Growth of Vertically Aligned Carbon Nanotubes by DCPECVD System and the Effects of C$_2$H$_2$ Concentration and Plasma Current on the Growth Behavior of CNTs

Abstract A direct current plasma enhanced chemical vapor deposition (DC PECVD) apparatus was designed and constructed to synthesize high purity vertically well-aligned carbon nanotubes (VACNTs) at relatively low temperatures. The effect of C$_2$H$_2$ concentration and plasma current on CNT growth was investigated. The DC PECVD synthesis of CNTs consisted of two steps: (1) reduction with gaseous H$_2$ and NH$_3$ to form catalyst nanoparticles, and (2) subsequent CNT growth in the presence of gaseous H$_2$ and C$_2$H$_2$. High-resolution transmission electron microscopy images confirmed the presence of multi-walled carbon nanotubes (MWCNTs). Their graphitic structure was then confirmed by Raman spectroscopy. Scanning electron microscopy (SEM) results illustrated the relationship between the plasma, C$_2$H$_2$ concentration and CNT growth. Deviation of acetylene flow rate from an optimal rate led to deterioration of CNT growth. Comparing SEM images of CNTs grown with and without plasma showed that plasma had an important role in VACNT formation.

1 Introduction

Since 1991, when carbon nanotubes (CNTs) were discovered by Iijima [1], different methods, including electrical arc discharge, laser ablation and chemical vapor deposition (CVD), have been suggested for their
synthesis [2–6]. CVD is advantageous because of its high product purity and yield, selective growth and ability to facilitate well-aligned CNTs [7,8]. Plasma-enhanced CVD (PECVD) allows the efficient growth of high purity vertically aligned carbon nanotubes (VACNTs) at lower temperatures [9]. Many applications of CNTs have been reported, including their use as probes in atomic force microscopy (AFM), as electron emitters for field emission displays (FED), as nanofillers for composite materials, as electrodes for fuel cells and as nanoscale electronic devices for micro-/nano-electro mechanical systems (MEMS/NEMS) [10–13].

VACNTs can be used for various electrical purposes, including as flat pageant and metal–oxide–semiconductor field-effect transistors (MOSFET). In the present study, the effects of plasma current and acetylene (C₂H₂) gas concentration on CNT growth behavior have been evaluated using a purpose-built PECVD apparatus. The primary objective was to ascertain the optimal plasma current and inlet gas ratio, in which VACNTs could be synthesized in high yield.

2 Experimental

2.1 PECVD System

Well-aligned CNTs were produced using a purpose-built PECVD apparatus, shown schematically in Fig. 1. Features of this system include the main reactor chamber, vacuum pumps, power supplies, and heating and cooling systems. A gas mixer was employed at the main chamber gas inlet to thoroughly mix the entering gases. The direct DC plasma between the Si substrate (cathode) and a steel mesh plate (anode) was enhanced with a 1 KW DC power supply.

2.2 Techniques

CNT morphology was investigated using scanning electron microscopy (SEM). Raman spectroscopy was carried out using a Jobin Yvon LabRam HR-800, in Stokes mode with 532 nm frequency-doubled Nd:YAG laser
Table 1 Gas flow rate during growth step at constant plasma current of 50 mA

| Sample number | S1   | S2   | S3   | S4   | S5   |
|---------------|------|------|------|------|------|
| Acetylene flow (sccm) | 140  | 120  | 110  | 100  | 90   |
| Hydrogen flow (sccm)    | 60   | 80   | 90   | 100  | 110  |

Table 2 Plasma current in growth process at H2:C2H2 = 100/100

| Sample number | P1   | P2   | P3   | P4   | P5   |
|---------------|------|------|------|------|------|
| Plasma current (mA) | 20   | 30   | 50   | 70   | 0    |

excitation. A SIMS analysis was performed to estimate the thickness of the oxide layer on the silicon wafer. Transmission electron microscopy (TEM: CM200 FEG Philips) operated at 200 kV was used to characterize CNTs.

