(Dated: March 26, 2020)

Recently, the first ever lattice computation of the $\gamma W$-box radiative correction to the rate of the semileptonic pion decay allowed for a reduction of the theory uncertainty of that rate by a factor of $\sim 3$. A recent dispersion evaluation of the $\gamma W$-box correction on the neutron also led to a significant reduction of the theory uncertainty, but shifted the value of $V_{ud}$ extracted from the neutron and superallowed nuclear $\beta$ decay, resulting in a deficit of the CKM unitarity in the top row. A direct lattice computation of the $\gamma W$-box correction for the neutron decay would provide an independent cross-check for this result but is very challenging. Before those challenges are overcome, we propose a hybrid analysis, converting the lattice calculation on the pion to that on the neutron by a combination of dispersion theory and phenomenological input. The new prediction for the universal radiative correction to free and bound neutron $\beta$-decay reads $\Delta_0^{\text{CKM}} = 0.02477(24)$, in excellent agreement with the dispersion theory result $\Delta_0^{\text{V}} = 0.02467(22)$. Combining with other relevant information, the top-row CKM unitarity deficit persists.

Universality of the weak interaction, conservation of vector current and completeness of the Standard Model (SM) finds its exact mathematical expression in the requirement of unitarity of the Cabibbo-Kobayashi-Maskawa (CKM) matrix. Of various combinations of the CKM matrix elements constrained by unitarity, the top-row constraint is the best known both experimentally and theoretically. The 2018 value, $\Delta_{\text{CKM}}^{u} \equiv |V_{ud}|^2 + |V_{us}|^2 + |V_{ub}|^2 - 1 = -0.0006(5)$ \cite{1} \cite{2} is in good agreement with zero required in the SM, putting severe constraints on Beyond Standard Model (BSM) physics.

Notably, the main source of the uncertainty in the $\Delta_{\text{CKM}}^{u}$ constraint is theoretical: the $\gamma W$-box radiative correction (RC), prone to effects of the strong interaction described by Quantum Chromodynamics (QCD), affects the value of $|V_{ud}|$ extracted from the free neutron and superallowed nuclear $\beta$ decays. In a series of recent papers, this RC was reevaluated within the dispersion relation technique \cite{3} \cite{4}, in particular, Ref.\cite{3} observed that the universal, free-neutron correction received a significant shift, later confirmed qualitatively by Ref.\cite{4}. This shift is the main cause of the current apparent unitarity deficit, $\Delta_{\text{CKM}}^{u} = -0.0016(6)$ (using an average of $V_{us}$ from $K_{12}$ and $K_{34}$ decays \cite{2}). The slight increase in the uncertainty is due to nuclear structure effects \cite{4} \cite{5}.

Since in superallowed $\beta$ decays one aims for a $10^{-4}$ precision, it is highly desirable to assess the uncertainty and possible, unaccounted for, systematic effects in the non-perturbative regime of QCD in a model-independent way. A common limitation of the studies above is the lack of experimental data to directly constrain the hadronic matrix element relevant to the RC. By means of isospin symmetry, Ref.\cite{3} relates the input to the dispersion integral at low photon virtuality $Q^2$ to a very limited and imprecise set of data on neutrino scattering on light nuclei from the 1980s \cite{7} \cite{8}. The analysis of Ref.\cite{6} consists of pure model studies.

A complete change of landscape is expected following the first direct application of the lattice QCD to RC in lepton meson decays, $K \to \mu \nu_\mu$ and $\pi \to \mu \nu_\mu$ \cite{9}. Very recently, the first ever direct lattice calculation of the RC in semi-leptonic $\beta$ decay was presented, where the relevant hadronic matrix element responsible for the $\gamma W$-box diagram in the pion is calculated to high precision as a function of $Q^2$ \cite{10}. As a result, the theory uncertainty of the $\pi_{e3}(\pi^{-} \to \pi^{0}e\bar{\nu}_e)$ decay rate is reduced by a factor of 3. While theoretically very clean, $\pi_{e3}$ is not the easiest avenue to extract $V_{ud}$ due to its tiny branching ratio $\sim 10^{-8}$. Nonetheless, it provides useful information about the involved nonperturbative dynamics, especially its low-$Q^2$ behavior and its smooth transition to the perturbative regime. Using the same method or other approaches such as Feynman-Hellmann theorem \cite{11}, a first-principle calculation of the RC to the free neutron $\beta$ decay, while very challenging, is expected to be performed in the near future.
In this Letter, we perform a combined lattice QCD – phenomenological analysis. Making use of a body of hadron-hadron scattering data, known meson decay widths and the guidance of Regge theory and vector dominance, along with constraints from isospin symmetry, analyticity and unitarity, we are able to unambiguously relate the input into the dispersion integral for the $\gamma W$-box RC on the pion and on the neutron. Fixing the strength of the pion matrix element from the lattice, we thus obtain an estimate of an analogous matrix element on the neutron, in accord with all the aforementioned physics constraints.

