Type 1 diabetes (T1D) is an autoimmune disease leading to β-cell destruction. MicroRNAs (miRNAs) are small noncoding RNAs that control gene expression and organ formation. They participate in the pathogenesis of several autoimmune diseases, but the nature of miRNAs contributing to β-cell death in T1D and their target genes remain to be clarified. We performed an miRNA expression profile on human islet preparations exposed to the cytokines IL-1β plus IFN-γ. Confirmation of miRNA and target gene modification in human β-cells was performed by real-time quantitative PCR. Single-stranded miRNAs inhibitors were used to block selected endogenous miRNAs. Cell death was measured by Hoechst/propidium iodide staining and activation of caspase-3. Fifty-seven miRNAs were detected as modulated by cytokines. Three of them, namely miR-23a-3p, miR-23b-3p, and miR-149-5p, were downregulated by cytokines and selected for further studies. These miRNAs were found to regulate the expression of the proapoptotic Bcl-2 proteins DP5 and PUMA and consequent human β-cell apoptosis. These results identify a novel cross talk between a key family of miRNAs and proapoptotic Bcl-2 proteins in human pancreatic β-cells, broadening our understanding of cytokine-induced β-cell apoptosis in early T1D.

Type 1 diabetes (T1D) is a multifactorial autoimmune disease characterized by selective pancreatic β-cell destruction in the course of islet inflammation (insulitis), which is triggered by a complex dialogue between the immune system and the target β-cells (1). Many of the key steps of this dialog are regulated by candidate genes for T1D (2–4), in cross talk with environmental cues such as viral infections (5–7). The inflammatory process is mediated by T cells (mostly CD8+ and, to a lesser extent, CD4+ lymphocytes) and macrophages (8–10). These invading immune cells contribute to selective β-cells destruction via both cell-to-cell contact and through the local release of proinflammatory cytokines such as IL-1β, IFN-γ, tumor necrosis factor-α (TNF-α), and IL-17A (1,11,12).

MicroRNAs (miRNAs) are a family of endogenous small noncoding RNAs with ~22 nucleotides in length. They bind to the 3’ untranslated region (UTR) of target genes and inhibit gene expression by degrading and/or preventing translation of their target messenger RNAs (13). miRNAs play a crucial role in organ formation during embryogenesis, including pancreas development and β-cell differentiation (14). Moreover, they display an important role in maintaining functional β-cell mass (15–17) and endocrine cell identity (18,19) during adult life.

Several recent studies have indicated a role for miRNAs in the regulation of autoimmune progression and diabetes development (20–23), including the regulation of inflammatory cytokine-mediated β-cell dysfunction.
and death (24–26). Additionally, there may be a link between miRNAs and regulation of T1D candidate genes (27) and β-cell responses to viral infection (28). The ultimate mechanisms by which these miRNAs and their target genes regulate human β-cell dysfunction and death remain, however, to be clarified. Particularly, it remains unclear whether miRNAs, individually or as families, regulate the activity of the proapoptotic Bcl-2 family members that execute pancreatic β-cell death (1,7). Against this background, we presently aimed to identify novel cytokine-modulated miRNAs in human pancreatic islets and, departing from these findings, to elucidate the proapoptotic pathways regulated by these miRNAs in the human β-cells. Our findings identified a novel family of miRNAs that regulate two key proteins involved in human β-cell apoptosis, namely DP5 and PUMA.

RESEARCH DESIGN AND METHODS

Culture of Human Islet Cells and the Human β-Cell Line EndoC-βH1

Human islets from 13 donors without diabetes were isolated in Pisa using collagenase digestion and density gradient purification (29). The donors (seven men and six women) were 71 ± 3 years old and had a BMI of 25 ± 1 kg/m² (Supplementary Table 1). Islet β-cell percentual content, as evaluated by immunofluorescence for insulin using a specific anti-insulin antibody (Supplementary Table 2) was 54 ± 3%. The islets were cultured at 6.1 mmol/L glucose as previously described (2,30). The human β-cell line EndoC-βH1 (provided by Dr. R. Scharffmann, University of Paris, Paris, France) (31) was cultured as previously described (12,32).

