly polarized with an essentially constant polarization angle within each burst (but can vary among bursts). More intriguingly, these bursts have a very large value of Faraday rotation measure (RM) that varies in the range from $+1.46 \times 10^5$ to $+1.33 \times 10^5$ radians per square meter within seven months in the source reference frame. Such a large value of RM was discovered in the vicinity of the supermassive black hole in our galaxy, Sagittarius A* and toward the active galactic nuclei (AGNs) in some galaxies (Bower et al. 2003; Marrone et al. 2007). Michilli et al. (2018) argued that the Faraday screen is local to FRB 121102 and estimated that the magnetic field strength along the line of sight is $B_\parallel = (0.6 - 2.4) f_{\text{DM}}$ mG, where $f_{\text{DM}} > 1$ is a parameter to denote the ratio between the dispersion measure (DM) in the host and the DM that contributes to the RM. This magnetic field is orders of magnitude stronger than that in the interstellar medium but is consistent with the environment in the vicinity of a supermassive black hole (Eatough et al. 2013). According to this picture, the steady radio source associated with FRB 121102 (Chatterjee et al. 2017; Marcote et al. 2017) could be powered by a low-luminosity accreting supermassive black hole, and the surrounding star formation (Bassa et al. 2017) could represent a circum-black-hole starburst (Michilli et al. 2018).

Here, we show that all of the observations of FRB 121102 can be adequately interpreted within the framework of the “cosmic comb” model (Zhang 2017). Within this model, an FRB is generated when an astrophysical gas flow (stream) interacts with the magnetosphere of a foreground neutron star. If the ram pressure of the stream exceeds the magnetic pressure at the light cylinder of the neutron star, the magnetosphere would be combed toward the opposite direction of the stream origin. As the combed magnetosphere sweeps the line of sight, an Earth-based observer detects an FRB. For FRB 121102, the source of the stream is the low-luminosity accreting supermassive black hole, which sporadically ejects a nearly isotropic disk wind outflow with a varying ram pressure during the accretion process (e.g., Yuan et al. 2012).

2. The Model

2.1. Model Setup

Michilli et al. (2018) stated that the large RM value detected from FRB 121102 is similar to those seen toward massive black holes. For example, RM $\approx -5 \times 10^5$ rad m$^2$ is measured in the Milky Way’s central black hole Sagittarius A*, and RM $\approx -7 \times 10^5$ rad m$^2$ is measured at a projected distance $\sim 0.1$ pc ($\sim 10^6$ Schwarzschild radii) for the Galactic Center magnetar PSR J1745-2900 (Eatough et al. 2013). It is not known how magnetic field strength and configuration of supermassive black holes vary from case to case. Considering that the putative massive black hole is $\sim 2$ orders of magnitude less massive than the Sagittarius A* black hole (Michilli et al. 2018)

\footnote{In the original paper (Zhang 2017), the source of the stream was not specified, even though a young magnetar was regarded as a plausible source.}
and assuming that the magnetic field strengths of supermassive black holes are similar near the event horizon, the physical distance of the neutron star from the putative black hole of FRB 121102 would be of the order of 0.001 pc. For easy discussion, in the following, we perform our quantitative estimations with the distance of the neutron star normalized to the fiducial distance \( r_{\text{NS}} = 0.001 \text{ pc} \) from the central black hole.\(^2\) Consider a sporadic wind from the black hole with a typical dimensionless velocity \( \beta = 0.01 \beta_2 \) (i.e., 3000 km s\(^{-1}\)), the ram pressure of the stream at \( r_{\text{NS}} \) is (Zhang 2017)

\[
P_{\text{ram}} \simeq (160 \text{ erg cm}^{-3}) \left( \frac{M}{M_\odot} \right) \left( \frac{r_{\text{NS}}}{10^{-3} \text{ pc}} \right)^2 \beta_2^2.
\]

Requiring \( P_{\text{ram}} \gtrsim P_{\text{BLC}} = (B_z^2/8\pi)(\Omega R/c)^6 \), one can constrain the neutron star parameters

\[
B_{\text{z,13}} P^{-6} \lesssim 46 \left( \frac{M}{M_\odot} \right) \beta_2 \left( \frac{r_{\text{NS}}}{10^{-3} \text{ pc}} \right)^2.
\]

Here, \( P, \Omega, B_z \), and \( R \) are the period, angular frequency, surface magnetic field, and radius, respectively. Many Galactic pulsars satisfy such a condition. So the neutron star invoked in our model is a typical radio pulsar, which is otherwise undetectable in a distant galaxy.