We start by writing down the dispersive representation of the contribution of the $\gamma W$ box diagram (see Fig.1) to the rate of the Fermi part of a semileptonic $\beta$ decay process $H_1 \rightarrow H_f e^-\bar{\nu}_e$:

$$\delta^V_{\gamma W,H} = \frac{3\alpha}{\pi} \int_0^\infty \frac{dQ^2}{Q^2} \frac{M_{H}^2}{M_{H}^2 + Q^2} M_{3H}^{H(1, Q^2)},$$  

where $\alpha$ is the fine-structure constant. The above definition of the $\gamma W$-box correction corresponds to a shift $|V_{ud}|^2 \rightarrow |V_{ud}|^2 (1 + \delta^V_{\gamma W,H})$, affecting the apparent value of $V_{ud}$ extracted from an experiment. The function

$$M_{3H}^{H(1, Q^2)} = \frac{4}{3} \int_0^1 dx \frac{\frac{1}{1 + r_H^2} F_3^{H(1, Q^2)}(x, Q^2)}{F_+^H}$$  

stands for the first Nachtmann moment of the (spin-independent) parity-odd structure function $F_3^{H(1, Q^2)}(x, Q^2)$, resulting from the product between the axial charged current and the isoscalar electromagnetic current:

$$\frac{i\epsilon^{\mu\nu\alpha\beta} p_\alpha q_\beta}{2p \cdot q} F_3^{H(1, Q^2)}(x, Q^2) = \frac{1}{8\pi} \sum_x (2\pi)^4 \delta^{(4)}(p + q - px) \times \langle H_f(p) | J_{\mu(0)}^\mu | X \rangle \langle X | (J_W^H)_A | H_i(p) \rangle.$$

Above, $M_H$ is the average mass of $H_i$, $H_f$, $Q^2 = -q^2$, $x = Q^2/2p \cdot q$, and $r_H = \sqrt{1 + 4M_H^2x^2/Q^2}$, and the factor $F_+^H$ defines the normalization of the tree-level hadronic matrix element of the vector charged weak current:

$$\langle H_f(p) | (J_W^H)_V | H_i(p) \rangle = V_{ud} F_+^H 2p^\mu.$$

By isospin symmetry, $F_+^0 = 1$ and $F_+^{\pm} = \sqrt{2}$.

The quantity $\delta^V_{\gamma W,H}$ is the source of the largest theory uncertainty of the RC in the $\pi_{3\pi}$, free neutron $\beta$ decay, and the universal RC in superallowed nuclear $\beta$ decays, and has long been the limiting factor for the precise determination of $V_{ud}$. To obtain $\delta^V_{\gamma W,H}$ we need to know the Nachtmann moment $M_{3H}^{H(1, Q^2)}$ as a function of $Q^2$. At large $Q^2$, the product of currents in Eq. (3) is given by the leading-order (LO) operator product expansion (OPE) and the perturbative QCD (pQCD) corrections. The LO OPE + pQCD result is independent of the external state $H$ and is known up to order $O(\alpha_s^2)$, with $\alpha_s$ the strong coupling constant. However, at low $Q^2$ the structure function $F_3^{H(1, Q^2)}(x, Q^2)$ depends on details of different on-shell intermediate states $|X\rangle$ that dominate different regions of $\{x, Q^2\}$ (see Fig.2 of Ref.[4] for the explanation). Also, the transition point between perturbative and non-perturbative regime is a priori unknown, or uncertain.