Cell Treatment

Both human islet cells and the EndoC-βH1 cells were exposed to the following cytokine concentrations, based on previous dose-response experiments performed by our group (30,32,33): recombinant human IL-1β (R&D Systems, Abingdon, U.K.), 50 U/mL; and recombinant human IFN-γ (PeproTech, London, U.K.), 1,000 U/mL.

TaqMan miRNA Array Profiling

Total RNA was isolated with the miRNeasy micro kit (Qiagen, Venlo, the Netherlands). DNase digestion was performed using RNase-Free DNase kit (Qiagen) following the manufacturer’s instructions. The quality of the extracted RNA was evaluated using a BioDrop instrument (Isogen manufacturer) formed using RNase-Free DNase kit (Qiagen) following the manufacturer’s instructions (29). The donors (seven men and six women) were 71 ± 3 years old and had a BMI of 25 ± 1 kg/m² (Supplementary Table 1). Islet β-cell percentual content, as evaluated by immunofluorescence for insulin using a specific anti-insulin antibody (Supplementary Table 2) was 54 ± 3%. The islets were cultured at 6.1 mmol/L glucose as previously described (2,30). The human β-cell line EndoC-βH1 (provided by Dr. R. Scharffmann, University of Paris, Paris, France) (31) was cultured as previously described (12,32).

Scharffmann, University of Paris, Paris, France) (31) was cultured as previously described (12,32).

Measurement of miRNA and mRNA Expression

A total of 40 and 150 ng total RNA was reverse-transcribed using Megaplex RT primers Human Pool A v2.1 (Thermo Fisher Scientific). A total of 500 ng RNA was used for each reaction, which included 1.33 μL of 10× Megaplex RT primers, 0.33 μL of 100 mmol/L deoxynucleotide nucleoside triphosphate, 1.33 μL of 10× RT buffer, 1.50 μL of 25 mmol MgCl2, 0.17 μL of 20 U/μL RNase Inhibitor, 2.50 μL of 50 U/μL Multiscribe Reverse Transcriptase, and 0.33 μL H2O (all from Life Technologies). The product of this reaction was then incubated for 40 cycles at 16°C for 2 min, 42°C for 1 min, 50°C for 1 s, and then at 85°C for 5 min. Then, 9 μL synthesized cDNA was loaded in TaqMan Array Human MicroRNA Cards following the manufacturer’s instructions (Life Technologies). A ViiA7 Real Time PCR instrument (Applied Biosystems-Life Technologies) was used to perform TaqMan Array Human MicroRNA Cards reaction runs.

RNA Interference

The short interfering RNAs (siRNAs) and single-stranded miRNA inhibitors used in this study are described in Supplementary Table 3. The siRNAs targeting DP5 and PUMA have been previously validated, including comparison against a second siRNA causing similar biological effects (34). The optimal concentration of siRNAs used for cell transfections (30 nmol/L) was previously established by our group (30,35). Single-stranded miCURY LNA inhibitors (Exiqon, Vedbaek, Denmark) that specifically block endogenous miRNAs were used at a concentration of 120 nmol/L based our own dose-response experiments (data not shown) and as described (25). Allstar Negative Control siRNA (siCTRL; Qiagen) was used as negative control in all experiments. This siCTRL does not affect β-cell gene expression or insulin release as compared with non-transfected cells (35). Transient transfection was performed with Lipofectamine RNAiMAX lipid reagent (Invitrogen-Life Technologies) following the manufacturer’s instruction. After an 8-h transfection, cells were cultured for a 48-h recovery period before exposure to cytokines.