2.3 CNT Preparation

The n-type silicon substrates were cleaned in an ultrasonic ethanol/acetone bath for 5 min. It was necessary to initially oxidize the silicon surface layer to suppress the formation of Si–Ni bimetallic species during the coating procedure. Samples were placed in a conventional cylindrical resistive furnace and heated to 800°C for 2 h to allow the oxide layer to form. The oxidized Si substrate was then placed in a sputtering chamber, the base pressure reduced to $8 \times 10^{-4}$ Pa, and the Ni target then sputtered using a Kaufman ion gun at a 30 sccm Ar flow rate (working pressure and temperature were $12 \times 10^{-4}$ Pa and 400°C). The oxide layer thickness was estimated to be approximately 8 nm by SIMS profile analysis. A thin layer (40 nm) of Ni film was deposited onto the SiO2/Si substrate during ion beam sputtering.

Samples were then introduced to the DC PECVD system, and a typical two stage CVD process was carried out:

– The coated Ni was reduced with a 1:1 H2 : NH3 corrosive gas at 10 mbar and 750°C, under 8 W DC plasma irradiation for 5 min. During reduction, the Ni layer changed to Ni islands which became active sites for CNT nucleation.
– The second stage was CNT growth on catalyst nanoparticles with varying ratios of acetylene and hydrogen inlet gases, for 20 min. Acetylene was used as a substitute for gaseous ammonia, and gas flow rates and plasma conditions are summarized in Tables 1 and 2, respectively.

Finally, samples were slowly cooled to room temperature under a hydrogen atmosphere.

3 Results and Discussion

Figure 2 shows SEM images with corresponding Raman spectra at different C2H2 concentrations. In the Raman spectra, low frequency absorptions between 200 and 300 cm$^{-1}$ arose from the radial breathing mode (RBM). Frequencies at $\approx 1,350$ and $\approx 1,580$ cm$^{-1}$ were assigned to G and D bands, respectively. The G band is reported to be related to graphitic structure (sp$^2$ hybridization), and the D band related to defects and disorder [13].

It is clear from Fig. 2a that at a C2H2 flow rate of 90 sccm, CNT formation was limited to the initial stage of growth. At a C2H2 flow rate of 140 sccm, the surface was covered by a thick layer of graphite and amorphous carbon as indicated by the Raman spectrum (Fig. 2c). The optimal flow rate was found to be 100 sccm, where dense vertical aligned carbon nanotubes were observed covered with nickel particles on their extremities (Fig. 2b). A low acetylene precursor concentration led to a low surface carbon concentration and resulted in limited CNT growth. Tanemura et al [14] reported that at high acetylene concentration, the catalyst surface could be covered or reacted with carbon forming metallic carbide. In that case, C2H2 fragments showed a greater tendency to form graphite or amorphous structures rather than CNTs.

Samples were prepared at various plasma currents (Table 2) to evaluate its effect on CNT growth. Figure 3 shows SEM images and corresponding Raman spectra of these samples. CNT formation only took place at a plasma current of 50 mA. Low quantities of CNTs without a well-defined shape were observed at higher
Fig. 2 SEM images and corresponding Raman spectra of samples prepared at acetylene flow rates of \(a\) 90, \(b\) 100 and \(c\) 140 sccm at 10 torr. The inset presents the radial breathing mode (RBM) and corresponding CNT diameter.

currents. Such behavior was rationalized by the inherent relationship between plasma current and surface carbon concentration, where higher plasma current led to a higher surface carbon concentration.

A sample was prepared where CNT growth was attempted at the same flow rate but in the absence of DC plasma (P5). A CNT network on the surface was clearly observed in the absence of DC current (Fig. 4). Studies have been carried out to ascertain the effect of DC plasma on the formation of VACNTs [15]. The Fig. 3 insets suggested that thicker single-walled CNTs (SWCNTs) would be formed at higher plasma current. The tendency to form multi-walled CNTs (MWNTs) was particularly noticeable at higher plasma current. SWCNT diameter was estimated using the equation $\nu = 223.75/d$ [16], where $\nu$ is the RBM frequency in cm$^{-1}$ and $d$ is SWNT diameter in nm. Figure 5 shows TEM micrographs of sample P4, in which MWNTs with an average diameter of $\approx 7$ nm were formed.
4 Conclusions

VACNT growth on Ni/SiO$_2$/Si substrates was investigated using a purpose built DC PECVD reactor. The Ni layer acted as a catalyst after being transformed into islands on the surface by reduction. Our reactor was able to form VACNTs under suitable plasma current and acetylene flow rate conditions in a mixture of gaseous C$_2$H$_2$ and H$_2$.