The first calculation of $M_{3H}^{H(1, Q^2)}$ on the lattice in Ref.[10] serves as an important step in addressing the questions above. Its result is presented in Fig.[2] as a function of $Q^2$. At low $Q^2$ where the integral (1) is strongly weighted, lattice provides an extremely precise description of $M_{3H}^{H(1, Q^2)}$, but its uncertainty increases at large $Q^2$ due to the discretization error. Fortunately, at $Q^2 > 2\text{GeV}^2$ there exists very precise data for the first Nachtmann moment of the parity-odd structure function $F_3^{pp+\bar{p}p}$ measured in the $\nu/\bar{\nu}$ scattering on light nuclei by the CCFR Collaboration [14-15]. Their good agreement with pQCD prediction indicates a smooth transition to the perturbative regime at $Q^2 > 2 \text{GeV}^2$, which also implies that these data, upon simple rescaling, can be converted to $M_{3H}^{H(1, Q^2)}$. On the other hand, be-

---

1 Strictly speaking, the pQCD correction to $F_3^{pp+\bar{p}p}$ differs from...
low 2 GeV^2 effects of generic higher-twist terms start to show up, and the LO OPE+pQCD prediction disagrees significantly with the lattice result.

We shall describe how the lattice result for \( \delta \gamma A \) on the pion can be used to improve our understanding of \( \delta \gamma A \) on the neutron. First, for the neutron we parametrized the structure function \( F_{3N}^{(0)} \) (hence, also \( M_{3N}^{(0)} \)) as \[ F_{3N}^{(0)} = F_{3N,\text{el}}^{(0)} + \left\{ \begin{array}{l} F_{3N,\text{res}}^{(0)} + F_{3N,\pi N}^{(0)} + F_{3N,\pi \pi}^{(0)}, \quad Q^2 \leq Q_0^2, \\ F_{3N,\text{pQCD}}, \quad Q^2 \geq Q_0^2, \end{array} \right. \tag{5} \]

where \( Q_0^2 \approx 2 \text{ GeV}^2 \) is the scale above which the LO OPE + pQCD description is valid. Above, we isolated the contributions from the elastic intermediate state (el) fixed by the nucleon magnetic \([10, 17]\) and axial elastic form factor \([18]\), from the non-resonance \( \pi N \) continuum \((\pi N)\) in the low-energy region, from the \( N^* \) resonances \((\text{res})\) \(^2\), and the Regge contribution \((R)\) that allow to economically describe the multi-hadron continuum.

In a similar way, we parametrize the respective pion structure function as

\[ F_{3\pi}^{(0)} = \left\{ \begin{array}{l} F_{3\pi,\text{el}}^{(0)} + F_{3\pi,\pi N}^{(0)} + F_{3\pi,\pi \pi}^{(0)}, \quad Q^2 \leq Q_0^2, \\ F_{3\pi,\text{pQCD}}, \quad Q^2 \geq Q_0^2, \end{array} \right. \tag{6} \]

We note the absence of the elastic and the low-energy continuum contributions. The former is identically zero because the axial current does not couple to the spin-0 pion ground state. The latter would correspond to the non-resonant part of the \( \pi \pi \) continuum in the \( p \)-wave; however, this partial wave is known to be entirely dominated by the \( \rho^0 \) resonance up to the \( KK \) threshold.

Comparing the parameterizations of Eqs. (5,6), we make an important observation. Among the various contributions there are the process-specific ones that reside in the lower part of the spectrum (elastic, resonance and low-energy continuum). They have to be explicitly calculated for the pion and for the nucleon and cannot be related to each other. On the other hand, the asymptotic contributions (Regge and pQCD) are universal. This is the central point of our analysis.

The universality of the OPE is straightforward. The only difference between \( F_{3N,\text{pQCD}}^{(0)} \) and \( F_{3\pi,\text{pQCD}}^{(0)} \) is in the normalization of the isospin states, thus \( F_{3N,\text{pQCD}}^{(0)} = \left( F_{3\pi,\text{pQCD}}^{(0)} / \rho \right) F_{3N,\text{pQCD}}^{(0)} \).