Assessment of Cell Viability

The percentage of viable, apoptotic, and necrotic cells was determined by staining with the DNA-binding dyes propidium iodide (5 μg/mL; Sigma-Aldrich, Bornem, Belgium) and Hoechst dye 33342 (5 μg/mL; Sigma-Aldrich) as described (30,36). A minimum of 600 cells were counted for each experimental condition by two independent observers, with one of them unaware of sample identity. The agreement between findings obtained by the two observers was always >90%. In some cases, apoptosis was also confirmed by caspase-3 cleavage by Western blot (see below).
micromRNAs Regulate Human β-Cell Apoptosis

RESULTS

Cytokine Treatment Modifies miRNA Expression in Human β-Cells

To identify relevant miRNAs involved in cytokine-induced β-cell apoptosis and dysfunction, three independent human islet preparations were left untreated or treated for 48 h in the presence of proinflammatory cytokines IL-1β plus IFN-γ. A global miRNA expression profile was determined by TaqMan Human MicroRNA Array Cards (Fig. 1A). Data were exported using VIA7 RUO software and then analyzed using Expression Suite software v1.0.3 (Life Technologies). Only miRNAs with a Ct <35, in which the Ct is the threshold cycle to detect fluorescence for specific miRNAs, and a high efficiency amplification plot were taken into consideration for subsequent analysis. A total of 231 of 384 miRNAs analyzed were considered as present in our samples. All raw data were normalized using three small nuclear RNAs included in the card (RNU6, RNU44, and RNU48). Twenty-two miRNAs were found upregulated in cytokine-exposed human islets (considering a cutoff value of fold change ≥2 versus untreated islets), whereas 35 miRNAs were found downregulated after cytokine treatment (considering a cutoff value of fold change ≤0.75 versus untreated islets) (Supplementary Table 4). Comparison of this list of cytokine-modulated miRNAs against available data on miRNA expression profile performed in purified human α and β-cells (19) indicates that 12 modified miRNAs, namely miR-101-5p, miR-129-5p, miR-145-5p, miR-149-5p, miR-154-5p, miR-193b-3p, miR-23b-3p, miR-27a-3p, miR-27b-3p, miR-361-5p, miR-494-5p, and miR-654-3p, are enriched in β-cells, whereas 3 modified miRNAs, namely miR-146a-5p, miR-221-3p, and miR-708-5p, are more expressed in α cells. Using the miRWalk database (40) and the miRecords target prediction program (41) and based on the available literature (42), we initially selected for subsequent studies on two miRNAs, namely miR-23a-3p and miR-23b-3p, targeting key genes potentially involved in β-cell death. Cytokine-induced downregulation of miR-23a-3p and miR-23b-3p was confirmed in the same set of samples by real-time quantitative PCR (qPCR), using custom-designed primers (Fig. 1B and C). Moreover, downregulation of additional miRNAs potentially involved in cell death (i.e., miR-149-5p, miR-221-3p, and miR-27a-3p) was also evaluated (Supplementary Fig. 1B–D). Of note, there was no modification in the expression of miR-375-3p, a well-established islet-specific miRNA involved in pancreas development and maintenance of β-cell identity (17) (Supplementary Fig. 1A), whereas miR-146a-5p and miR-155-5p (Supplementary Fig. 1E and F), two well-established proinflammatory miRNAs (24,43), were upregulated. Similar results were observed in additional human islet preparations (independent experiments from the array screening) (Supplementary Fig. 2) and insulin-producing human EndoC-βH1 cells (Supplementary Fig. 3). There were, however, some
differences between human islets and human EndoC-
βH1 cells regarding miRNA modulation. Specifically,
the observed downregulation of miR-27a-3p in human
islets (Supplementary Figs. 1 and 2) was not con-
firmed in EndoC-βH1 cells (Supplementary Fig. 3),
and there was a very low expression (Ct >35 or unde-
tectable) of miR-155-5p in EndoC-βH1 cells. These small
differences observed between human islets and human
EndoC-βH1 cells may be due at least in part to the cell
heterogeneity within the pancreatic islet. Thus, compar-
isson between the miRNA expression profiles of whole
human islets against the FACS-enriched β-cell popula-
tion (44) indicates a higher miR-23a-3p and miR-155-
5p expression in human islets as compared with enriched
β-cells (44), whereas there is a good similarity for most of
the other miRNAs.