### 2.2. Data Interpretation

Such a setup can account for all of the observational data of FRB 121102:

1. **Large RM:** One may not be able to estimate the magnetic field strength near a supermassive black hole from first principles. However, analogous to observations of the Galactic supermassive black hole Sagittarius A\(^*\) (Bower et al. 2003; Marrone et al. 2007; Eatough et al. 2013), our setup implies a magnetic field strength in the milli-Gauss range in the environment of the FRB source, which can account for the large RM as observed.

2. **RM variation:** The variation of the RM value is about \((9–10)\%\) during a period of seven months. Within our model, this variation may be accounted for by the change of \( B_1 \) integral due to the orbital motion of the neutron star around the black hole (Figure 1(a)).\(^3\) For a black hole of mass \( M_{\text{BH}} \sim (10^4–10^6) M_\odot \), so that significant RM variation is expected during the spin of observations. As the observations were not continuous, the Arecibo observations and the

\[ P_{\text{orb}} = 9.4 \Delta \left( \frac{r_{\text{NS}}}{10^{-3} \text{ pc}} \right)^{3/2} \left( \frac{M_{\text{BH}}}{10^5 M_\odot} \right)^{-1/2}. \]

In view of the uncertainty in \( r_{\text{NS}} \) and \( M_{\text{BH}} \), there is a large parameter space where seven months is of the order or much longer than \( P_{\text{orb}} \), so that significant RM variation is expected during the span of observations. As the observations were not continuous, the Arecibo observations and the GBT observations likely picked up the neutron star at different orbital phases, and a \((9–10)\%\) variation of RM can be accounted for. Observationally, there is only a small \((\sim 0.2\%)\) but systematic decrease of RM within the timescale of \((1–2)\) days (when the first 15 bursts reported in Table 1 of Michilli et al. 2018 were discovered). On the other hand, a more significant decrease in RM is seen during the next two observational epochs spanning in the months timescale (Michilli et al. 2018). As a result, \( P_{\text{orb}} \) would be much longer than a day, but may not be much longer than the timescale of months. This is consistent with Equation (3) given the uncertainty in both \( r_{\text{NS}} \) and \( M_{\text{BH}} \). If the RM variation is mostly caused by the geometric effect (i.e., \( B_1 \) integral variation as the neutron star orbits the black hole) rather than the fluctuation of the electron number density (which would also be associated with a variation in DM),

\[ e.g., B \propto r^{-3} \text{ for a dipolar configuration} \]

\[ \text{so that the RM of the bursts is most sensitively related to the magnetic field strength and orientation at the immediate environment of the neutron star.} \]

\[ \text{The discussion can be generalized to any distance based on the scaling laws with respect to } r_{\text{NS}}. \]

\[ \text{The magnetic field strength in the black hole vicinity is expected to decrease with radius rapidly (e.g., } B \propto r^{-3} \text{ for a dipolar configuration) so that the RM of the bursts is most sensitively related to the magnetic field strength and orientation at the immediate environment of the neutron star.} \]
then one would expect a periodic variation of RM in the timescale of weeks to months (period defined by $P_{\text{orb}}/2$). Long-term monitoring of the source with RM measurements is encouraged to test such a prediction.

3. Linear polarization and non-varying polarization angle: The emission mechanism of an FRB in the cosmic comb model is bunching coherent curvature radiation (Zhang 2017; Yang & Zhang 2017a). The emission is expected to be highly polarized with the polarization angle defined by the direction of the magnetic field lines. Because in the combing model the magnetosphere of the neutron star is always combed from the black hole to the direction of the neutron star, the polarization angle is defined by the projection of that direction in the sky for each burst, which remains constant across the burst (Figure 1(b)). Different bursts are produced as the neutron star is at different phases within the orbit, so that the polarization angle may vary from burst to burst.\(^4\) For a nearly edge-on system, the polarization degree may vary moderately for most phases but more significantly as the neutron star moves close to the line of sight. These are all consistent with the observations of FRB 121102 (Michilli et al. 2018). Michilli et al. (2018) disfavored the possibility that an emission beam sweeps across the line of sight based on the non-varying polarization angle. This is certainly a valid argument against the models invoking emission from the inner magnetosphere of a rotation-powered pulsar or magnetar (e.g., Connor et al. 2016; Cordes & Wasserman 2016; Metzger et al. 2017; Kumar et al. 2017). However, for the comb model, this is not a concern, as the field line direction remains the same during each combing event, so that the duration of an FRB can be defined by the time when the combed beam sweeps across the line of sight (Zhang 2017).