The Regge universality is among the central predictions of Regge theory. In fact, it dictates that the upper and lower vertices in the Regge-\( \rho \)-exchange amplitudes \( T^\rho(W^+ + \pi^- \rightarrow \gamma + \pi^0) \) and \( T^\rho(W^+ + n \rightarrow \gamma + p) \) in Fig. 3 factorize, so that, e.g.,

\[ R_{\pi/N} = \frac{T^\rho_{W^+ + \pi^- \rightarrow \gamma + \pi^0}}{T^\rho_{N + n \rightarrow \gamma + p}} = \frac{T^\rho_{\pi^0 \rightarrow \pi^0 \pi^0}}{T^\rho_{NN \rightarrow NN}}, \tag{7} \]

where \( T^\rho_{\pi^0 \rightarrow \pi^0 \pi^0} \) and \( T^\rho_{NN \rightarrow NN} \) stand for the amplitudes in elastic \( \pi \pi, \pi N, NN \) scattering in the channel that corresponds to an exchange of the quantum numbers of the \( \rho \) meson in the \( t \)-channel. Regge factorization has been tested on global data sets for elastic pion, pion-nucleon and nucleon-nucleon scattering.

This leads to a prediction based on Regge universality,

\[ F_{3N,\text{el}}^{(0)}(x, Q^2) = R_{\pi/N}^{-1} F_{3\pi,\text{el}}^{(0)}(x, Q^2), \tag{8} \]

\[ F_{3\pi,\text{el}}^{(0)}(x, Q^2) = \frac{A(Q^2)}{f_{\text{th}}(W^2)} \frac{(Q^2)}{x} \alpha^0_0, \tag{9} \]

with \( \alpha_0^0 = 0.477 \) \([20]\). Here we define the threshold function \( f_{\text{th}}^H = \Theta(W^2 - W_{\text{th},H}^2)(1 - \exp(-r(W_{\text{th},H}^2 - W^2)/\Lambda^2)) \), where \( W^2 = M_H^2 + Q^2(\frac{1}{2} - 1) \) and \( \Lambda = 1 \text{ GeV}^2 \) \([21]\). The threshold parameter \( W_{\text{th},H} \) characterizes the threshold for the multi-hadron contributions. In Ref. \([19]\) we fixed \( W_{\text{th},N} = m_N + 2M_\pi \), such that the threshold function \( f_{\text{th}}^N \) \( \approx 1 \) for \( W \gtrsim 2.5 \text{ GeV} \). In the pion sector, one expects \( W_{\text{th},\pi} \) to lie between \( M_\rho \) and 1.2 GeV, the scale above which Regge description is valid \([19]\). In this work we choose \( W_{\text{th},\pi} \approx 1 \text{ GeV} \), and account for the uncertainty due to its variation between the two boundaries.

The function \( A(Q^2) \) describes the interaction at the upper half of Fig.3 and is, within the Regge framework, common for neutron and pion. It is in principle a complicated function of \( Q^2 \) but is now completely fixed by the lattice curve in Fig.2 upon subtracting the resonance contribution. With these, we obtain the following ratio between the first Nachtmann moments of the Regge contributions:

\[ M_{3N,\text{el}}^{(0)}(1, Q^2) = \frac{1}{R_{\pi/N}} \int_0^1 dx \frac{1 + 2r_{\pi N}}{1 + r_{\pi N}} f_{\text{th}}(W^2) x^{-\alpha^0_0} \]

\[ M_{3\pi,\text{el}}^{(0)}(1, Q^2) = \int_0^1 dx \frac{1 + 2r_{\pi \pi}}{1 + r_{\pi \pi}} f_{\text{th}}(W^2) x^{-\alpha^0_0}. \tag{9} \]

To fully specify the parametrization of \( F_{3\pi}^{(0)} \) we turn now to the resonance contribution depicted in Fig. 4.