miR-23a-3p and miR-23b-3p Regulate the Expression of
Proapoptotic Bcl-2 Family Members in Human β-Cells

We next investigated whether predicted target genes
involved in β-cell death were regulated by cytokine
treatment, in an opposite direction as compared with
miR-23a-3p and miR-23b-3p. The Ct values of expression
of miR-23 family members under basal condition in hu-
man islets and human EndoC-βH1 cells were, respec-
tively, 18.3 ± 0.1 and 19 ± 0.1 for miR-23a-3p and
18.3 ± 0.1 and 19 ± 0.1 for miR-23b-3p (n = 7). A de-
crease in miR-23a-3p and miR-23b-3p expression in hu-
man islets (Fig. 2A and B) and human EndoC-βH1 cells
(Fig. 3A and B) was paralleled by increased mRNA expres-
sion of PUMA and NOXA (Fig. 2D and E) in human islets
and DP5, PUMA, NOXA, BAX, BIM-total, and BIM-small
(Fig. 3C–H) in human EndoC-βH1 cells. These results
support the hypothesis that proapoptotic Bcl-2 family
members are regulated, directly or indirectly, by miR-
23a-3p and miR-23b-3p in β-cells.

To elucidate the molecular mechanisms by which miR-
23a-3p and miR-23b-3p regulate β-cell survival, single-
stranded miRNAs inhibitors were used to block these
endogenous miRNAs. An 80 and 60% decrease of miR-
23a-3p expression was, respectively, observed in human

Figure 1—miRNA profile of human islets exposed or not to proinflammatary cytokines. Human islets (A–C) were left untreated or treated
with IL-1β plus IFN-γ for 48 h. miRNAs were then isolated, and miRNA expression profiling was performed using TaqMan Array Human
MicroRNA Cards Panel A v2.1 as described in RESEARCH DESIGN AND METHODS. A: Dendrogram of the global miRNA expression profile.
Columns correspond to individual samples exposed or not to cytokines, whereas rows correspond to the individual miRNAs analyzed.
The scale color from blue to red corresponds to the abundance of miRNA expression reported as normalized delta cycle threshold
(dCT; blue: dCT value, −2.18; red: dCT value, 18). All raw data were normalized using three small nucleolar RNAs included in the card
(RNU6, RNU44, and RNU48). Expression of miR-23a (B) and miR-23b (C) was assayed in the same samples by RT-PCR and normalized
by two different small nucleolar RNAs (RNU6 and RND61). The results are from three independent human islet preparations (A–C).
islets and in human EndoC-βH1 cells (Fig. 4A and C) using an miR-23a-3p inhibitor, followed or not by cytokine exposure. A >90% decrease of miR-23b-3p expression was observed in human EndoC-βH1 cells using an miR-23b-3p inhibitor in both untreated and IL-1β plus IFN-γ-treated cells (Fig. 4D). Because of the close similarity between miR-23a-3p and miR-23b-3p, we observed an important cross-reaction between the inhibitors, which decreased expression of both miRNAs in parallel in human EndoC-βH1 cells (Fig. 4C and D). Thus, findings with the individual inhibitors should be interpreted as mediated by inhibition of both miR-23a-3p and miR-23b-3p.

The miR-23a-3p inhibitor exacerbated basal apoptosis, as evaluated by nuclear dyes, in both human islets and human EndoC-βH1 cells (Fig. 4B and E and Supplementary Fig. 4A and B, respectively). A similar increase in apoptosis was observed using the miR-23b-3p inhibitor in human EndoC-βH1 cells (Fig. 4E and Supplementary Fig. 4A and B). Cytokine-induced apoptosis was also augmented in both human islets and human EndoC-βH1 cells using miR-23a-3p inhibitor (Fig. 4B and E and Supplementary Fig. 4A and B) and in EndoC-βH1 cells after exposure to the miR-23b-3p inhibitor (Fig. 4E and Supplementary Fig. 4A and B). In line with these
observations, the inhibitors for miR-23a-3p and miR-23b-3p increased expression of cleaved caspase-3 in human EndoC-βH1 cells (Fig. 4F and G), confirming apoptosis activation. Similar findings were observed by double immunofluorescence for insulin and cleaved caspase-3 in human islets after use of the miR-23a-3p inhibitor (Fig. 5), indicating that at least part of the observed cell death in human islet cells takes place at the β-cell level, which is in line with the observed increase in cell death in the human β-cell line EndoC-βH1 cells (Fig. 4E and Supplementary Fig. 4).