4. Repetition and temporal structure of the bursts: FRB 121102 was observed to emit multiple bursts within the time span of several years. Within the cosmic comb model, the neutron star magnetosphere needs to be repeatedly combed. This requires that the outflow from the central black hole is unsteady with a variable velocity and density so that the ram pressure $P_{\text{ram}} = \rho v^2$ fluctuates with time. As a stream with $P_{\text{ram}} > P_{\text{B,LC}}$ reaches the neutron star, the magnetosphere is combed to produce one burst. After the stream passes by, $P_{\text{ram}}$ drops below $P_{\text{B,LC}}$ and the magnetosphere would relax to the original configuration. Another burst is produced when another stream with $P_{\text{ram}} > P_{\text{B,LC}}$ arrives. The sporadic behavior of the bursts detected from FRB 121102 reflects the sporadic accretion behavior of the central black hole. Some repeating bursts from FRB 121102 have separations as short as $\Delta t \sim 20$ s. This requires that the spatial variation of the black hole outflow can be as small as $v(\Delta t) \sim 6 \times 10^3 \beta_{-2}(\Delta t/20 \text{ s})$ cm. The timescale is shorter than the dynamical timescale at the black hole horizon, suggesting that the variability is caused by local small-scale processes in the disk wind, most likely due to magnetic reconnection (e.g., Giannios et al. 2009; Zhang & Yan 2011). As the neutron star is repeatedly combed, given a certain range of $P_{\text{ram}}$ variation, the combing events must be “marginal”, i.e., $P_{\text{ram}}$ is slightly greater than $P_{\text{B,LC}}$ when a combing event happens. The magnetospheric structure of the neutron star is not completely removed. The produced FRB would have a temporal structure as an imprint of the original magnetospheric structure, and may occasionally even have double peaks when the two pressures are comparable. This is consistent with the observed temporal features of the FRB 121102 bursts (Spitler et al. 2016; Michilli et al. 2018).

5. Non-varying DM: Unlike a very young supernova remnant, the massive-black-hole-powered radio source is likely in a quasi-steady state within the timescale of years (e.g., in analogy to AGNs). Our model requires that the neutron star orbit (with a nominal radius of $\sim 0.001$ pc) is much smaller than the extent of the persistent radio source, the projected size of which is $\sim 0.7$ pc (Marcote et al. 2017). With such a configuration, the electron column density at the source likely remains essentially constant as the neutron star moves in its orbit. In principle, a small periodic variation of DM (with period $P_{\text{orb}}/2$) is possible, but the amplitude of variation is much smaller than that of RM, so that it may not be detectable.

6. Energy budget and luminosity of the bursts: The burst energy budget in the comb model ultimately comes from the accretion power of the supermassive black hole, which is essentially unlimited.\(^5\) Within the theoretical framework of coherent curvature radiation by bunches, the luminosity (and brightness temperature) of an FRB depends on the fluctuating charge density in the magnetosphere (which scales with the local Goldreich-Julian density), the cross section, and the opening angle (of the order $1/\gamma_e$, where $\gamma_e$ is the Lorentz factor of electrons flowing inside the sheath) of the bunches. An advantage of the comb model is that the magnetic fields are combed to be nearly parallel to each other, so that the cross section of the bunch is much larger than the bunches from the polar cap region. The desired extremely high brightness temperature of FRBs is achievable with reasonable parameters without demanding a strong local magnetic fields (in contrast to the magnetar model). See Section 7.2 of Yang & Zhang (2017a) for details.

7. Duration: The duration of a burst is defined by the timescale when the combed emission beam sweeps the line of sight, which may be estimated as $\Delta t \sim \frac{R_{\text{sh}}}{v_{e}} \approx (3.3 \text{ ms})R_{\text{sh}}/\beta_{-2}^{\frac{1}{3}}\gamma_e^{\frac{1}{3}}$, where $R_{\text{sh}}$ is the sheath radius, $\gamma_e$ is the typical electron Lorentz factor (Zhang 2017).

8. Spectrum: Given reasonable parameters, the typical frequency is in the GHz range (Zhang 2017; Yang & Zhang 2017a). The spectral index in the high-frequency regime varies from $-1.3$ to $-3.3$ for a reasonable value of electron energy spectral index. In the low-frequency regime, synchrotron self-absorption from the FRB-heated nebula would play a role to shape the spectrum and make a positive spectral index (Yang et al. 2016; Yang & Zhang 2017a). The predicted spectrum is therefore narrow. For different bursts, the peak frequency may vary slightly. This would result in a significant variation of the spectral indices in individual bursts, from steep

---

\(^4\) Due to the sporadic nature of the incoming streams that comb the neutron star, the evolution of the polarization angle may not be monotonic in a short period of time. However, long term, one would observe a global trend of orbital evolution.