---

\(^2\)Resonances do not contribute due to the isoscalar nature of the photon.
Its strength is derived from the following effective Lagrangian densities \[22\],

\[
\mathcal{L}_{\rho\gamma\pi} &= \frac{1}{2} \varepsilon_{\mu\nu\rho} \varepsilon_{\lambda\sigma\tau} (F_\mu^a)(F^\nu)^b_{\lambda\tau} F^{\mu\nu}_{\rho\sigma}, \\
\mathcal{L}_{a_1\rho\pi} &= \frac{1}{2} \varepsilon_{abc} (F^a_{\mu}(F^b_{\nu})(F^c_{\rho})), \\
\mathcal{L}_{W_{a_1}} &= \frac{g M_{a_1}^2}{2g_\rho} w_{a_1} V_{ud} W_{\tau}^{-} a_{1\rho}^\mu + h.c. \quad (10)
\]

The respective couplings are obtained as follows: \(|g_{\rho\gamma\pi}| = 0.645(43)\) from the \(\rho \to \gamma\pi\) decay width, \(|g_{a_1\rho\pi}| = 5.7(1.3)\) from the total width of \(a_1\), assuming that \(a_1 \to \rho\pi\) is the dominant channel \[2\], and \(|w_{a_1}/g_\rho| = 0.133\) from the \(\tau^- \to a_1^\mu \nu\tau\) decay width \[23\]. They give, upon the narrow-width approximation of \(\rho^0\),

\[
M^{(0)}_{3\pi,\text{res}}(1, Q^2) = \frac{1}{6} \frac{2\tilde{r}}{1 + 2\tilde{r}} \left| \frac{w_{a_1}}{g_\rho} g_{a_1\rho\pi} g_{\rho\gamma\pi} \right| F_{a_1}(Q^2) F_{\omega}(Q^2) \frac{M_{a_1}^2 - M_{\rho}^2}{M_{\rho}^2 - M_{a_1}^2} \frac{Q^2}{M_{a_1}^2 + Q^2 M_{\rho}^2 M_{a_1} M_{\rho}}, \quad (11)
\]

where \(\tilde{r} = (1 + 4M_{\rho}^2 x_R/Q^2)^{1/2}, x_R = Q^2/(Q^2 + M_{\rho}^2 - M_{a_1}^2)\), and \(F_\omega(Q^2) = (1 + Q^2/M_{\omega}^2)^{-1}\). The overall sign is fixed by requiring that it matches the sign of the \(\pi\pi\) contribution calculated in Chiral Perturbation Theory at small \(Q^2\). Numerically, the size of \(M^{(0)}_{3\pi,\text{res}}\) is rather small, \(\leq 10\%\) of the total, as can be seen in the bottom-right subview of Fig.5 where the resonance estimate of Eq. (11) (red dashed curves and band) is plotted along with the full lattice calculation \(M^{(0)}_{3\pi,\text{res}}\) (blue solid curves and band). This smallness guarantees that the removal of the non-universal resonance contribution does not introduce an uncontrollable systematic uncertainty in our analysis.

With Eq. (9), one could now obtain \(M^{(0)}_{3\pi,\text{res}}(1, Q^2)\) directly from the lattice results and the rescaling factor \(R_{\pi/N}\). On the one hand, the most recent analysis of \(\pi\pi\) scattering \[19\] made the factorization test with respect to \(\pi N\) analysis and found (omitting the isospin factor \(F_{\pi^-}/F_{\pi^+}\))

\[
T_{\pi^-\rightarrow\pi^-\pi^-}^{\rho} / T_{\pi^-\rightarrow\pi^-\pi^+}^{\rho} = 1.35^{+0.31}_{-0.26}. \quad (12)
\]

On the other hand, the OPE suggests that \(R_{\pi/N} = 1\) in the perturbative regime (note also the \(\rho\) coupling universality hypothesis in the hidden local symmetry \[24\]). Therefore, to ensure a continuous matching at all \(Q^2\) values we allow \(R_{\pi/N} \) to slightly depend on \(Q^2\),

\[
R_{\pi/N}(Q^2) = R_{\pi/N}(0) + bQ^2, \quad (13)
\]

where \(R_{\pi/N}(0)\) is fixed by Eq. (12), and \(b\) is fixed by requiring \(M^{(0)}_{3\pi,\text{res}}\) to reproduce the CCFR data at the matching point \(Q_0^2 = 2\ \text{GeV}^2\),

\[
M^{(0)}_{3\pi,\text{res}}(1, Q_0^2) = 0.0667(35). \quad (14)
\]

The result reads \(b = -0.076_{-0.072}^{+0.100}\ \text{GeV}^{-2}\).