Exposure of cells to the miR-23a-3p inhibitor increased mRNA expression of the proapoptotic Bcl-2 family members DP5, PUMA, BAX, and BIM (Fig. 6A, B, D, and E, respectively), whereas inhibition of miR-23b-3p increased expression of DP5 and PUMA (Fig. 6A and B) in human EndoC-βH1 cells following or not exposure to IL-1β plus IFN-γ. No increase in NOXA was observed after inhibition of miR-23a-3p or miR-23b-3p (Fig. 6C). A mild increase of protein expression of DP5 and PUMA was observed after the use of miR-23a-3p and miR-23b-3p inhibitors in human EndoC-βH1 cells (Supplementary Fig. 5A, B, C, and D, respectively), whereas no modification in BAX and BIM protein expression after miR-23 family inhibition was detected (data not shown). In contrast, there was no change in expression of the antiapoptotic Bcl-2 family members Mcl-1 and BCL-XL or in APAF-1 after the use of
Figure 4—Inhibition of miR-23a-3p and miR-23b-3p exacerbates apoptosis in human islets and human EndoC-βH1 cells. Dispersed human islets (A and B) and human EndoC-βH1 cells (C–G) were transfected with siCTRL or anti-miRNAs targeting miR-23a-3p (human islets and EndoC-βH1 cells) or miR-23b-3p (EndoC-βH1 cells) for 8 h. After a 48-h recovery, cells were left untreated or treated with IL-1β plus IFN-γ for 48 h as indicated. Expression of miR-23a-3p (A and C) and miR-23b-3p (D) was assayed by RT-PCR and normalized by two different small nucleolar RNAs (RNU6 and RND61) (A) or by miR-375-3p expression (C and D). Apoptosis was evaluated by Hoechst/propidium iodide staining after 48 h of cytokine treatment (B and E). Cleaved caspase-3 and β-actin protein expression were evaluated by Western blot after 48 h of cytokine treatment; one representative blot of five independent experiments is shown (F). The optical density quantification of cleaved caspase-3 (as shown in F) was corrected by β-actin expression (G). Results are represented as box plots, indicating lower quartile, median, and higher quartile, with whiskers representing the range of the remaining data points (A–E). In G, results were normalized against the highest value in each independent experiment, considered as 1. *P < 0.05, **P < 0.01, ***P < 0.001 vs. siCTRL untreated cells; §P < 0.05, §§§P < 0.001, #P < 0.05, #PPP < 0.01 as indicated by bars; ANOVA followed by paired Student t test with Bonferroni correction. Data are shown as mean ± SEM of five to seven independent experiments.
miR-23a-3p or miR-23b-3p inhibitors in human EndoC-βH1 cells following or not exposure to IL-1β plus IFN-γ (data not shown). Taken together, these results suggest that miR-23a-3p and miR-23b-3p regulate β-cells apoptosis by modulating expression of key proapoptotic Bcl-2 protein family members.

To evaluate if DP5 is a direct target of miR-23a-3p, HeLa cells were transfected with a luciferase construct containing the 3′ UTR sequence of DP5 (Supplementary Fig. 6A). miR-23a-3p did not decrease the luciferase activity in cells transfected with the construct containing 3′ UTR of DP5, suggesting an indirect effect of miR-23a-3p on DP5 modulation. We next evaluated whether depletion of the miR-23 family upregulated expression of c-JUN, a key regulator of DP5 expression in β-cells (45). Inhibition of miR-23a-3p and miR-23b-3p increased by >16-fold c-JUN mRNA expression in human EndoC-βH1 cells under basal condition or following exposure to IL-1β plus IFN-γ (Fig. 6F). Interestingly, analysis on whether miR-23 family members target negative regulators of c-JUN mRNA expression, identified ARNT, HDAC4, MEF2C, NCOA2, TNFAIP3, ZNF382, and ZNF384 as predicted targets of miR-23 family.

