Abstract—Deep neural networks are behind many of the recent successes in machine learning applications. However, these models can produce overconfident decisions while encountering out-of-distribution (OOD) examples or making a wrong prediction. This inconsistent predictive confidence limits the integration of independently-trained learning models into a larger system. This paper introduces separable concept learning framework to realistically measure the performance of classifiers in presence of OOD examples. In this setup, several instances of a classifier are trained on different parts of a partition of the set of classes. Later, the performance of the combination of these models is evaluated on a separate test set. Unlike current OOD detection techniques, this framework does not require auxiliary OOD datasets and does not separate classification from detection performance. Furthermore, we present a new strong baseline for more consistent predictive confidence in deep models, called fitted ensembles, where overconfident predictions are rectified by transformed versions of the original classification task. Fitted ensembles can naturally detect OOD examples without requiring auxiliary data by observing contradicting predictions among its components. Experiments on MNIST, SVHN, CIFAR-10/100, and ImageNet show fitted ensemble significantly outperform conventional ensembles on OOD examples and are possible to scale.

I. INTRODUCTION

Classification is a fundamental problem of machine learning [1]–[9], where, the goal is to assign an observation (instance) to a set of classes.

An important subclass of classifiers is probabilistic classifiers, which predict a probability distribution over a set of classes rather than just the most likely class. The classifier’s decision can then be the class with the highest probability. More formally, while a classifier is a mathematical function \( h : X \rightarrow Y \) that assigns an instance \( x \in X \) to a class \( y \in Y \), a probabilistic classifier outputs the conditional probability \( p(Y|X) \). This approach is appealing because, for example, these probability values can be considered as confidence values that can be used to reject uncertain observations.

Neural networks are naturally probabilistic classifiers. They are designed to assign probability values to different classes so that the sum of these values is one. However, a possible caveat in this approach is vulnerability to out-of-distribution examples (overgeneralization) or in-distribution examples that the classifier is wrongly confident about (confident misclassification).

We combine these two problems, i.e. overgeneralization, and confident misclassification, and refer to them as inconsistent prediction confidence.

Fitted ensembles can naturally detect OOD examples without requiring auxiliary data by observing contradicting predictions among its components. Experiments on MNIST, SVHN, CIFAR-10/100, and ImageNet show fitted ensemble significantly outperform conventional ensembles on OOD examples and are possible to scale.

In short, the contributions of this paper are:

- Introduction of separable concept learning framework to streamline measurement of classifiers’ performance in presence of relevant OOD examples. This framework does not rely on auxiliary OOD datasets and combines classification and detection performance.
- We propose a new ensembling strategy, called fitted ensembles, to achieve more consistent predictive confidence in deep models.

II. RELATED WORKS

Inconsistent prediction confidence is related to model calibration [10], [11], out-of-distribution detection [12]–[22], and uncertainty estimation [23]–[26]. Model calibration in neural networks tries to calibrate their predictive probabilities so that they match their accuracy. A common technique for calibration is temperature scaling [10], where outputs of the neural network are divided by a scalar, called temperature, before passing to the softmax layer.

By contrast, for consistent predictive confidence, the goal in regards to in-distribution (familiar) examples, is to introduce techniques that minimize predictive confidence for misclassified examples. The discrepancy between the expected confidence of the model and its classification accuracy can then possibly be corrected by a model calibration method.

In the out-of-distribution detection problem, a threshold over the confidence values for each prediction teases out out-of-distribution examples. Like model calibration, this is also done as a postprocessing procedure. LeCun et. al. [12] utilize the difference of the first and the second highest class probabilities as such confidence measure. Hendrycks et. al. [14] showed that simply applying the maximum softmax probability is a good baseline for out-of-distribution detection in deep NNs.
DeVries et. al. [17] train a NN with an additional output unit responsible for confidence estimation. Liang et. al. [13] propose to detect out-of-distribution examples in a pretrained model based on temperature scaling and input preprocessing, where small perturbations are added to an input to boost prediction confidence before inference. Their method assumes access to a representative set for out-of-distribution data. As an example of a metric-based out-of-distribution detection method, in [16] each class is modeled by a Gaussian distribution with a joint covariance matrix. Later Mahalanobis distance is applied to detect out-of-distribution and adversarial examples. Finally, Hendrycks et. al. [18] propose to expose the model with auxiliary data during training to minimize the model’s confidence (a uniform output) on the extra examples. Their work can be thought of as an application of universum examples [27] for out-of-distribution detection.

