Abstract. We report the detection of the extremely red object (ERO), HR 10 ($I-K \sim 6.5$, $z=1.44$), at 4.9 and 6.1 $\mu$m (rest-frame) with ISOCAM, the mid-infrared (MIR) camera onboard the Infrared Space Observatory (ISO). HR 10 is the first ERO spectroscopically identified to be associated with an ultra-luminous IR galaxy (ULIG) detected in the radio, MIR and sub-millimeter. The rest-frame spectral energy distribution (SED) of HR 10 is amazingly similar to the one of Arp 220, scaled by a factor 3.8 ± 1.3. The corresponding 8-1000 $\mu$m luminosity ($\sim 7 \times 10^{12} L_{\odot}$) translates into a star formation rate of about 1200 $M_{\odot} \text{yr}^{-1}$ if HR 10 is mostly powered by star formation. We address the key issue of the origin of the powerful luminosity of HR 10, i.e. starburst versus active galactic nucleus (AGN), by using the similarity with its closeby clone, Arp 220.

Key words. Galaxies: evolution – Infrared: galaxies

1. Introduction

HR 10 (or ERO J164502+4626.4, Dey et al. 1999), is the first and presently only Extremely Red Object (ERO, usually defined as galaxies with $I-K > 4$) known to be associated with the class of ultra-luminous infrared galaxies (ULIGs, $L_{\text{IR}} = L(8-1000 \mu m) \geq 10^{12} L_{\odot}$). It was detected by Hu & Ridgway (1994, hereafter HR) together with another ERO (HR 14 or ERO J164457+4626.0) in the field of the QSO PC 1643+4631A ($z=3.79$). HR initially suggested that both galaxies with extreme colors ($I-K > 6$) could be distant ellipticals lying at $z \sim 2-3$. More generally, deep near IR (NIR) surveys indicate that EROs present the same clustering properties (Daddi et al. 2000, McCarthy et al. 2001) and surface brightness distribution (Moriondo, Cimatti & Daddi 2000) as elliptical galaxies. But dusty starbursts being potential progenitors of local ellipticals, they may also show similar clustering properties and some local examples, as NGC 7252 (Hibbard et al. 1994) or Arp 220 (Scoville et al. 2000), already show a de Vaucouleurs luminosity profile typical of ellipticals. High resolution NIR imagery and spectroscopy with the Keck telescopes (Graham & Dey 1996) revealed that HR 10 was a moderately distant ($z = 1.44$) galaxy with an asymmetric morphology and Hα in emission. Another evidence against HR 10 being an early-type galaxy is its strong sub-millimeter luminosity as measured with SCUBA at the JCMT (Cimatti et al. 1998, Dey et al. 1999). The detection in HR 10 of a large CO luminosity, hence molecular hydrogen mass, was recently reported by Andreani et al. (2000) and presented as evidence favoring a star formation origin for the bulk of the IR luminosity rather than an AGN. However, a large gas mass may not only feed star formation but also gas accretion onto an AGN (see Papadopoulos et al. 2001). Another test for the presence of an AGN in a dusty galaxy is the warm over cold dust, i.e mid IR (MIR, 3-40 $\mu$m) over far IR (FIR, 40-300 $\mu$m), luminosity ratio as well as the shape of the MIR spectrum. We present the first detection of HR 10 in two MIR bands of ISOCAM onboard ISO corresponding to the rest-frame 3.3-6.1 and 4.9-7.4 $\mu$m wavelength ranges. A comparison to local galaxies SEDs is presented. We show that the SED of HR 10 is a scaled version of that of the closest ULIG, Arp 220. We discuss the origin of the luminosity of HR 10 on the basis of this similarity.
Throughout this paper, we will assume $H_0 = 70 \text{ km s}^{-1}\text{ Mpc}^{-1}$, $\Omega_{\text{matter}} = 0.3$ and $\Omega_{\Lambda} = 0.7$. For this cosmology, the luminosity distance of HR 10 ($z = 1.44$) is 10373 Mpc.