With the prescription above we fully fix \(M^{(0)}_{3\pi,\text{res}}(1, Q^2)\) at low \(Q^2\) using the lattice curve of \(M^{(0)}_{3\pi}(1, Q^2)\). The result is shown in Fig.4 with the uncertainties from \(R_{\pi/N}(Q^2)\) and \(W_{\rho,\pi}\) added in quadrature. Integrating over \(Q^2\) gives an updated estimate of the Regge contribution to \(\delta^{VA}_{W,N}\):

\[
\left(\delta^{VA}_{W,N}\right)_0 = 1.12(18) \times 10^{-3}, \quad (15)
\]

in excellent agreement with the previous determination \[8\] \(\left(\delta^{VA}_{W,N}\right)_0 = 1.02(16) \times 10^{-3}\). One can also study the effect of varying the perturbative matching point by evaluating the \(Q^2\)-integral in Eq. (11) between 2 GeV\(^2\) and 3 GeV\(^2\) using the CCFR data instead of the pQCD expression. That gives an insignificant extra uncertainty of \(1 \times 10^{-5}\), confirming the robustness of our error analysis.

We next discuss the impact of this result on the extraction of \(V_{ud}\). From superallowed nuclear \(\beta\) decay, we

Figure 4: The \(\rho\)-exchange diagram that contributes to \(F^{(0)}_{3\pi,\text{res}}\) in the physical region.

Figure 5: The new determination of \(M^{(0)}_{3\pi,\text{res}}(1, Q^2)\) (blue band with solid boundaries) is compared to the result of Ref. [3] (orange band with dashed boundaries), the pQCD prediction (red curve) and the CCFR data [14, 15] (green points). In the bottom-right subview, the resonance contribution to \(M^{(0)}_{3\pi,\text{res}}\), Eq. (11) (red dashed curves and band) is shown along with the full lattice calculation \(M^{(0)}_{3\pi,\text{res}}\) (blue solid curves and band).
have |V_{ud}| = \frac{2984.43 \text{ s}}{\mathcal{F}(1 + \Delta_R^V)} , \quad (\text{superallowed}) \quad (16)

where \mathcal{F}t is the ft-value corrected by nuclear effects, \Delta_R^V = \delta_{W,N}^V + \ldots \text{ is the nucleus-independent RC that}

contains the largest theoretical error. In this paper we update the Regge contribution to \delta_{W,N}^V according to Eq. (15).

Meanwhile, we also update the pQCD contribution above 2 GeV^2 from \mathcal{O}(a_s^3) to \mathcal{O}(a_s^4) [12, 13], which reduces \Delta_R^V by mere \times 10^{-5}. As a result we obtain a slight shift upward with respect to the result of Ref. [15]:

\Delta_R^V = 0.02467(22) \rightarrow 0.02477(24). \quad (17)

The recent Ref. [16] estimated a lower value, \Delta_R^V = 0.02426(32), based on the assumption that the full Nachtmann moment should follow the perturbative curve down to as far as Q^2 = 1 GeV^2, and only afterwards higher-twist effects (estimated in a holographic QCD model) become important. The lattice calculation on the pion [10] suggests that already at Q^2 \leq 2 GeV^2 the higher twist contributions are non-negligible.

The implication of Eq. (17) on \Delta_R is as follows. First, if we take \mathcal{F}t = 3072.07(63) \text{ s} [25], then |V_{ud}| = 0.97365(15).

However, recent studies in Ref. [4, 5] unveil two mutually competing new nuclear corrections (NNC) whose net effect is to enhance the uncertainty, \mathcal{F}t = 3072(2)\text{ s}. Taking that into account gives |V_{ud}| = 0.97366(33).