Knockdown of PUMA or DP5 Protects Human EndoC-βH1 Cells From Cytokine-Induced Apoptosis in the Context of miR-23a-3p Inhibition

To determine whether the observed effects of miR-23a-3p on proapoptotic Bcl-2 proteins is causally related to β-cell death, we next knocked down PUMA or DP5 in combination with the miR-23a-3p inhibitor. This abrogated miR-23a-3p inhibitor–dependent induction of PUMA and DP5 (Fig. 7A and B, respectively) in both untreated and cytokine-treated human EndoC-βH1 cells; the inhibition of miR-23a-3p was confirmed by real-time qPCR (Fig. 7C and D). Importantly, blocking PUMA and DP5 induction in parallel to miR-23a-3p inhibition also prevented the increase in...
apoptosis secondary to depletion of this miRNA (Fig. 7E and F), indicating that upregulation of these two BH3-only proteins is part of the mechanisms by which a cytokine-induced miR-23a-3p decrease contributes to apoptosis of human pancreatic β-cells. This, and the above-described activation of caspase-3, indicates that miR-23a-3p regulates the intrinsic or mitochondrial apoptotic pathway in human β-cells.

To investigate whether additional miRNAs contribute to cytokine-induced apoptosis mediated by Bcl-2 family members, we studied miR-149-5p, another miRNA observed as downregulated by cytokines in our initial screening (Supplementary Fig. 1B and Supplementary Table 5). miRNA target prediction programs indicated miR-149-5p as a possible modulator of the Bcl-2 family members PUMA and BIM. Using an miR-149-5p inhibitor, there was a 60–80% decrease of miR-149-5p expression in human EndoC-βH1 cells exposed or not to cytokines (Supplementary Fig. 6A–F). Results are represented as box plots, indicating lower quartile, median, and higher quartile, with whiskers representing the range of the remaining data points (A–F). *P < 0.05, **P < 0.01, ***P < 0.001 vs. siCTRL untreated cells; §P < 0.05, §§P < 0.01, §§§P < 0.001, #P < 0.05, ##P < 0.01, ###P < 0.001 as indicated by bars; ANOVA followed by paired Student t test with Bonferroni correction. Data are shown as mean ± SEM of six to seven independent experiments.
Fig. 7G), whereas no modification in Mcl-1 and BCL-XL was observed (data not shown). This supports the concept that individual genes can be regulated by different miRNAs and that several miRNAs can participate in the regulation of key genes (13), such as the ones involved in β-cell death. We next knocked down PUMA or DP5 in combination with the miR-149-5p inhibitor. This abrogated miR-149-5p inhibitor-dependent induction of PUMA and DP5 (Supplementary Fig. 8A and B, respectively) in both untreated and cytokine-treated human EndoC-βH1 cells; the inhibition of miR-149-5p was confirmed by real-time qPCR (Supplementary Fig. 8C and D). Importantly, blocking PUMA and DP5
MicroRNAs Regulate Human β-Cell Apoptosis

induction in parallel to miR-149-5p inhibition also prevented the increase in apoptosis secondary to depletion of this miRNA (Supplementary Fig. 8E and F), as we previously observed for miR-23a-3p (Fig. 7E and F).