2. Observations

Deep images of a field of $13' \times 13'$ centered on the QSO PC 1643+4631A ($z = 3.79$) were obtained with the ISOCAM broadband filters LW3 (12–18 $\mu$m, centered at 15 $\mu$m) and LW10 (8–15 $\mu$m, centered at 12 $\mu$m) for a total integration time of 16 and 13 minutes respectively. The 15 $\mu$m image results from the co-addition of two overlapping mosaics slightly rotated one with respect to the other resulting in an improved spatial resolution (2$''$ pixels). The 12$\mu$m image being made of one single mosaic of 6$''$ pixels suffers from a lower spatial resolution. A given position of the sky was observed by 18 (20) different pixels at 15 $\mu$m (12 $\mu$m), resulting in a better flat-fielding and correction of cosmic ray impacts. The data reduction and source extraction was done with PRETI (Pattern REcognition Technique for ISOCAM data, Starck et al. 1999). The gaussian noise (photon plus detector noise) in the 15 $\mu$m (12 $\mu$m) image is 58 $\mu$Jy (31 $\mu$Jy). This field was also observed with ISOPHOT onboard ISO at 90 and 170 $\mu$m (P.I. R. Livan). The total exposure time per sky position is 11.5 and 6.6 minutes respectively. HR 10 is not detected with a 5-$\sigma$ upper limit of $S_\nu \approx 200 \text{ mJy}$ in both bands.

On Fig. 1, the MIR contours are overlayed on the I-band image of a field containing both HR 10 and PC 1643+4631A. Both galaxies are detected in each MIR band with the flux densities given in Table 1. The uncertainty on the flux density related to the correction for the transient behavior of the detectors and to the pixel size relative to the point spread function is given in a second line in italics. While the 15 $\mu$m contours are centered on the optical positions, the 12 $\mu$m contours of HR 10 present an offset of 4$''$. The astrometry was first calculated over the whole 13$'$ field using several stars from the US Naval Observatory Catalog which were detected in the MIR. A relative astrometric correction was then applied to check the position of the MIR detection at the optical position of HR 10 by using a set of six objects included in a field of 2$'$$\times$2$'$ centered on HR 10 and including PC 1643+4631A. The probability of a chance association with an optical object with an I-band magnitude lower than $I$ within a distance $d$ was estimated using the following formula assuming a Poissonian distribution of sources: $P = 1 - \exp[-n(1)\pi d^2]$. The offset of 4$''$ for the 12 $\mu$m detection is attributed a probability of a chance association with the optical position of HR 10 of 20%. This is not surprising because of the lower spatial resolution of the 12 $\mu$m image (6$''$ pixels). However the probability of a random association of the 12 $\mu$m source within 4$''$ of the 15 $\mu$m detection of HR 10 is equal to 0.1% ($n[0.2 \text{ mJy at } 15 \mu\text{m}] = 0.8 \pm 0.1 \text{ m}\text{arcsec}^{-2}$). In order to quantify the risk of detecting “ghost” sources produced by cosmic ray residuals in the MIR images, we performed Monte-Carlo simulations by inserting fake sources in real datacubes. Down to a flux density limit of $S_\nu \sim 100 \mu$Jy, we find that about 6 and 12% of the sources are false in the 15 and 12 $\mu$m images respectively. However, we were able to reduce the fraction of ghost sources to zero in the 15 $\mu$m image by requiring that a source be detected in both mosaics (before coaddition) at a lower detection level. Only above 0.3 mJy do we reach the zero probability of a false detection in the 12 $\mu$m image, but again the probability of a random association of a spurious 12 $\mu$m source with the 15 $\mu$m detection of HR 10 is negligible. The upper limits on HR 14 ($I - K = 6.2$, see Table 1) imply that it cannot be a ULIG unless it is more distant than $z \sim 1.8$. PC 1643+4631A is one of the most distant sources detected in the MIR ($z = 3.79$ corresponds to an age of the universe of only 1.6 Gyr) and belongs to the class of ULIGs, with rest-frame luminosities of: $nL_{\nu}[3.1 \pm 0.63 \mu\text{m}] = (2.3 \pm 0.5) \times 10^{12} h_{70}^{-2} L_\odot$ and $nL_{\nu}[2.5 \pm 0.84 \mu\text{m}] = (1.2 \pm 0.8) \times 10^{12} h_{70}^{-2} L_\odot$. 