\(^5\) This is different from the magnetar model whose energy budget is limited by the spin and magnetic energy of the neutron star.
positive spectral slopes (when the peak frequency is above the observational band) to steep negative spectral slopes (when the peak frequency is below the observational band), as observed in the bursts of FRB 121102 (e.g., Spitler et al. 2016; Law et al. 2017). See Section 7.2 of Yang & Zhang (2017a) for a more detailed discussion.

### 2.3. Falsifiable Predictions

This model has three falsifiable predictions that can be tested with future data:

1. In order to have a combed beam sweep an Earth-based observer, Earth must be on the “night” side of the neutron star with respect to the supermassive black hole. As a result, only during half of the time in the neuron star orbit could repeating bursts be detected. The detected bursts should in principle have a $P_{\text{orb}}/2$ period, but as another condition $P_{\text{ram}} > P_{B,LC}$ is needed to trigger a burst, one may not detect a periodic signal of the detected bursts due their sporadic nature. In any case, an “on” phase and an opposite “off” phase will alternate, even though it is possible to detect no bursts during the “on” phase. Applying an “on-off” template with different assumed $P_{\text{orb}}$ to the available data may lead to a constraint on the allowed range of $P_{\text{orb}}$.

2. As explained above, this model predicts a periodic variation of the RM (with period $P_{\text{orb}}/2$). For those bursts detected in the “on” phase, one could measure their RM and systematically search for possible periodicity of its variation to constrain $P_{\text{ram}}$. As the occurrence of the bursts is rather sporadic, very long-term monitoring of the source is needed to verify this prediction.

3. Different bursts correspond to different phases in the neutron star orbit. One therefore predicts a periodic variation of the polarization angle with period $P_{\text{orb}}/2$, even though it is constant in each individual burst (Figure 1(b)). The orbital variations of polarization angle and RM should be correlated.

### 3. Discussion

We have shown that the currently available data of FRB 121102 can be adequately interpreted within the framework of the cosmic comb model (Zhang 2017). In the following, we discuss the implications of this conclusion for other FRBs and other FRB models.

#### 3.1. Other FRBs

Thus far, FRB 121102 is the only FRB observed to repeat. One may speculate that other FRBs also repeat but their repeated bursts have not been detected. However, considering the non-detection limits of other FRBs and assuming that all FRBs are similar to FRB 121102, the probability that other bursts are not detected yet is found to be very low ($<10^{-5}$), so that there could be more than one population of FRBs (Palaniswamy et al. 2018). Observationally, most non-repeating FRBs seem to have no temporal structure, with the width mainly defined by the scattering tail as the burst propagates in the interstellar/intergalactic medium (Keane et al. 2016).

It is possible that some non-repeating FRBs might be of a different physical origin, e.g., related to catastrophic events such as collapse of supermassive neutron stars (Falcke & Rezzolla 2014; Zhang 2014) or mergers of compact objects (Totani 2013; Zhang 2016; Wang et al. 2016). On the other hand, if all FRBs have the same physical origin, then those non-repeating FRBs may be understood in terms of strong (rather than marginal) combing events with $P_{\text{ram}} \gg P_{B,LC}$. As the magnetosphere pressure is much smaller than the ram pressure, the imprint of the magnetosphere structure in the light curve would be diminished, so that the detected burst would not show a significant temporal structure. The magnetosphere hardly relaxes during the passage of the stream so that no repeating burst is detectable short term. Another burst may be detected when another violent flare occurs. This would suggest a much longer waiting time than the typical waiting time of FRB 121102, consistent with the non-detection of repeating bursts despite intense searches (Petroff et al. 2015b). The astrophysical streams invoked in these events should be more violent. One example is FRB 150418 (Keane et al. 2016), whose bursting time coincided with an AGN flare in the field of view (Williams & Berger 2016; Johnston et al. 2017). Because the chance probability of such an occurrence is quite low (Li & Zhang 2016), it is possible that FRB 150418 was actually produced by a foreground neutron star combed by the AGN flare (Zhang 2017). The discovery of a possible supermassive black hole near FRB 121102 (Chatterjee et al. 2017; Marcote et al. 2017; Michilli et al. 2018) greatly strengthened this possibility.