Most of these methods model out-of-distribution data by an auxiliary dataset, which effectively reduces out-of-distribution detection to a binary classification problem. By contrast, in this paper, we model out-of-distribution data as a complement of in-distribution data and assume no access to auxiliary data.

Confidence values can be interpreted as the inverse of uncertainty values, which are not restricted to the classification problem. In the context of deep models, [23] derive a connection between Bayesian inference in Gaussian processes and neural networks that apply dropout which enables them to model uncertainty. Lakshminarayanan et. al. [28] estimate uncertainty statistics from an ensemble of classifiers and subsequently detect out-of-distribution examples. Unlike most methods, they showed their technique is scalable by applying it to the ImageNet-2012 dataset. Our proposed fitted ensemble improves upon this approach by adding a new dimension to regular ensemble classifiers that rectify their predictive confidence by reformulating the original classification problem and lowering conflict between different components.

III. SEPARABLE CONCEPT LEARNING

Recall that inductive biases are the assumptions that the model have about the unseen instances. For example, some of the common biases in machine learning are:

- minimum cross-validation error,
- maximum margin,
- nearest neighbors, and
- minimum description length (Occam’s razor).

To mitigate overgeneralization, in this section we introduce another bias, called separable concept learning (SCL). In SCL we assume a combined classifier should work well if multiple instances of it are trained on disjoint subsets of classes (a mathematical partition of the set of classes).

Here we assume evaluation of a classifier consists of two components: model performance on instance $x$ when $x \sim D^*(x | y \in Y)$, and (2) when $x \sim D^*(x | y \in Y^c)$, where $D^*$ is the data distribution over similar data as in the original data distribution $D$ (including $D$), and $Y^c$ denotes the complement of set of classes $Y$. We call the second component the inhibition ability of the model because it must inhibit its tendency to activate any output class. While the first component can be evaluated by any classification metric, e.g. classification accuracy, to also account for the inhibition ability we apply separable concept learning (SCL).

The advantage of SCL over previous evaluation procedures applied in out-of-distribution detection tasks is that it does not rely on any threshold and measures the rejection ability of the model implicitly without requiring auxiliary data to simulate $D^*$. This is an important property because, in light of no free lunch [29], current evaluation techniques are highly dependent on the choice of this auxiliary set. The SCL provides a more natural and arguably useful way to measure the inhibition ability of learning models.

Intuitively, a set of classifiers should be able to learn different concepts separately from each other because they are aware of the limits of their knowledge. As a result, these models can learn new non-overlapping concepts simply by accepting new output nodes from a separately trained model. In other words, it is possible to train several classifiers over different concepts and merge them to get a single model over the union of concepts. In this way, SCL is simulating the way learning models can handle new emerging relevant concepts and work together.

A closely related subject to SCL is incremental concept learning (ICL), where concepts are presented to the learning model incrementally [30]. The SCL can be conceived as the extreme case of ICL where after learning a few concepts their training instances diminish from the memory. Interestingly, ICL and SCL are more reminiscent of human learning than the current full concept learning approach. Furthermore, in most realistic applications the size of $Y$ is unknown at the beginning or could grow over time, which makes ICL a practically important subject in supervised learning.

Formally, to evaluate the inhibition ability of a model, let $concat$ be the concatenation operator that merges class scores according to a predefined order over the set of classes $Y$ and then normalizes them, $l(.,.)$ be a loss function, and $\rho$ be a partition of $Y$ such that every set in $\rho$ (part of the partition) is at least of size 2 (contains at least two classes from $Y$). The empirical separable risk of a classifier $g$ with respect to $\rho$ is then defined as:

$$r_\rho(g) = \frac{1}{n} \sum_{i=1}^{n} l(concat_{\rho \in \rho}(g_k(x_i)), y_i),$$

where $g_k$ is an instance of $g$ trained on $\rho_k$ (for convenience assume members of $\rho$ are indexed by $k$), i.e. a learning model trained on the subset of training set samples whose classes are only included in $\rho_k$.

Definition 1. SCL Accuracy. The SCL accuracy is calculated according to equation [7] where the predicted class is chosen according to the optimal decision rule [27] that predicts the class with the highest probability, and loss function is the indicator function.