**Fig. 1.** MIR contours over I-band image (WHT archives): N: up, E: left. a) 15 $\mu$m contours at 2.5 to 5-$\sigma$, with a 0.5-$\sigma$ step. b) 12 $\mu$m contours at $S/N$=1.6, 1.9, 2.2, 2.8, 3.5, 4.1, 6, 9, 11.
Table 1. MIR flux densities at 15 and 12 μm, signal-to-noise ratios and probability of chance association.

|       | $S_{15.7μm}$ (μJy) | $S/N$ (%) | $S_{12μm}$ (μJy) | $S/N$ (%) |

| HR 14  | < 290             | 5         | < 135            | 5         |

3. Discussion: Nature of HR 10

The least-square fit of the SED of HR 10 using the SED of Arp 220 (Fig. 3a) illustrates the amazing similarity of both spectra. The 8-1000 μm luminosity of Arp 220 is $L_{IR} = 1.8 \times 10^{12} h_7^{-2} L_\odot$, for a distance of $d= 81.8 h_7^{-1} \text{Mpc}$, corrected from the Virgo infall ($cz = 5439+206 \text{km s}^{-1}$). The resulting normalization factor of 3.8 ± 1.3 (1-σ) implies an IR luminosity of $L_{IR} = (6.8±2.3) \times 10^{12} h_7^{-2} L_\odot$ for HR 10. If the dust was mostly heated by massive young stars, then this IR luminosity would translate into a star formation rate (SFR) of about $(1170±396) h_7^{-2} M_\odot \text{yr}^{-1}$, for a 10-100 Myr continuous burst, solar abundance and a Salpeter IMF ($SFR [M_\odot \text{yr}^{-1}] = 1.72 \times 10^{-10} L_{IR}$, Kennicutt 1998).

A consistent normalization factor also applies for the molecular gas mass of HR 10, estimated from its CO luminosity ($M_{H_2} = 1.2 \times 10^{10} M_\odot$, Andreani et al. 2000), which is 2.9 times larger than in Arp 220 ($M_{H_2}[\text{Arp 220}] = 4.1 \times 10^{10} M_\odot$, Scoville, Yun & Bryant 1997). If the molecular gas mass over dust mass ratio of HR 10 is the same as the one measured in the center of Arp 220, i.e. $M_{\text{gas}}/M_{\text{dust}} \sim 400$ (Scoville, Yun & Bryant 1997), then we obtain $M_{\text{dust}}[\text{HR10}] \sim 4 \times 10^8 h_7^{-2} M_\odot$, in agreement with the one estimated by Dey et al. (1999, $\sim 7 \times 10^8 h_7^{-2} M_\odot$) using a black body fit to the FIR part of the SED with $T_{\text{dust}} \sim 40 \text{K}$.

The SED of Arp 220 is limited to wavelengths above the U-band (3550 Å) which corresponds to 8670 Å in the observed frame of HR 10. In Fig. 2b, we have fitted the SED of HR 10 with the model STARDUST2 (Chianial et al., in preparation) from the observed B-band (1800 Å in the rest-frame) to the radio. If we assume that there is only one component responsible for both the optical and IR light in HR 10, then the best-fit is obtained for a visual extinction of $A_V = 3 \text{mag}$ (± 0.2 mag, extinction law $A(\lambda)/A_V$ from Calzetti et al. 2000), with an age of 0.2 Gyr at the time of the observation and a characteristic timescale for the starburst of $\tau = 95 \text{Myr}$ ($\text{SFR} = M_{\text{gas}}(t)/\tau$). The optical-UV part of the spectrum alone can be fitted with an $A_V= 2-2.8$, an age of 2-4 Gyr and $\tau = 0.4-0.9 \text{Gyr}$, resulting in $L_{IR} \sim 8 \times 10^{10} h_7^{-2} L_\odot$ which does not fit the MIR and sub-millimeter part of the SED. However, detailed studies of local luminous IR galaxies have shown that the region from which the bulk of the IR luminosity arises can contribute very weakly to the optical light, e.g. the Antennae galaxies (Mirabel et al. 1998). In such a scenario, a second component with a larger $A_V$ would contribute dominantly to the IR regime and nearly not to the optical part. In both cases, we obtain an IR luminosity and SFR within the error bars associated with the fit using Arp 220. The main difference between the model and Arp 220’s SED is that the FIR over MIR luminosity ratio of Arp 220 is higher. The fit of Arp 220’s SED...
requires an \(A_V > 30\) mag for the component responsible for the bulk of the IR light.