For completeness, we also quote the impact of our result to neutron beta decay, where \Delta_R^V is determined by [27]:

\begin{align}
|V_{ud}|^2 = \frac{5099.34 \text{ s}}{\tau_n(1 + 3\lambda^2)(1 + \Delta_R)} . \quad (\text{neutron}) \quad (18)
\end{align}

Our new analysis implies \Delta_R = 0.04002(24) (\Delta_R is the sum of \Delta_R^V and the Sirlin’s function [28]), which leads to |V_{ud}| = 0.97297(58) given the neutron lifetime \tau_n = 879.7\text{ s} [29, 31] and the axial-vector ratio \lambda = -1.27641(56) [32]. The result is consistent with that from the superallowed nuclear \beta decays.

Finally, we discuss the current situation of the top-row CKM unitarity. There are two different measurements of V_{us}, using K_{e2} [2] and K_{e3} [33] decay separately:

\begin{align}
|V_{us}|_{K_{e2}} = 0.2253(7), \quad |V_{us}|_{K_{e3}} = 0.2233(6). \quad (19)
\end{align}

They disagree with each other at 2\sigma level, K_{e3} giving a smaller |V_{us}| which leads to a larger unitarity violation.

This, however, depends critically on the existing lattice calculation of the K\pi vector form factor F_\pi^{K\pi}(0) which is recently questioned by theory [34] and a new lattice paper [35]. Another possible issue is the electromagnetic RC in K_{e3}, which may be re-analyzed in a dispersive approach [36]. We summarize the resulting \Delta_{CKM} from different combinations in Table I.

In short, we observe a (3 - 5)\sigma unitarity violation excluding the NNC, and (1.7 - 3)\sigma violation with the NNC.

| |V_{ud}| | \Delta_{CKM}^{V} with K_{e2} | \Delta_{CKM}^{V} with K_{e3} |
|---|---|---|---|
| w/o NNC | 0.97365(15) | -0.0012(4) | -0.0021(4) |
| w/ NNC | 0.97366(33) | -0.0012(7) | -0.0021(7) |

Table I: Summary of \Delta_{CKM}^V for different cases.

To conclude, we devise the value of the universal, hadronic structure-dependent electroweak RC to the free neutron and superallowed nuclear \beta decays from the value of that correction evaluated in lattice QCD for the semileptonic pion decay. To connect the two, we combine the available phenomenological input. The lattice evaluation of the first Nachtmann moment M^{(0)}_{3\pi}(1, Q^2) of the parity-violating spin-independent structure function of the pion, F^{(0)}_{3\pi} provides the full control of its low-Q^2 behavior, overcoming the main deficiencies of previous works. The proposed method offers an independent assessment of systematic uncertainties of the theory of RC, and confirms the previously found deficit of the top-row CKM unitarity. In our new analysis the main source of uncertainty comes from the rescacle factor R_{\pi/N}, the relative strength of the Regge \rho trajectory in high-energy \pi\pi and \pi N scattering. If future studies of \pi\pi and \pi N scattering will allow one to improve the uncertainty of R_{\pi/N}, our prediction of \Delta_R^V will also become more precise. However, a more straightforward solution is expected from a direct lattice calculation of the \gamma W-box on the neutron. Either way, it will shift the emphasis to a reassessment of the nuclear structure corrections that enter the analysis of superallowed nuclear decay. On the other hand, with upcoming more precise measurements of the neutron lifetime and of neutron \beta decay asymmetries, neutron decay will become competitive as the source of our precise knowledge of V_{ud} and CKM unitarity.

We appreciate Guido Martinelli and Ulf-G. Meiβner for for inspiring discussions. The work of C.Y.S. is supported in part by the DFG (Grant No. TRR110) and the NSFC (Grant No. 1162131001) through the funds provided to the Sino-German CRC 110 “Symmetries and the Emergence of Structure in QCD”, and also by the Alexander von Humboldt Foundation through the Humboldt Research Fellowship. M.G. is supported by EU Horizon 2020 research and innovation programme, STRONG-2020 project, under grant agreement No 824093 and by the German-Mexican research collaboration Grant No. 278017 (CONACyT) and No. SP 778/4-1 (DFG). X.F. was supported in part by NSFC of China under Grant No. 11775002. L.C.J. acknowledges support by DOE grant de-sc0010339.