Note that in the case of $\rho = \{|Y|\}$, SCL accuracy will reduce to the classification accuracy measure. More generally:
Proposition 1. The SCL accuracy is a lower bound for the average classification accuracy of the component classifiers $g_k$ when the test set is partitioned according to $\rho$ and each $g_k$ is evaluated on its corresponding set, i.e.,

$$ r_\rho(g) \leq \frac{1}{n} \sum_{i=1}^{n} l(g_k: y_i \in \rho_k(x_i), y_i). \quad (2) $$

Proof. The final normalization of the $\text{concat}$ operator does not change the order of class probabilities, thus it does not affect the final classification decision and can be ignored in our analysis. To assign test example $x_i$ to its actual label $y_i$, its corresponding probability $p(y_i|x_i)$ should be maximum. Because $p(y_i|x_i)$ is assigned by the $g_k$ that is trained on this class, i.e. $y_i \in p_k$, and concatenation cannot increase this value, therefore $\text{concat}$ can only either decrease the accuracy or preserve it.

While SCL accuracy is a simple measure to compute classification accuracy in presence of out-of-distribution examples, equation 2 provides a way to measure the exact amount of accuracy reduction in SCL tasks that occur due to the existence of out-of-distribution data. Abstractly, while comparing two learning models, $M_1$ is strictly better than $M_2$ if $\forall \rho : r_\rho(M_1) \leq r_\rho(M_2)$. However, the possible ways of partitioning $Y$ grows exponentially with the size of $Y$. Thus in practice, an approximation is used by sampling from all the possible partitions.

Informally, to apply equation 1 one can train several components of a SCL model on different subsets of the set of classes and measure the performance of the whole (merged) model over the test set. This approach provides a simple procedure to evaluate the inhibition ability of different learning models. As we will later see, fitted ensembles can significantly boost performance over conventional NNs on SCL tasks.

IV. FITTED ENSEMBLES

Lakshminarayanan et al. [28] showed that applying conventional ensembles is more effective than MC-dropout for detecting out-of-distribution examples. They showed this approach scales well to higher-dimensional spaces while at the same time improving the overall classification accuracy. In the out-of-distribution experiment section we will show that:

- conventional ensemble techniques fail to reliably detect many out-of-distribution examples on popular datasets, and
- additionally, ensemble methods suffer from overconfident predictions.

Our proposed model addresses both of these drawbacks and adjusts the class probabilities directly. Moreover, fitted ensembles do not sacrifice classification accuracy to reduce overgeneralization.

The main idea is to diversify the induced feature space by changing the original classification task. This is achieved by deriving new classification problems from the original problem. We extract new classification problems by combining original classes into larger superclasses to form new superclass spaces. A set of one or more such superclass spaces is referred to as a sequel. A fitted ensemble is a non-empty set of sequels.

To provide more clarity on sequels, consider a four-class classification problem with output space $Y = \{A, B, C, D\}$. We construct a sequel $H$ consisting of two superclass spaces $\{h^0, h^1\}$ in the following manner, $H = \{h^0, h^1\}$, where,

$$ h^0 = \{h^0_0, h^0_1\}, h^1 = \{h^1_0, h^1_1\}, $$

$$ h^0_0 = \{A, D\}, h^0_1 = \{B, C\}, $$

$$ h^1_0 = \{A, B\}, h^1_1 = \{C, D\}. $$

Here, each superclass $(h^0_0, h^0_1, h^1_0, h^1_1)$ includes two classes from the original problem. In practice, we simplify sequels by assuming that each superclass space $h^j$ is a partition of set of original classes. A sequel consists of only those superclass spaces that can solve the original classification problem. In the sequel $H$ discussed earlier, superclass space $h^0$ can only inform that an example belongs to either $\{A, D\}$ or $\{B, C\}$, but not to one particular class. With the addition of space $h^1$, we can deduce to which original class the example belongs and solve the original classification problem. Essentially, a sequel is a conceptual means to construct better superclass spaces.