**DISCUSSION**

A significant reduction of functional β-cell mass because of increased β-cell death is the key feature of T1D. During the early stages of the disease, pancreatic islets are exposed to proinflammatory mediators released by the invading immune cells. Available information, mostly from animal models and in vitro experiments, suggests that this results into changes in the expression of key β-cell gene networks involved in β-cell function and phenotype, induction of endoplasmic reticulum (ER) stress, and inflammation (1,46,47). Locally produced proinflammatory mediators recruit further immune cells that enhance release of chemokines and cytokines, leading to amplification of the inflammatory process. Prolonged cytokine exposure and the consequent persistent ER stress, possibly in combination with environmental factors such as viral infections, may activate downstream pathways such as JNK phosphorylation and the transcription factors nuclear factor-κB and STAT1, eventually triggering expression of proapoptotic Bcl-2 proteins, cleavage, and activation of caspases and cell death (1,7,48). The fine regulation of this process, particularly in human β-cells, remains to be clarified.

The Bcl-2 family members can be subdivided into three different groups: antiapoptotic (i.e., Bcl-2, Bcl-XL, Mcl-1, and A1), proapoptotic (i.e., BAX, BAK, and BOK) Bcl-2 proteins, and proapoptotic BH3-only proteins (48). Additionally, the BH3-only proteins can be divided into two subgroups: the sensitizers (i.e., DP5, BAD, and NOXA) and the activators (i.e., BID, BIM, and PUMA) of apoptosis (48,49). It has been previously shown that PUMA and DP5, two of the most important regulators of the intrinsic apoptotic pathway, are induced in β-cells by exposure to the cytokines IL-1β plus IFN-γ or to chemical ER stressors, leading to BAX translocation to the mitochondria, caspase-3 activation, and β-cell death (45,50).

miRNAs are key regulators of gene expression, and some have been shown to sensitize β-cells to cytokine-induced apoptosis (24,25). Thus, prolonged exposure of mouse islets to IL-1β or to TNF-α results in upregulation of miR-146a-5p, miR-34a-5p, and miR-21-5p (24). Furthermore, cytokine-induced upregulation of miR-101a-3p and miR-30b-5p decreases expression of antiapoptotic Bcl-2 proteins in the mouse insulín-producing cell line MIN6 (26), whereas suppression of Bcl-2 upon miR-34a-5p induction contributes to palmitate-induced apoptosis in MIN6 cells (51). In line with these observations, cytokines upregulate miR-29-5p, which exacerbates cytokine-induced apoptosis via inhibition of the antiapoptotic Bcl-2 protein Mcl-1 (25). In contrast, the possible contribution of miRNAs to the cytokine-induced upregulation of proapoptotic BH3-only proteins in β-cells remains to be clarified.

Against this background, we presently performed a global miRNA expression profile on three independent human islets preparations treated or not with the cytokines IL-1β plus IFN-γ. Twenty-two and 35 miRNAs were found up- and downregulated, respectively, in human islets after IL-1β plus IFN-γ treatment. Of particular interest, these cytokines induced a significant downregulation of miR-23a-3p, miR-23b-3p, and miR-27a-3p, all belonging to the same miRNA family. miR-23b-3p is also downregulated in islets from 4- and 8-week NOD mice (25). Downregulation of miR-23a-3p and miR-27a-3p in posttraumatic brain injury contributes to neuronal cell death by directly upregulating the proapoptotic Bcl-2 family members BAX, NOXA, and PUMA (42), suggesting that this may be an important mechanism by which cytokines upregulate these key proapoptotic Bcl-2 family members. To test this hypothesis, miR-23a-3p and miR-23b-3p were inhibited in