The key issue remains to determine whether the bulk of the luminosity of HR 10 is powered by star formation or accretion by a black hole. Two other EROs have been spectroscopically identified and detected in the MIR and radio (ISO J1324-2016, Pierre et al. 2001, and ERO J164023+4644, Smith et al. 2001). The upper limits established for their bolometric IR luminosities in the absence of a detection in the FIR or sub-millimeter are consistent with their belonging to the class of ULIGs too. NIR spectroscopy in both galaxies favor the presence of an AGN. In the case of HR 10, the width of the observed H\(\alpha\) emission feature or the [NII]/H\(\alpha\) ratio are too uncertain to be used as an indication of the presence of an AGN (Graham & Dey 1996). The H\(\alpha\) line is strongly affected by dust extinction (\(SFR[H\alpha] \approx 80 \, M_\odot \text{yr}^{-1}\) only).

Most authors favor the starburst hypothesis as a dominant source of energy in Arp 220: its MIR spectrum up to 40\(\mu\)m shows no evidence for high ionization lines expected for AGNs (Sturm et al. 1996), its “IR excess” (\(L_{IR}/L_{[\text{Ly}\alpha]} \sim 24\), Anantharamaiah et al. 2000) is much lower than for AGNs (\(\sim 45 - 65\)) and typical of starburst galaxies (\(\sim 12 - 45\), Genzel et al. 1998), its radio emission is produced by several compact sources (Smith et al. 1998), the ratio of aromatic features over MIR continuum (Genzel et al. 1998) and the slope of the MIR continuum (Laurent et al. 2000) are typical of starbursts. More recently, Haas et al. (2001) suggested that the MIR luminosity of Arp 220 could be underestimated because of dust extinction in the MIR and that after dereddening, its FIR over MIR luminosity ratio would be closer to the one for AGNs. But the dereddening factor varies by a factor five depending on the dust geometry assumed. Finally, the flat 2-10 keV hard X-ray spectrum of Arp 220 implies that in order to be mostly powered by an AGN, it would need to be Compton thick with a column density larger than \(10^{25}\) cm\(^{-2}\) (Iwasawa et al. 2001).

In Fig. 2b, the SED of HR 10 is compared to the mean SEDs of a Seyfert 2 (Sy2) and of a starburst with high reddening (SBH), from Schmitt et al. (1997), normalized to the 15\(\mu\)m luminosity density of HR 10. The 1-\(\sigma\) error bars corresponding to the distribution of the 15 SBH and 15 Sy2 galaxies are shown in the radio and at \(\lambda_{\text{rest}} = 100\mu\)m. Sub-millimeter data are missing in these SEDs but they should decrease in luminosity density above 100\(\mu\)m as in local galaxies, e.g. the Seyfert 1 Mrk 231 (\(d = 180.9 \, h^{-1}_{70} \, \text{Mpc}, L_{IR} = 3.5 \times 10^{12} \, h^{-1}_{70} \, L_\odot\), dotted line). Without MIR data, Mrk 231 was a candidate template for HR 10 (see Dey et al. 1999). Although not as red as HR 10, the SBH fits the MIR-FIR region of HR 10 while the FIR luminosity of the Sy2 is about ten times fainter.

Finally, even if the presence of a combination of an AGN and a starburst is still an option for both HR 10 and Arp 220, most studies favor a dominant contribution from star formation to their IR luminosities, implying that HR 10 presents the largest SFR known at present. This study clearly shows the need for direct MIR and FIR/sub-millimeter observations of distant dusty galaxies to improve our understanding of a population of objects which plays a major role in galaxy evolution (Chary & Elbaz 2001), hence emphasizes the importance of the next generation IR satellites to come, i.e. SIRTF, FIRST and NGST.

Acknowledgements. We wish to thank Guillaume Lagache for the reduction of the ISOPHOT images. DE wishes to thank the American Astronomical Society for their support through the Chretien International Research Grant, and Joel Primack & David Koo for helping funding this research with the NASA grants NAG5-8218 and NAG5-3507.