More formally, assume output space $Y$ consists of $n$ categories $y_i$, where $i \in \{1,...,n\}$. We map $Y$ into $r$ new superclass spaces $h^j$ each with $|h^j| \leq n$ elements. In this new space, $\forall i,j : h^j_i \supseteq Y$ and $\forall i \neq k : h^j_i \cap h^j_k = \emptyset$. As mentioned earlier, each superclass space sets up a new classification problem. And, for each such space we have its corresponding member-classifier. To put it simply, a fitted ensemble model consists of $r$ member-classifiers $g^j j \in \{1,...,r\}$, where $g^j$ is trained on $h^j$. Each superclass space $h^j$ defines an upper bound on the predictive confidence of the model. Given an example $x$, a class probability cannot be greater than the probability of any superscalars it belongs to, i.e. $\forall y_i \in h^j_k : p(y_i|x) \leq p(h^j_k|x)$. During inference, each $g^j$ corrects the current confidence about class probabilities by adjusting the estimated probability values for each class in a fitted ensemble. In particular, the class probabilities should satisfy all the inequalities in the form of $p(y_i|x) \leq g^j_k(x)$, where $y_i \in h^j_k$, and $g^j_k(x)$ denotes the estimation of $p(y_i|x)$ by the model. In this manner, a fitted ensemble can indirectly make inferences about OOD examples by deducing that the class probabilities are closer to zero for unknown examples. Algorithms 1 summarizes the necessary steps for constructing and training a fitted ensemble. The procedure for rectifying class probabilities during inference phase is outlined in algorithm 2.

V. FITTED ENSEMBLE EXPERIMENTS

In this section the MNIST, CIFAR-10/100, SVHN, and ImageNet-2012 datasets support a variety of experiments that assess the performance of fitted ensembles. The general setup is to train a model on a dataset that is representative of the true data distribution, and then evaluate the confidence of the
model predictions on both unseen and in-distribution classes. Following [20], [28] and unlike many new out-of-distribution modeling methods, we assume the model has no access to any out-of-distribution data, neither directly as in [15], [16], [19], nor indirectly as in [14], [18], [21]. Hence, it is not comparable to these methods. Therefore, we focus our comparison to conventional ensembles as an established strong method [24] to address out-of-distribution problem.

Following [28], we plot histograms of different confidence values, where a good model should be less confident about out-of-distribution examples. Moreover, a model’s confidence should decrease for in-distribution examples that it misclassifies. The results suggest fitted ensembles are indeed successful at both of these tasks and significantly improve on conventional ensembles in recognizing examples from unfamiliar classes.

For consistency following [28], all the models applied in these experiments follow a small VGG-like [32] architecture for each classification/member problem, except for ImageNet experiment in which we use DenseNet [33] architecture to show the results are generalizable to different architectures.

A. The Set of Sequels

Except for in the ImageNet experiment, each fitted ensemble includes four extra superclass spaces (two sequels) in addition to the regular classification problem. Two of these spaces are created by combining every two consecutive classes from the original dataset, starting from 0 and 1, respectively, to form superclasses. For datasets with 10 classes that means $H = \{h^0, h^1\}$, where $h^0 = \{y_{2i}, y_{1+2i} : i \in \{0..4\}\}$, and $h^1 = \{h^1_i = \{y_{i+2i}, y_{(2+2i) mod 10} : i \in \{0..4\}\}\}.

The next two superclass spaces are created similarly, except that we combine every other class. These four superclass spaces add 20 constraints to adjust the primary probability values (four for each class). In the ImageNet experiment, in addition to the regular classification problem, the fitted ensemble includes two extra superclass spaces (one sequel), each of which is constructed by combining every two consecutive classes (according to the PyTorch\footnote{https://pytorch.org/} framework’s default class ordering) from the original dataset.

To confirm that adding superclass spaces does not negatively affect classification performance, first we trained an ensemble of five CNNs and compared its performance to an ensemble of five fitted ensembles. Note that each fitted ensemble contains the five member networks as just explained. While the aggregate of fitted ensembles takes more space, the question is whether that additional space affords superior detection of out-of-distribution examples without loss of in-distribution accuracy.

For the aggregate of fitted ensembles, we combined the results of the five different fitted ensembles at the superclass spaces level. That is, Algorithm 2 is applied after combining outputs of all corresponding member-classifiers. The combination is always a weighted average with uniform weights.