Another example was a putative gamma-ray burst associated with FRB 131104 (DeLaunay et al. 2016; Gao & Zhang 2017; Murase et al. 2017). If the association is genuine, the FRB can be from a foreground neutron star combed by the blastwave of the GRB (Zhang 2017).

#### 3.2. Other Repeating FRB Models

The current data of FRB 121102 seem to pose great challenges to most other repeating FRB models discussed in the literature.

The leading model invokes a young magnetar that was born about a decade (or decades) ago, with the coherent radio emission powered by the spin energy or the magnetic energy of the magnetar (Katz 2016; Chatterjee et al. 2017; Marcote et al. 2017; Tendulkar et al. 2017; Kashiyama & Murase 2017; Metzger et al. 2017). The strongest support to the model was the resemblance of the FRB host galaxy with the host galaxies of long GRBs and superluminous supernovae (Tendulkar et al. 2017; Nicholl et al. 2017). However, with the high-RM measurement and the possibility of a circum-black-hole starburst to interpret the data, this initial motivation to invoke a young magnetar is no longer necessary. One may argue that the magnetar wind may provide the required $B_{\odot}$ to interpret the large RM. However, such a high RM has never been observed in the vicinity of known magnetars unless it is close to the Galactic center (Michilli et al. 2018). Alternatively, one may invoke a young magnetar in the vicinity of the black hole and still require the magnetar itself to produce the bursts. However, the chance of having a young magnetar is much lower than having a typical pulsar near a supermassive black hole. One has to address the very small odds that the first young magnetar that generates repeating FRBs happens to be close to a

---

6 The stream may also have a variable ram pressure. However, as $P_{\text{ram}}$ is always much greater than $P_{B,LC}$, no repeating bursts are expected.
supermassive black hole. In any case, in order to satisfy the energy and luminosity constraints from FRB 121102 using the magnetar energy budget (spin and magnetic energy), the magnetar cannot be too young. The young magnetar model is therefore subject to tight constraints in model parameters (Piro et al. 2016; Cao et al. 2017; Kashiyama & Murase 2017; Metzger et al. 2017; Yang & Zhang 2017b; Zhang & Zhang 2017). Interpreting the variation of RM and the constant polarization angle in each burst is also non-trivial, which requires an emission site near the light cylinder. However, the extremely high brightness temperature of FRBs favors radio emission being produced in an emission region with strong magnetic fields close to the magnetar surface (Kumar et al. 2017). Such a model would predict an “S” or “reverse-S” shaped polarization angle evolution, and hence, is disfavored by the data.

Other models invoking an AGN to power FRBs (e.g., Romero et al. 2016; Vieyro et al. 2017) encounter great difficulties. In these models, FRBs are produced when a relativistic electron-positron beam hits ambient turbulent plasma clouds called cavitons to produce coherent radio emission through two-stream-instability-driven bunches. It is unclear whether such a coherent mechanism can produce the extremely high brightness temperature as observed in FRBs, and how a jet-cloud interaction may produce a narrow spectrum with a characteristic frequency in the GHz range. More severely, unlike curvature radiation in a pulsar magnetosphere, such emission is not expected to be polarized unless there is a local ordered magnetic field. Even if there is an ordered magnetic field in the medium, this field must be much weaker than that in a neutron star magnetospheric so that the emission must be greatly depolarized in the turbulent emission region. A near 100% polarization degree of the bursts from FRB 121102 has ruled out such a scenario. The same argument also applies to other FRB models invoking a maser mechanism outside the magnetosphere of a neutron star (e.g., Ghisellini 2017; Waxman 2017; Beloborodov 2017).

Finally, the asteroid-neutron-star interaction model (Geng & Huang 2015; Dai et al. 2016, 2017) also needs to explain why such systems tend to stay close to a supermassive black hole, or why there is a large and variable RM. A high-RM model within such a scenario is being developed (Z.-G. Dai 2018, private communication).

In summary, the discovery of large and variable RM from FRB 121102 bursts (Michilli et al. 2018) provides strong observational constraints on most repeating FRB models. As elaborated, the cosmic comb model can interpret all of the available data so far and has three specific falsifiable predictions. Future long-term monitoring of the source as an effort of constraining the orbital period of the neutron star using the “off” phase and the periodicity of RM and polarization angle can eventually test this model.

9 The inter-pulses of the Crab pulsar have a flat polarization angle curve, and it is commonly suggested that the emission originates from an emission region close to the light cylinder (e.g., Manchester 2005).