**Figure 8**—Proposed model for the cytokine-induced cross talk between miRNAs and proapoptotic Bcl-2 proteins in β-cells. The proinflammatory cytokines IL-1β plus IFN-γ downregulate expression of miR-23a-3p, miR-23b-3p, and miR-149-5p in β-cells. Decreased expression of these inhibitory miRNAs leads to increased miRNA expression of key proapoptotic Bcl-2 proteins. Specifically, miR-23a-3p and miR-23b-3p modulate the BH3-only sensitizer DP5 (at least in part via upregulation of c-JUN) and the BH3-only activator PUMA, whereas miR-23a-3p regulates both the BH3-only sensitizer BIM and the proapoptotic Bcl-2 protein BAX. Additionally, inhibition of miR-149-5p expressions results in increased mRNA expression of both DP5 and PUMA. This complex interaction between miRNAs, transcription factors, and downstream proapoptotic proteins leads to cleavage and activation of caspase-3 and, subsequently, to β-cell apoptosis.
human β-cells. Because miR-23a-3p and miR-23b-3p are very similar and differ by only one nucleotide in their 3' ends, which is less important for miRNA action than the 5' end, the inhibitors of miR-23a-3p and miR-23b-3p used led to inhibition of both miRNAs. Thus, all data obtained based on these inhibitors should be interpreted as indicating broad effects of the miR-23 family. miR-23 inhibition increased apoptosis under both basal condition and following cytokine treatment. This was paralleled by upregulation of several BH3-only proteins, with the most consistent findings observed for DP5 and PUMA. Importantly, knocking down PUMA or DP5 reverted the proapoptotic effects of miR-23a-3p inhibition, suggesting that these two BH3-only proteins are regulated in an indirect way by proinflammatory cytokines (i.e., via the inhibition of miRNAs of the miR-23 family). Using HeLa cells, we did not observe a direct interaction between the miR-23 family and DP5 (for technical reasons, these experiments could not be performed in human EndoC-BH1 cells). This suggests the possibility of an indirect effect of these miRNAs on DP5 via upregulation of c-Jun (current study), a transcription factor previously shown by us to regulate DP5 expression (45). It remains to be determined how miR-23 cross talk with PUMA. Of note, the results described above show additive effects of PUMA/DP5 and miR-23 in that they both affect apoptosis, and the BH3-only proteins seem to be regulated downstream of the miRNAs. It remains to be proven, however, that these signals interact and the ultimate mechanisms involved. The current study should therefore be interpreted with caution.

The fact that these novel observations were obtained in human islets and in a human β-cell line increases their potential relevance to human T1D. Additional miRNAs targeting Bcl-2 family members, such as miR-221-3p and miR-149-5p, were also found downregulated in our screening, suggesting a more complex cross talk between miRNAs and proapoptotic Bcl-2 family members in β-cells. In line with this, inhibition of miR-149-5p also led to upregulation of DP5, PUMA, and BAX. An overview of this complex cross talk is provided in Fig. 8.

In conclusion, the results of this study identify a potential novel cross talk between a family of miRNAs and key proapoptotic Bcl-2 proteins in human pancreatic β-cells, providing a new mechanistic understanding of inflammation-induced β-cell apoptosis.

Acknowledgments. The authors thank the personnel of the ULB Center for Diabetes Research, including I. Millard, A. Musuaya, M. Pangerl, and N. Pachera, for excellent technical support.

Funding. This work was supported by grants from European Union (Seventh Framework Project of the European Union, Project NAMIT, and the European Union’s Horizon 2020 research and innovation programme, Project T2DSytems; grant 667191), the Fonds National de la Recherche Scientifique (Belgium), and the National Institutes of Health National Institute of Diabetes and Digestive and Kidney Diseases–Human Islet Research Network Consortium (grant 1U44-DK-104166-01) to D.L.E. P.M., F.D., and D.L.E. have received funding from the Innovative Medicines Initiative 2 Joint Undertaking (grant 115797; INNODIA). This Joint Undertaking receives support from the Union’s Horizon 2020 research and innovation programme, the European Federation of Pharmaceutical Industries and Associations, JDRF, and The Leona M. and Harry B. Helmsley Charitable Trust.

Duality of Interest. No potential conflicts of interest relevant to this article were reported.

Author Contributions. F.A.G., G.S., R.R., P.M., F.D., and D.L.E. conceived and designed the experiments. F.A.G., G.S., J.J.-M., D.V., L.M., L.L., K.T., and M.B. acquired data. P.M., F.D., and D.L.E. supervised the study and contributed to reagent. F.A.G. and D.L.E. wrote the manuscript. All authors revised the manuscript. D.L.E. is the guarantor of this work and, as such, had full access to all the data in the study and takes responsibility for the integrity of the data and the accuracy of the data analysis.