Table I depicts the classification accuracy of each of the two ensembles when run once on a variety of datasets. The table shows that the aggregate of fitted ensembles successfully maintains (or improves) the classification performance of its base classifiers after adding sequels. Note that we utilize small network architectures (wider architectures can improve accuracy on CIFAR-100).

| DATA SET | CNNNS | FITTED ENSEMBLES |
|----------|-------|------------------|
| MNIST    | 99.65 | 99.70            |
| SVHN     | 96.95 | 97.10            |
| CIFAR-10 | 93.1  | 93.4             |
| CIFAR-100| 69.15 | 69.85            |

B. Confidence Consistency Experiments

In the rest of the experiments of this section, we evaluate the out-of-distribution recognition and overconfidence reduction ability of fitted ensemble. In these experiments, we apply an ensemble of five fitted ensembles (each with five superclass spaces) and compare its performance with an ensemble of 50 CNNs, which is twice as many neural networks as the aggregate of fitted ensembles. A large number of neural networks in regular ensembles (50) rules out any further improvement
of confidence values because of conventional ensembling. Because [28] have already shown that ensembles significantly outperform MC-dropout for uncertainty estimation we did not include MC-dropout results in these experiments.

All the experiments in this section include a VGG-like architecture for neural networks. This architecture includes nine $(3 \times 3)$ convolutional layers each with 100 output feature maps, followed by two fully-connected layers (of size 1,000) and a softmax layer. All layers are followed by ReLU non-linearity and an additional batch-normalization layer. Furthermore, there is a max-pooling layer, after three consecutive convolutional layers. The weight initialization follows [34] for convolutional layers and [35] for linear layers.

The models are trained by Adam optimizer [36] with a batch size of 40 in all our experiments. The learning rate always starts at 0.01 and is decayed by multiplying by 0.4 after every 10 epoch. All the models are trained for 52 epochs. Even though the hyperparameters are not optimized for any specific dataset, we found our setup generally robust on all the four datasets studied in this work.

The loss function is always cross-entropy and no dropout or any other regularization, except for batch-normalization, was applied. For preprocessing all the datasets were normalized.

A light data augmentation was performed on each dataset. For MNIST and SVHN dataset, the images are first zero padded to obtain 34 x 34 resolution images and then randomly cropped to get to 32 x 32 images. The CIFAR-10/100 datasets are first padded to 36 x 36 images and then randomly cropped to obtain 32 x 32 images. The training images in these datasets are also randomly horizontally flipped.

1) MNIST Experiment: The MNIST dataset consists of gray-scale images of digits and is separated into 60,000 training and 10,000 testing images. First an ensemble of 50 regular CNNs and five fitted ensembles (25 CNNs) were trained on MNIST.

For out-of-distribution data we applied notMNIST [2] a dataset similar to MNIST but consisting of alphabet letters.

Due to space limitations, we exclude the graph of this experiment. Nevertheless, we observe a substantial decrease of highly-confident out-of-distribution examples in the aggregate of fitted ensembles (from about 34% down to about 15.5%), which is evidence of the effectiveness of our approach. Furthermore, there is a large amount of highly-confident examples from the notMNIST dataset in the CNN ensemble that showcases the ubiquity of the overgeneralization (all 50 CNN models are over 95% confident about 34% of out-of-distribution examples).

It is also noteworthy that a considerable amount (about 15%) of out-of-distribution examples have been correctly rejected by the fitted ensemble aggregate ensemble, whereas the CNN ensemble is never totally unsure (considering that random probability is 10%) about any out-of-distribution example.

2) SVHN Experiments: This next experiment evaluates fitted ensembles on the SVHN dataset of colorful digit images. Higher noise in examples and greater input space makes this dataset more challenging than MNIST. The test set of the CIFAR-10/100 dataset serves as the out-of-distribution data.

Considering the CIFAR-10 test set as out-of-distribution data, histograms of confidence values are depicted in figure 1 for an ensemble of (a) 50 CNNs (b) five fitted ensembles. Note that there are 26,032 test examples in SVHN (some of the bars go above 10,000 examples). The plots illustrate that both ensembles are successful in this task. However, the aggregate of fitted ensembles rejects more out-of-distribution examples and adjusts the confidence values more accurately.

In contrast, the ensemble of CNNs assigns high-confidence values to many out-of-distribution examples and is very confident about a significant proportion of misclassified examples. A similar result is observed when applying CIFAR-100 as an out-of-distribution dataset (graphs are excluded due to space constraints). The results reaffirm that the aggregate of fitted ensembles performs better in out-of-distribution recognition.

3) CIFAR-10 and CIFAR-100 Experiments: CIFAR-10/100 are datasets of tiny images of 10 and 100 different types of animals and moving objects, respectively. The datasets are considerably more challenging than MNIST and SVHN because of the greater variety of images. We observe similar trends when we compare an ensemble of 50 regular CNNs versus five fitted ensembles trained on these datasets and treat SVHN and the remaining CIFAR-10/100 as out-of-distribution data. However, due to space constraints, we only include the result for models trained on CIFAR-10 compared against CIFAR-100 data as unseen classes in Figure 2.

Overall, the results exhibit again the superior performance of fitted ensembles in assigning low confidence values or rejecting out-of-distribution data on out-of-distribution data. Furthermore, fitted ensembles assign lower confidence values to misclassified examples.

C. SCL Experiments

To demonstrate the performance of fitted ensemble on SCL we evaluated the accuracy of an ensemble of three fitted ensembles versus an ensemble of three conventional CNNs. We applied the same datasets, neural network architecture, and training procedure from the past experiments for all neural networks. However, we applied four superclass spaces (including the original classification problem) for each fitted ensemble. The set of sequels for fitted ensembles are changed to conform with five total number of classes.

In addition to regular classification problem, we added three extra constraint-problems for MNIST, SVHN and CIFAR-10 datasets, as follows: $H = \{h^0 = \{h_0^0 = \{y_0\}, h_1^0 = \{y_1\}, h_2^0 = \{y_2\}, h_3^0 = \{y_3, y_4\}\}, h_1^1 = \{h_0^1 = \{y_0, y_1\}, h_1^1 = \{y_2, y_3\}, h_2^1 = \{y_3, y_4\}\}, h_2^2 = \{h_0^2 = \{y_0\}, h_1^2 = \{y_1, y_2\}, h_2^2 = \{y_3\}, h_3^2 = \{y_4\}\}\}$. Finally, for CIFAR-100 with 50 classes in the SCL task, we applied the same four superclass spaces as in the out-of-distribution examples experiments.
Fig. 1: **Distribution of confidence values for SVHN (in-distribution) and CIFAR-10 (out-of-distribution) examples.** (a) the result from 50 CNNs of the ensemble show the limit of ensembling for improving confidence values. (b) an aggregate of five fitted ensembles significantly outperform the regular ensemble. Note that some of the bars go above the 10,000 upper bound of the graph because there are 26,032 test examples in SVHN.

For SCL, each training set was split into two sub-training sets. The split ensures that the first sub-training set includes all the examples from the first half of classes from the original training set, and the second sub-training set includes the rest. This split is arbitrary because the set of classes are independent in each dataset.

After training two classifiers on each dataset, the classifiers are merged and applied to classify the test data. Table II summarizes the classification accuracy results with this procedure on different datasets. Each experiment is repeated five times except for CIFAR-100, which is a single run. The results show that the aggregate of fitted ensembles significantly ($p < 0.01$ based on the Wilcoxon test) outperforms conventional ensembles on each SCL task with multiple runs (MNIST, SVHN, and CIFAR-10).

TABLE II: SCL accuracy of ensembles of CNNs and fitted ensembles on various data sets (mean and standard deviation is from five runs). Aggregate of fitted ensembles lead to significantly better classification accuracy in the presence of unseen classes.

| DATA SET  | CNNS (STD)  | FITTED ENSEMBLES (STD) |
|-----------|-------------|------------------------|
| MNIST     | 98.27 (0.17)| 98.70 (0.08)           |
| SVHN      | 93.11 (0.09)| 94.01 (0.08)           |
| CIFAR10   | 82.39 (0.36)| 83.45 (0.19)           |
| CIFAR100  | 60.80       | 62.80                  |

D. **ImageNet Experiments**

ImageNet-2012 dataset consists of about 1.2 million images with 1,000 classes that were originally used for a vision competition in 2012. All the images in the dataset are first resized to $299 \times 299$ images and normalized. Then, each image
is padded by 15 pixels on each side, after which a random crop of size $299 \times 299$ is extracted for data augmentation. The test and out-of-distribution data are resized to $299 \times 299$ as well and then normalized by the same normalization parameters as training data.

To our knowledge, the ensemble baseline of [28] is the only technique that can scale up to ImageNet for out-of-distribution detection. To show that fitted ensembles are also scalable to large-scale real-world problems we trained a fitted ensemble consisting of three member-classifiers on ImageNet-2012. The first two constraint-problems are formed by merging every two consecutive classes from the total 1,000 classes of ImageNet. That is, the process merges the first and second classes, third and fourth classes, etc., to form the first superclass space, and then merges second and third classes, fourth and fifth classes, etc to construct the second superclass space. Note that these two superclass spaces define a sufficient set of constraints to make a classifier over the entire 1,000 classes (one sequel). In this section, we call such a combined classifier, classifier1.

The last sequel is simply the original dataset with the same 1,000 classes, and, for simplicity, we refer to its corresponding member-classifier as classifier2. All the member-classifiers are neural networks with DenseNet-BC [33] architecture with growth rate of 64, 16 initial features (with no additional layers before entering the first block) and block configurations of sizes 6, 6, 12, 12, respectively.

Each network is trained for 40 epochs, where in the first 20 epoch the learning rate is increased by a factor of 1.25 after each epoch and is decayed by a factor of 0.8 after each epoch during the rest of the training. The initial learning rate is 0.001.

The optimizer is SGD with Nesterov momentum, batch size of 64, the momentum of 0.9, and weight decay of $10^{-4}$. In the interest of time, we did not optimize the architecture or training procedure because the goal of this experiment is not to improve classification accuracy but rather the consistency of predictive confidence values.

1) Results: To confirm that fitted ensembles can adjust predictive confidences more accurately we have calculated the average predictive confidence (maximum activation) for all correctly classified and misclassified examples for classifier1, classifier2, and the whole fitted ensemble, along with the classification accuracy of each. Furthermore, to compare the performance of the fitted ensemble with a conventional ensemble we trained a regular ensemble consisting of two models (comparable to two sequels) following the same architecture, data preprocessing/augmentation, and optimization procedure as the networks of the fitted ensemble.

Table III summarizes the confidence statistics of classifier1, classifier2, the overall fitted ensemble (denoted by f-ensemble in the table), and the conventional ensemble. The overall result is more consistent predictive confident values in the fitted ensemble, where the average predictive confidence for misclassified examples is about 23% better (lower) compared to the conventional ensemble, while the average confidence of the correctly classified examples is about 11% lower.

In the next experiment, the performance of this fitted ensemble against out-of-distribution data is evaluated. We apply four out-of-distribution datasets. The first two are artificial images generated by sampling from Rademacher and isotropic Gaussian distributions, respectively. The third dataset is Texture [4] which consists of 5,640 images of 47 different type of textures, and the last dataset is SVHN. We use these datasets because they do not include any objects that resemble those in ImageNet.

Table IV shows the performance of each model in handling out-of-distribution data. There are three metrics applied in this experiment. The first metric, called FPR-at-95%-TPR [17], [18], reports a false positive rate with the threshold that results in a 95% true positive rate. Here the in-distribution data are positive and out-of-distribution data are considered negative examples. Intuitively by applying the threshold value on confidence values that 95% of in-distribution examples pass, this metric measures the rate of out-of-distribution examples that are more confident than the least 5% in-distribution examples.

The second metric is the area under the ROC curve (AU-ROC), the curve that plots true positive rate against false positive rate for all different threshold values. This holistic metric can be interpreted as the probability that the classifier is more confident about an in-distribution example than an out-of-distribution example. Therefore, the higher AUROC the better. An AUROC of 100% shows that the classifier always detects out-of-distribution data, regardless of the threshold value, and an AUROC of 50% is no better than a random classifier.

The last metric, called detection error, reports the highest possible detection error if we choose the optimal threshold value [37]. Note that these metrics can be sensitive to the relative size of in-distribution versus out-of-distribution sets. For the two artificial datasets, we used the same amount of in- and out-of-distribution data, while for the Textures and SVHN datasets we included all images and all test images, respectively.

The results suggest that the fitted ensemble is overall superior to both of its component classifiers and to the regular ensemble in detecting out-of-distributed examples. On both artificial datasets, the fitted ensemble performs significantly better than the conventional ensemble on both FPR at 95% TPR and AUROC metrics.

The Texture images are also detected very significantly better by the fitted ensemble than the others. However, the SVHN images are detected significantly better by classifier1, and combining classifier1 by classifier2 slightly degrades the performance of the fitted ensemble. Even so, the fitted ensemble beats the conventional ensemble with a large margin (about 45% improvement by AUROC measure).

Interestingly, the AUROC value for the conventional ensemble, and that of classifier2, are both below 50%, implying

3Available at http://www.robots.ox.ac.uk/~vgg/data/dtd/
they both perform worse than a random classifier for detecting SVHN images. In contrast, the high detection rate of SVHN images by classifier1, as evidenced by AUROC, reaffirms that the reformulation of classification problems in fitted ensembles can indeed lead to a novel type of diversity in ensemble techniques, a kind of diversity that is not attainable by regular ensembling.

2) Dissimilar-architecture Ensemble Experiment: In the previous experiment, the conventional ensemble consisted of two CNNs with an identical architecture (similar to network components of the fitted ensemble). In this section, we evaluate the effect of including dissimilar network architectures in an ensemble on improving predictive confidence consistency. To our knowledge, this approach has not been investigated for this problem before. Nevertheless, it is interesting to compare the kind of diversity introduced to an ensemble by a fitted ensemble with the diversity induced by dissimilar network architectures in an ensemble.

To this end, we construct an ensemble by combining two pretrained models on ImageNet, namely DenseNet-121 and DenseNet-161, from the PyTorch framework, and compared them with the fitted ensemble from the previous experiments. Note that the two pretrained models are significantly deeper and more accurate than classifier1 and classifier2 of the fitted ensemble.

The confidence statistics of the fitted ensemble (f-ensemble), and the ensemble of the two pretrained models from PyTorch, are summarized in Table VI. Interestingly, the results show more consistent predictive confident values in the fitted ensemble, where the average predictive confidence for misclassified examples is about 10% better (lower) compared to the regular ensemble, while the average confidence of the correctly classified examples is only 1% lower.

Following the previous section, the next experiment evaluates the performance of the two ensembles while encountering out-of-distribution data. The experimental setup is the same as the out-of-distribution experiment in the previous section.

Table VI depicts the performance of the two ensembles in handling out-of-distribution data. Again the FPR at 95% TPR, area under the ROC curve, and detection error are applied to quantify the detection performance.

The results suggest that the fitted ensemble is performing better on three of the four benchmarks, namely Rademacher, Gaussian, and the Textures datasets. However, the dissimilar-architecture ensemble can detect the SVHN images far better than the fitted ensemble. These results suggest that applying different network architectures in an ensemble can be more advantageous than the common similar-architecture practice for detecting out-of-distribution data. Nevertheless, fitted ensembles can enjoy the same kind of diversity to perform even better.

VI. DISCUSSION AND CONCLUSIONS

This study addresses the confidence inconsistencies that can occur in modern neural network models. We proposed a new framework, called separable concept learning, that generalizes the rigid setup of the conventional classification framework to a more flexible setting that considers out-of-distribution exam-
TABLE VI: Performance of fitted versus regular ensemble towards out-of-distribution data.

| DATASET & METRIC | F-ENSEMBLE | ENSEMBLE |
|------------------|------------|----------|
| **FPR AT 95% TPR** |            |          |
| RadeMACHER       | 49.89      | 99.64    |
| GauSIAN          | 41.84      | 98.60    |
| TEXTURES         | 70.60      | 78.32    |
| SVHN             | 84.28      | 15.58    |
| **AREA UNDER ROC CURVE** |            |          |
| RadeMACHER       | 94.51      | 87.37    |
| GauSIAN          | 94.89      | 89.75    |
| TEXTURES         | 80.84      | 76.51    |
| SVHN             | 82.97      | 97.27    |
| **BEST DETECTION ERROR** |          |          |
| RadeMACHER       | 6.90       | 12.26    |
| GauSIAN          | 6.93       | 10.27    |
| TEXTURES         | 9.98       | 10.10    |
| SVHN             | 23.28      | 8.13     |

This new framework evaluates classifiers’ performance by simulating a system of classifiers that work in harmony to achieve a unified goal, while each classifier may encounter examples of new but relevant classes.

Furthermore, to handle the inconsistent prediction confidence in neural networks we introduced fitted ensembles. Fitted ensembles introduce a new dimension to boost ensembles, where the diversity is preserved by learning different superclasses as output units. Our experiments show that this new reformulation of the original problem can enable fitted ensembles to produce less overconfident predictions and detect even more out-of-distribution examples compared to regular ensembles. Furthermore, our ImageNet experiments with fitted ensembles show scalability of this approach.

Overall, a new method is introduced to rectify neural network predictions and make them more suitable for handling unknown situations, and a new paradigm for evaluation is introduced to reveal their advantages. The hope is that these contributions can lead to better techniques to eventually make reliable classifiers and pave the way to a more consistent evaluation of them.
